W. W. NORTON & COMPANY
Independent Publishers Since 1923

W. W. Norton & Company has been independent since its founding in 1923, when William Warder Norton and Mary D. Herter Norton first published lectures delivered at the People's Institute, the adult education division of New York City's Cooper Union. The firm soon expanded its program beyond the Institute, publishing books by celebrated academics from America and abroad. By midcentury, the two major pillars of Norton's publishing program—trade books and college texts—were firmly established. In the 1950s, the Norton family transferred control of the company to its employees, and today—with a staff of five hundred and hundreds of trade, college, and professional titles published each year—W. W. Norton & Company stands as the largest and oldest publishing house owned wholly by its employees.

Brief Contents

1. Particles of Matter: Measurement and the Tools of Science 2
2. Atoms, Ions, and Molecules: Matter Starts Here 46
3. Stoichiometry: Mass, Formulas, and Reactions 86
4. Reactions in Solution: Aqueous Chemistry in Nature 148
5. Properties of Gases: The Air We Breathe 212
6. Thermochemistry: Energy Changes in Chemical Reactions 270
7. A Quantum Model of Atoms: Waves, Particles, and Periodic Properties 334
8. Chemical Bonds: What Makes a Gas a Greenhouse Gas? 392
9. Molecular Geometry: Shape Determines Function 444

1. Intermolecular Forces: The Uniqueness of Water 506
2. Solutions: Properties and Behavior 548
3. Solids: Crystals, Alloys, and Polymers 600
4. Chemical Kinetics: Reactions in the Atmosphere 648
5. Chemical Equilibrium: How Much Product Does a Reaction Really Make? 708
6. Acid–Base Equilibria: Proton Transfer in Biological Systems 754
7. Additional Aqueous Equilibria: Chemistry and the Oceans 802
8. Thermodynamics: Spontaneous and Nonspontaneous Reactions and Processes 850
9. Electrochemistry: The Quest for Clean Energy 898
10. Nuclear Chemistry: Applications in Science and Medicine 946
11. Organic and Biological Molecules: The Compounds of Life 986
12. The Main Group Elements: Life and the Periodic Table 1044
13. Transition Metals: Biological and Medical Applications 1082

Contents

- List of Applications xv
- List of Animations xvii
- About the Authors xix
- Preface xx

- 1
- Particles of Matter: Measurement and the Tools of Science 2
    - 1.1How and Why 4
    - 1.2Macroscopic and Particulate Views of Matter 5
        - Classes of Matter 5 • A Particulate View 7
    - 1.3Mixtures and How to Separate Them 9
    - 1.4A Framework for Solving Problems 11
    - 1.5Properties of Matter 12
    - 1.6States of Matter 14

  - 1.7The Scientific Method: Starting Off with a Bang 16
  - 1.8SI Units 18
  - 1.9Unit Conversions and Dimensional Analysis 20
  - 1.10Evaluating and Expressing Experimental Results 22
    - Significant Figures 22 • Significant Figures in Calculations 23 • Precision and Accuracy 27
  - 1.11Testing a Theory: The Big Bang Revisited 32
    - Temperature Scales 32 • An Echo of the Big Bang 34
    - Summary 37 • Particulate Preview Wrap-Up 37 • Problem-Solving Summary 38 • Visual Problems 38 • Questions and Problems 40

- 2
- Atoms, Ions, and Molecules: Matter Starts Here 46
  - 2.1Atoms in Baby Teeth 48
  - 2.2Discovering the Structure of Atoms 49

    - Electrons 49 • Radioactivity 51 • Protons and Neutrons 52

- 2.3Isotopes 54
- 2.4Average Atomic Mass 56
- 2.5The Periodic Table of the Elements 58

    - Navigating the Modern Periodic Table 59

- 2.6Trends in Compound Formation 61

    - Molecular Compounds 62 • Ionic Compounds 62

- 2.7Naming Inorganic Compounds and Writing Their Formulas 64

    - Binary Molecular Compounds 65 • Binary Ionic Compounds 66 • Compounds of Metals That Form More than One Cation 67 • Polyatomic Ions 68 • Acids 69

- 2.8Organic Compounds: A First Look 70

    - Hydrocarbons 71 • Heteroatoms and Functional Groups 72

- 2.9Nucleosynthesis: The Origin of the Elements 74

    - Primordial Nucleosynthesis 74 • Stellar Nucleosynthesis 75

    - Summary 77 • Particulate Preview Wrap-Up 78 • Problem-Solving Summary 78 • Visual Problems 79 • Questions and Problems 80

- 3
- Stoichiometry:
  Mass, Formulas, and Reactions 86
    - 3.1Air, Life, and Molecules 88
        - Chemical Reactions and Earth's Early Atmosphere 89
    - 3.2The Mole 91
        - Molar Mass 93 • Molecular Masses and Formula Masses 95 • Moles and Chemical Equations 98
    - 3.3Writing Balanced Chemical Equations 100
    - 3.4Combustion Reactions 105
    - 3.5Stoichiometric Calculations and the Carbon Cycle 107
    - 3.6Limiting Reactants and Percent Yield 112
        - Calculations Involving Limiting Reactants 113 • Actual Yields versus Theoretical Yields 116
    - 3.7Determining Empirical Formulas from Percent Composition 119

- 3.8Comparing Empirical and Molecular Formulas 124
    - Molecular Mass and Mass Spectrometry 127
- 3.9Combustion Analysis 128
    - Summary 134 • Particulate Preview Wrap-Up 134 • Problem-Solving Summary 134 • Visual Problems 136 • Questions and Problems 139

- 4
- Reactions in Solution: Aqueous Chemistry in Nature 148
    - 4.1Ions and Molecules in Oceans and Cells 150
    - 4.2Expressing Concentrations 153
        - Concentration Units 153 • Molarity 154
    - 4.3Dilutions 159
        - Determining Concentration 162
    - 4.4 Electrolytes and Nonelectrolytes 163

    - Ions in Solution 163

- 4.5Acid–Base Reactions: Proton Transfer 165
- 4.6Titrations 171
- 4.7Precipitation Reactions 175

    - Precipitation Formation 176 • Using Precipitation in Analysis 180 • Saturated Solutions and Supersaturation 182

- 4.8Oxidation–Reduction Reactions Electron Transfer 184

    - Oxidation Numbers 184 • Changes in Oxidation Numbers in Redox Reactions 186 • Electron Transfer in Redox Reactions 187 • Balancing Redox Reactions by Using Half-Reactions 188 • The Activity Series of Metals 191 • Redox in Nature 193

    - Summary 198 • Particulate Preview Wrap-Up 199 • Problem-Solving Summary 199 • Visual Problems 200 • Questions and Problems 202

- 5
- Properties of Gases: The Air We Breathe 212
    - 5.1Air: An Invisible Necessity 214
    - 5.2Atmospheric Pressure and Collisions 215
    - 5.3The Gas Laws 220
        - Boyle's Law: Relating Pressure and Volume 220 • Charles's Law: Relating Volume and Temperature 223 • Avogadro's Law: Relating Volume and Quantity of Gas 225 • Amontons's Law: Relating Pressure and Temperature 226
    - 5.4The Ideal Gas Law 228
    - 5.5Gases in Chemical Reactions 232
    - 5.6Gas Density 235
    - 5.7Dalton's Law and Mixtures of Gases 238
    - 5.8The Kinetic Molecular Theory of Gases 243
        - Explaining Boyle's, Dalton's, and Avogadro's Laws 244 • Explaining Amontons's and Charles's Laws 245 • Molecular Speeds and Kinetic Energy 246 • Graham's Law: Effusion and Diffusion 249
    - 5.9Real Gases 250
        - Deviations from Ideality 251 • The van der Waals Equation for Real Gases 252
        - Summary 255 • Particulate Preview Wrap-Up 256 • Problem-Solving Summary 256 • Visual Problems 257 • Questions and Problems 261

- 6
- Thermochemistry: Energy Changes in Chemical Reactions 270
  - 6.1Sunlight Unwinding 272
  - 6.2Forms of Energy 273
    - Work, Potential Energy, and Kinetic Energy 273 • Kinetic Energy and Potential Energy at the Molecular Level 276
  - 6.3Systems, Surroundings, and Energy Transfer 279
    - Isolated, Closed, and Open Systems 279 • Exothermic and Endothermic Processes 281 • *P–V* Work and Energy Units 283
  - 6.4Enthalpy and Enthalpy Changes 286
  - 6.5Heating Curves, Molar Heat Capacity, and Specific Heat 289
    - Hot Soup on a Cold Day 289 • Cold Drinks on a Hot Day 294

- 6.6Calorimetry: Measuring Heat Capacity and Enthalpies of Reaction 297
  - Determining Molar Heat Capacity and Specific Heat 297 • Enthalpies of Reaction 299
- 6.7Hess's Law 304
- 6.8Standard Enthalpies of Formation and Reaction 308
- 6.9Fuels, Fuel Values, and Food Values 313
  - Alkanes 313 • Fuel Value 316 • Food Value 317
  - Summary 321 • Particulate Preview Wrap-Up 321 • Problem-Solving Summary 322 • Visual Problems 323 • Questions and Problems 325

- 7
- A Quantum Model of Atoms: Waves, Particles, and Periodic Properties 334

- 7.1Rainbows of Light 336
- 7.2Waves of Energy 339
- 7.3Particles of Energy and Quantum Theory 341

    - Quantum Theory 341 • The Photoelectric Effect 343 • Wave–Particle Duality 344
- 7.4The Hydrogen Spectrum and the Bohr Model 345
    - The Hydrogen Emission Spectrum 345 • The Bohr Model of Hydrogen 347
- 7.5Electron Waves 350
    - de Broglie Wavelengths 350 • The Heisenberg Uncertainty Principle 352
- 7.6Quantum Numbers and Electron Spin 354
- 7.7The Sizes and Shapes of Atomic Orbitals 359
    - *s* Orbitals 359 • *p* and *d* Orbitals 361
- 7.8The Periodic Table and Filling the Orbitals of Multielectron Atoms 362
- 7.9Electron Configurations of Ions 370
    - Ions of the Main Group Elements 370 • Transition Metal Cations 372
- 7.10The Sizes of Atoms and Ions 373
    - Trends in Atom and Ion Sizes 374
- 7.11Ionization Energies 376
- 7.12Electron Affinities 379
    - Summary 381 • Particulate Preview Wrap-Up 382 • Problem-Solving Summary 382 • Visual Problems 382 • Questions and Problems 384

- 8
- Chemical Bonds:
  What Makes a Gas a Greenhouse Gas? 392
  - 8.1Types of Chemical Bonds and the Greenhouse Effect 394
    - Forming Bonds from Atoms 395
  - 8.2Lewis Structures 398
    - Lewis Symbols 398 • Drawing Lewis Structures 399 • Lewis Structures of Molecules with Double and Triple Bonds 401 • Lewis Structures of Ionic Compounds 404
  - 8.3Polar Covalent Bonds 405
    - Polarity and Type of Bond 407 • Vibrating Bonds and Greenhouse Gases 408
  - 8.4Resonance 409
  - 8.5Formal Charge: Choosing among Lewis Structures

414

    - Calculating Formal Charge of an Atom in a Resonance Structure 415

  - 8.6Exceptions to the Octet Rule 418

    - Odd-Electron Molecules 418 • Molecules in Which Atoms Form More than Four Bonds 420 • Lewis Structures: Atoms with More than an Octet 421 • Lewis Structures: Atoms with Less than an Octet 423 • The Limits of Bonding Models 425

  - 8.7The Lengths and Strengths of Covalent Bonds 426

    - Bond Length 426 • Bond Energies 427

    - Summary 432 • Particulate Preview Wrap-Up 432 • Problem-Solving Summary 432 • Visual Problems 433 • Questions and Problems 435

- 9
- Molecular Geometry:

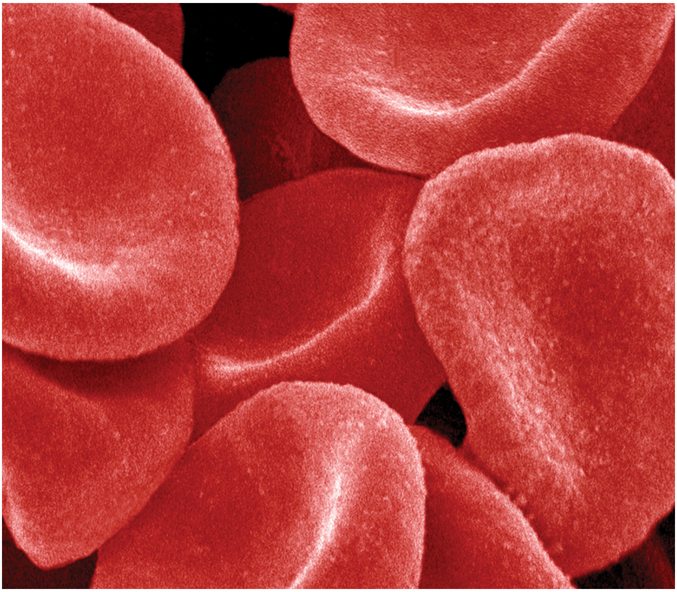
Shape Determines Function 444

- 9.1Biological Activity and Molecular Shape 446
- 9.2Valence-Shell Electron-Pair Repulsion (VSEPR) Theory 447
    - Central Atoms with No Lone Pairs 448 • Central Atoms with Lone Pairs 452
- 9.3Polar Bonds and Polar Molecules 457
- 9.4Valence Bond Theory 461
    - Bonds from Orbital Overlap 462 • Hybridization 463 • Tetrahedral Geometry: *sp*^{3} Hybrid Orbitals 463 • Trigonal Planar Geometry: *sp*^{2} Hybrid Orbitals 465 • Linear Geometry: *sp* Hybrid Orbitals 467
- 9.5Shape, Large Molecules, and Molecular Recognition 470
    - Drawing Larger Molecules 470 • Molecules with More than One Functional Group 472 • Chirality and Molecular Recognition 473
- 9.6Molecular Orbital Theory 477
    - Molecular Orbitals of Hydrogen and Helium 478 • Molecular Orbitals of Homonuclear Diatomic Molecules 480 • Molecular Orbitals of Heteronuclear Diatomic Molecules 484 • Molecular Orbitals of $N_2{}^+$ and Spectra of Auroras 486 • Using MO Theory to Explain Fractional Bond Orders and Resonance 486 • A Bonding Theory for SN > 4 487 • Metallic Bonds and Conduction Bands 490 • Semiconductors 491
    - Summary 495 • Particulate Preview Wrap-Up 496 • Problem-Solving Summary 496 • Visual Problems 496 • Questions and Problems 498

- 10
- Intermolecular Forces:
  The Uniqueness of Water 506

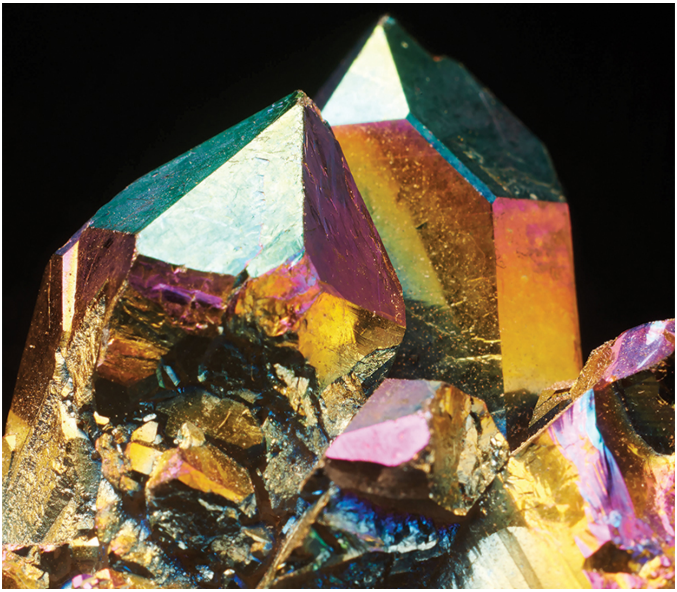
- 10.1Intramolecular Forces versus Intermolecular Forces 508
- 10.2Dispersion Forces 509
  - The Importance of Shape 510
- 10.3Interactions Involving Polar Molecules 511
  - Ion–Dipole Interactions 511 • Dipole–Dipole Interactions 512 • Hydrogen Bonds 513
- 10.4Vapor Pressure of Pure Liquids 519
  - Vapor Pressure and Temperature 520 • Volatility and the Clausius–Clapeyron Equation 521
- 10.5Phase Diagrams: Intermolecular Forces at Work 523
  - Phases and Phase Transitions 523

- 10.6Some More Remarkable Properties of Water 526
    - Surface Tension, Capillary Action, and Viscosity 526 • The Densities of Cold Water and Ice: Their Impact on Aquatic Life 528
- 10.7Polarity and Solubility 529
    - Combinations of Intermolecular Forces 532
- 10.8Solubility of Gases in Water 534
    - Summary 538 • Particulate Preview Wrap-Up 539 • Problem-Solving Summary 539 • Visual Problems 539 • Questions and Problems 541



- 11
- Solutions: Properties and Behavior 548
    - 11.1Interactions between Ions 550
    - 11.2Energy Changes during Formation and Dissolution of Ionic Compounds 553

    - Calculating Lattice Energies by Using the Born–Haber Cycle 556 • Enthalpies of Hydration 559
- 11.3Vapor Pressure of Solutions 561
    - Raoult’s Law 562
- 11.4Mixtures of Volatile Solutes 564
    - Vapor Pressures of Mixtures of Volatile Solutes 564
- 11.5Colligative Properties of Solutions 569
    - Molality 570 • Boiling Point Elevation 572 • Freezing Point Depression 573 • The van ’t Hoff Factor 575 • Osmosis and Osmotic Pressure 579 • Reverse Osmosis 583 • Using Osmotic Pressure to Determine Molar Mass • 585
- 11.6Ion Exchange 587
    - Summary 590 • Particulate Preview Wrap-Up 590 • Problem-Solving Summary 590 • Visual Problems 592 • Questions and Problems 595



- 12
- Solids: Crystals, Alloys, and Polymers 600
  - 12.1The Solid State 602
  - 12.2Structures of Metals 604
    - Stacking Patterns and Unit Cells 605 • Unit Cell Dimensions 607
  - 12.3Alloys and Medicine 612
    - Substitutional Alloys 613 • Interstitial Alloys 614
  - 12.4Ionic Solids and Salt Crystals 616
  - 12.5Allotropes of Carbon 620
  - 12.6Polymers 622
    - Polymers of Alkenes 622 • Polymers Containing Aromatic Rings 625 • Polymers of Alcohols and Ethers 626 • Polyesters and Polyamides 628
    - Summary 635 • Particulate Preview Wrap-Up 636 • Problem-Solving Summary 636 • Visual

Problems 637 • Questions and Problems 640

- 13
- Chemical Kinetics:
  Reactions in the Atmosphere 648
  - ○ 13.1Cars, Trucks, and Air Quality 650
  - ○ 13.2Reaction Rates 652
    - Experimentally Determined Reaction Rates 654 • Average Reaction Rates 656 • Instantaneous Reaction Rates 656
  - ○ 13.3Effect of Concentration on Reaction Rate 659
    - Reaction Order and Rate Constants 659 • Integrated Rate Laws: First-Order Reactions 664 • Reaction Half-Lives 668 • Integrated Rate Laws: Second-Order Reactions 670 • Zero-Order Reactions 672
  - ○ 13.4Reaction Rates, Temperature, and the Arrhenius Equation 674

- 13.5Reaction Mechanisms 680
    - Elementary Steps 680 • Rate Laws and Reaction Mechanisms 682 • Mechanisms and Zero-Order Reactions 686
- 13.6Catalysts 687
    - Catalysts and the Ozone Layer 687 • Catalysts and Catalytic Converters 690 • Enzymes: Biological Catalysts 691
    - Summary 694 • Particulate Preview Wrap-Up 695 • Problem-Solving Summary 695 • Visual Problems 696 • Questions and Problems 698

- 14
- Chemical Equilibrium: How Much Product Does a Reaction Really Make? 708
    - 14.1The Dynamics of Chemical Equilibrium 710
    - 14.2The Equilibrium Constant 712
    - 14.3Relationships between K_c and K_p Values 717

- ○ 14.4Manipulating Equilibrium Constant Expressions 719
    - ■ *K* for Reverse Reactions 719 • *K* for an Equation Multiplied or Divided by a Number 721 • Combining *K* Values 722
- ○ 14.5Equilibrium Constants and Reaction Quotients 724
- ○ 14.6Heterogeneous Equilibria 726
- ○ 14.7Le Châtelier’s Principle 728
    - ■ Effects of Adding or Removing Reactants or Products 729 • Effects of Pressure and Volume Changes 731 • Effect of Temperature Changes 734 • Catalysts and Equilibrium 736
- ○ 14.8Calculations Based on *K* 736
    - ■ Summary 744 • Particulate Preview Wrap-Up 745 • Problem-Solving Summary 745 • Visual Problems 746 • Questions and Problems 748

- 15

- Acid–Base Equilibria:
  Proton Transfer in Biological Systems 754
  - 15.1Acids and Bases: A Balancing Act 756
  - 15.2The Molecular Structures and Strengths of Acids and Bases 757
    - Strong and Weak Acids 758 • Strong and Weak Bases 763
  - 15.3Conjugate Pairs and Their Complementary Strengths as Acids and Bases 764
    - Recognizing Conjugate Pairs 765 • Relative Strengths of Conjugate Acids and Bases 766
  - 15.4pH and the Autoionization of Water 767
    - The pH Scale 768 • pOH, pK_a, and pK_b Values 771
  - 15.5K_a, K_b, and the Ionization of Weak Acids and Bases 772
    - Weak Acids 772 • Weak Bases 776
  - 15.6Calculating the pH of Acidic and Basic Solutions 778
    - Strong Acids and Strong Bases 778 • Weak Acids and Weak Bases 779 • pH of Very Dilute Solutions of Strong Acids 781
  - 15.7Polyprotic Acids 783
    - Acid Rain 783 • Normal Rain 785
  - 15.8Acidic and Basic Salts 788
    - Summary 793 • Particulate Preview Wrap-Up 794 • Problem-Solving Summary 794 • Visual Problems 796 • Questions and Problems 798

- 16
- Additional Aqueous Equilibria: Chemistry and the Oceans 802
  - 16.1Ocean Acidification: Equilibrium under Stress 804
  - 16.2The Common-Ion Effect 806
  - 16.3pH Buffers 809
    - Buffer Capacity 812
  - 16.4Indicators and Acid–Base Titrations 816
    - Acid–Base Titrations 818 • Titrations with Multiple Equivalence Points 824
  - 16.5Lewis Acids and Bases 827
  - 16.6Formation of Complex Ions 830
  - 16.7Hydrated Metal Ions as Acids 832
  - 16.8Solubility Equilibria 834
    - K_{sp} and Q 839
    - Summary 842 • Particulate Preview Wrap-Up 843 • Problem-Solving Summary 843 • Visual

Problems 844 • Questions and Problems 846

- 17
- Thermodynamics:
  Spontaneous and Nonspontaneous Reactions and Processes 850
    - 17.1Spontaneous Processes 852
    - 17.2Entropy and the Second Law of Thermodynamics 855
    - 17.3Absolute Entropy and the Third Law of Thermodynamics 859
        - Entropy and Structure 862
    - 17.4Calculating Entropy Changes 863
    - 17.5Free Energy 864
    - 17.6Temperature and Spontaneity 869
    - 17.7Free Energy and Chemical Equilibrium 872
    - 17.8Influence of Temperature on Equilibrium Constants 877
    - 17.9Driving the Human Engine: Coupled Reactions 880
    - 17.10Microstates: A Quantized View of Entropy 884

About the Authors

Thomas R. Gilbert has a BS in chemistry from Clarkson and a PhD in analytical chemistry from MIT. After 10 years with the Research Department of the New England Aquarium in Boston, he joined the faculty of Northeastern University, where he is currently associate professor of chemistry and chemical biology. His research interests are in chemical and science education. He teaches general chemistry and science education courses and conducts professional development workshops for K–12 teachers. He has won Northeastern’s Excellence in Teaching Award and Outstanding Teacher of First-Year Engineering Students Award. He is a Fellow of the American Chemical Society and in 2012 was elected to the ACS Board of Directors.

Rein V. Kirss received both a BS in chemistry and a BA in history as well as an MA in chemistry from SUNY Buffalo. He received his PhD in inorganic chemistry from the University of Wisconsin, Madison, where the seeds for this textbook were undoubtedly planted. After two years of postdoctoral study at the University of Rochester, he spent a year at Advanced Technology Materials, Inc., before returning to academics at Northeastern University in 1989. He is an associate professor of chemistry with an active research interest in organometallic chemistry. He has been awarded Northeastern’s Excellence in Teaching Award and received the John A. Timm Award from the New England Association of Chemistry Teachers in 2019.

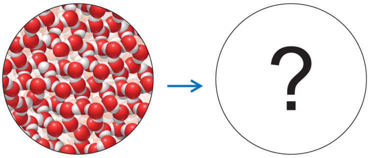
Stacey Lowery Bretz is a University Distinguished Professor in the Department of Chemistry and Biochemistry at Miami University in Oxford, Ohio. She earned her BA in chemistry from Cornell University, MS from Pennsylvania State University, and a PhD in chemistry education research from Cornell University. She spent one year at the University of California, Berkeley, as a postdoc in the Department of Chemistry. Her research expertise includes the development of assessments to measure chemistry students’ thinking with multiple representations (particulate, symbolic, and macroscopic) and to promote meaningful and inquiry learning in the chemistry laboratory. She is a Fellow of the American Chemical Society and a Fellow of the American Association for the Advancement of Science. She has been honored with both of Miami University’s highest teaching awards: the E. Phillips Knox Award for Undergraduate Teaching and the Distinguished Teaching Award for

Excellence in Graduate Instruction and Mentoring. Stacey won the prestigious, international award from the American Chemical Society for Achievement in Research for the Teaching and Learning of Chemistry in 2020.

Natalie Foster is emerita professor of chemistry at Lehigh University in Bethlehem, Pennsylvania. She received a BS in chemistry from Muhlenberg College and MS, DA, and PhD degrees from Lehigh University. Her research interests included studying poly(vinyl alcohol) gels by NMR as part of a larger interest in porphyrins and phthalocyanines as candidate contrast enhancement agents for MRI. She taught both semesters of the introductory chemistry class to engineering, biology, and other nonchemistry majors and a spectral analysis course at the graduate level. She is the recipient of the Christian R. and Mary F. Lindback Foundation Award for Distinguished Teaching and a Fellow of the American Chemical Society.

PARTICULATE **REVIEW**

Particles in the Gas Phase



In Chapter 5 we focus on the properties of gases, including those that serve as fuels in combustion reactions, as described in Chapter 3, and in other forms of energy production. One such fuel is hydrogen gas, which can be produced by passing an electric current through water, causing molecules of liquid H_2O to decompose into molecules of H_2 and O_2 gas.

- Write a balanced chemical equation describing this decomposition reaction.
- In the circle on the right, draw the products that would be produced by decomposition of six of the water molecules on the left.
- Classify the products as elements, compounds, or a mixture. Choose all that apply.

(Review Sections 1.1, 1.2, and 3.3 if you need help.)

(Answers to Particulate Review questions are in the back of the book.)

PARTICULATE **PREVIEW**

Pressure, Volume, and Temperature

As you read Chapter 5, look for ideas that will help you answer these questions.

- Draw particulate images of the helium in the tank and in one of the balloons. How do these drawings differ?
- Suppose the tank and several helium-filled balloons are placed in the trunk of a car on a hot summer day.
  - How would your particulate image for the helium in the balloon change?
  - How would your particulate image for the helium in the tank change?

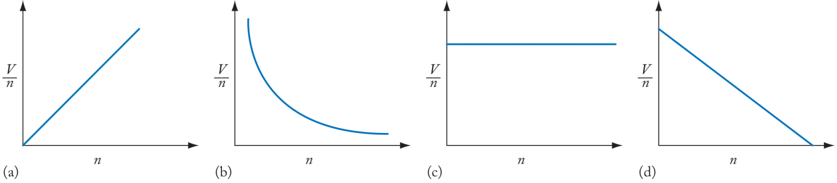


FIGURE 5.18

CONNECTION In Chapter 3 the number of particles in a mole was defined as Avogadro’s constant, in honor of Amedeo Avogadro’s early work with gases that led to determining atomic masses.

5.22. Use representations [A] through [I] in Figure P5.22 to answer questions (a)–(f). The pink balloons contain hydrogen, the yellow balloons contain nitrogen, and the gray balloons contain oxygen.

a. Identify three different changes that could be responsible for the change in size of the pink balloon from [A] to [C].
b. If the smaller pink balloon in [A] corresponds to the particulate view in [B], which of the changes identified in part (a) would result in the larger pink balloon in [C] also corresponding to the particulate view in [B]?
c. If the smaller yellow balloon in [D] corresponds to the particulate view in [E], which particulate view corresponds to the larger yellow balloon in [F] if no additional nitrogen has been added?
d. If the larger gray balloon in [I] corresponds to the particulate view in [E], which particulate view represents the gas at a lower temperature?
e. If each gray balloon contains 1 mol of gas at 25°C, in which balloon are the collisions between the oxygen molecules and the inside of the balloon more frequent?
f. Which balloon contains the gas with the shortest mean free path?

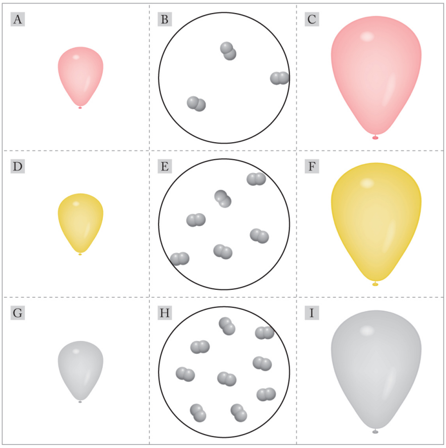

FIGURE P5.22

CHEMTOUR STEPWISE ANIMATION

PROBLEM-SOLVING SUMMARY

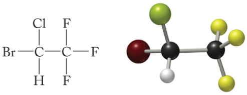
Type of Problem	Concepts and Equations	Sample Exercises
Calculating pressure of any gas; calculating atmospheric pressure	Divide the force by the area over which the force is applied, using the equation $P = \frac{F}{A}$ (5.1)	**5.1, 5.2**
Calculating changes in *P*, *V*, or *T* in response to changing conditions	Rearrange $\frac{P_1V_1}{T_1} = \frac{P_2V_2}{T_2}$ (5.18) for whichever variable is sought and then substitute given values. (*T* must be in kelvins, and *n* must be constant.)	**5.3, 5.4, 5.5, 5.6**
Determining *n* from *P*, *V*, and *T*	Rearrange $PV = nRT$ (5.15) for *n* and then substitute given values of *P*, *T*, and *V*. (*T* must be in kelvins.)	**5.7, 5.8, 5.9**
Calculating the density of a gas and calculating molar mass from density	Substitute values for pressure, absolute temperature, and molar mass into the equation $d = \frac{P\mathcal{M}}{RT}$ (5.21) Substitute values for pressure, absolute temperature, and density into the equation $\mathcal{M} = \frac{dRT}{P}$ (5.22)	**5.10, 5.11**
Calculating mole fraction for one component gas in a mixture	Divide the number of moles of the component gas by the total number of moles in the mixture: $X_x = \frac{n_x}{n_{total}}$ (5.24)	**5.12**
Calculating partial pressure of one component gas in a mixture and total pressure in the mixture	Substitute the mole fraction of the component gas and the total pressure in the equation $P_x = X_xP_{\text{total}}$ (5.25) Solve the equation $P_{\text{total}} = P_1 + P_2 + P_3 + P_4 + \ldots$ (5.23) for the partial pressure of the component gas and then substitute given values for other partial pressures and total pressure.	**5.13, 5.14**

5.87. Biological Effects of Radon Exposure Radon is a naturally occurring radioactive gas found in the ground and in building materials. It is easily inhaled and emits α particles when it decays. Cumulative radon exposure is a significant risk factor for lung cancer.

a. Calculate the density of radon at 298 K and 1.00 atm of pressure.
b. Are radon concentrations likely to be greater in the basement or on the top floor of a building?

*5.88. Four empty balloons, each with a mass of 10.0 g, are inflated to a volume of 20.0 L. The first balloon contains He; the second, Ne; the third, CO_2; and the fourth, CO. If the density of air at 25°C and 1.00 atm is 0.00117 g/mL, which of the balloons float in this air?

5.155. Anesthesia A common anesthesia gas is halothane, with the structure shown in Figure P5.155. Liquid halothane boils at 50.2°C and 1.00 atm. If halothane behaved as an ideal gas, what volume would 10.0 mL of liquid halothane (d = 1.87 g/mL) occupy at 60°C and 1.00 atm of pressure? What is the density of halothane vapor at 55°C and 1.00 atm of pressure?



$Br-\overset{Cl}{\underset{H}{C}}-\overset{F}{\underset{F}{C}}-F$

Chemistry

The Science in Context

Preface

Dear Student,

We wrote this book with three overarching goals in mind: to make chemistry interesting, relevant, and memorable; to enable you to see the world from a molecular point of view; and to help you become an expert problem-solver. You have a number of resources available to assist you to succeed in your general chemistry course. This textbook will be a valuable resource, and we have written it with you, and the different ways you may use the book, in mind.

If you are someone who reads a chapter from the first page to the last, you will see that the Sixth Edition introduces the chemical principles within a chapter by using contexts drawn from daily life as well as from other disciplines, including biology, environmental science, materials science, astronomy, geology, and medicine. We believe that these contexts make chemistry more interesting, relevant, and memorable.

Chemists' unique perspective of natural processes and insights into the properties of substances, from high-performance alloys to the products of biotechnology, are based on understanding these processes and substances at the particulate level (the atomic and molecular level). A major goal of this book is to help you develop this microscale perspective and link it to macroscopic properties.

With that in mind, we begin each chapter with a **Particulate Review** and **Particulate Preview**. The goal of these tools is to prepare you for the material in the chapter. The **Particulate Review** assesses important prior knowledge that you need to interpret particulate images in the chapter. The **Particulate Preview** asks you to speculate about new concepts you will see in the chapter and is meant to focus your reading.

If you want a quick summary of what is most important in a chapter to direct your studying on selected topics, check the **Learning Outcomes** at the beginning of each chapter. Whether you are reading the chapter from first page to last, moving from topic to topic in an order you select, or reviewing material for an exam, the Learning Outcomes can help you focus on the key information you need to know and the skills you should develop.

In every section, you will find **key terms** in boldface in the text and in a **running glossary** in the margin. We have inserted the definitions throughout the text, so you can continue reading without interruption but quickly find key terms when doing homework or reviewing for a test. All key terms are also defined in the Glossary in the back of the book.

Approximately once per section, you will find a **Concept Test**. These short, conceptual questions provide a self-check opportunity by asking you to stop and answer a question relating to what you just read. We designed them to help you self-assess, and you will find answers to Concept Tests in the back of the book.

CONCEPT TEST

Which graph in **Figure 5.18** correctly describes the relationship between the value of V/n as n is increased at constant P and T?

(Answers to Concept Tests are in the back of the book.)

New concepts naturally build on previous information, and you will find that many concepts are related to others described earlier in the book. We point out these relationships with **Connection** icons in the margins. These reminders will help you see the big picture and draw your own connections between concepts in the book.

At the end of each chapter are **Visual Problems** that ask you to interpret atomic and molecular views of elements and compounds, along with graphs of experimental data. The last Visual Problem in each chapter contains a **visual problem matrix**. This grid consists of nine images followed by a series of questions that will test your ability to identify the similarities and differences among the macroscopic and particulate images.

If you're looking for additional help visualizing a concept, we have nearly 140 animations and simulations, denoted by the **ChemTour** and **Stepwise Animation** icons. These animations, available at digital.wwnorton.com/chem6, show chemical concepts and processes to help you visualize events at the macro, micro, and symbolic level. Many of the ChemTours are interactive, allowing you to manipulate variables and observe changes in a graph or a process. Questions at the end of ChemTours offer step-by-step assistance in solving problems and provide useful feedback.

Another goal of the book is to help you improve your problem-solving skills. Sometimes the hardest parts of solving a problem is knowing where to start and distinguishing between information that is relevant and information that is not. Once you are clear on where you are starting and where you are going, planning for and arriving at a solution become much easier.

To help you hone your problem-solving skills, we have developed a framework that is introduced in Chapter 1 and used consistently throughout the book. It is a four-step approach we call **COAST**, which is our acronym for (1) **C**ollect and **O**rganize, (2) **A**nalyze, (3) **S**olve, and (4) **T**hink About It. We use these four steps in *every* Sample Exercise and in the solutions to *odd-numbered* problems in the Student Solutions Manual. They are also used in the hints and feedback embedded in the Smartwork5 online homework program. To summarize the four steps:

Collect and Organize helps you understand where to begin. In this step we often point out what you must find and what is given, including the relevant information that is provided in the problem statement or available elsewhere in the book.

Analyze is where we map out a strategy for solving the problem. As part of that strategy we often estimate what a reasonable answer might be.

Solve applies our strategy from the second step to the information and relationships identified in the first step as we solve the problem. We walk you through each step in the solution, using dimensional analysis consistently, so that you can follow the logic as well as the math.

Think About It reminds us that calculating or determining an answer is not the last step when solving a problem. We check whether the answer is reasonable in light of our estimate. Is it realistic? Are the units correct? Is the number of significant figures appropriate?

Many students use the **Sample Exercises** more than any other part of the book. Sample Exercises take the concepts being discussed and illustrate how to apply them to solve problems. We hope that repeated application of COAST will help you refine your problem-solving skills and become an expert problem-solver. When you finish a Sample Exercise, you'll find a **Practice Exercise** to try on your own. Notice that the Sample Exercises and the Learning Objectives are connected. We think this will help you focus efficiently on the main ideas in the chapter.

Students sometimes comment that the questions on an exam are more challenging than the Sample Exercises in a book. To address this, we have an **Integrating Concepts Sample Exercise** near the end of each chapter. These exercises require you to use more than one concept from the chapter and may expect you to use concepts from earlier chapters to solve a problem. Please invest your time working through these problems because we think they will further enhance your problem-solving skills and give you an increased appreciation of how chemistry is used in the world.

If you use the book mostly as a reference and problem-solving guide, we have a learning path for you as well. It starts with a **Summary** and a **Problem-Solving Summary** at the end of each chapter. The first is a brief synopsis of the chapter, organized by Learning Outcomes and referencing sections from the chapter. Key figures have been added to this Summary to provide visual cues as you review. The Problem-Solving Summary organizes the chapter by problem type and summarizes relevant concepts and equations you need to solve each type of problem. The Problem-Solving Summary also points you back to the relevant Sample Exercises that model how to solve each problem and cross-references the Learning Outcomes at the beginning of the chapter.

Following the summaries are groups of questions and problems. The first group is the **Visual Problems**. **Concept Review Questions and Problems** come next, arranged by topic in the same order as they appear in the chapter. Concept Reviews are qualitative and often ask you to explain why or how something happens. Problems are paired and can be quantitative, conceptual, or a combination of both. **Contextual problems** have a title that describes the context in which the problem is placed. **Additional Problems** can come from any section or combination of sections in the chapter. Some of them incorporate concepts from previous chapters. Problems marked with an asterisk (*) are more challenging and often require multiple steps to solve.

We want you to have confidence in using the answers in the back of the book as well as the Student Solutions Manual, so we continue to use a rigorous triple-check accuracy program for the Sixth Edition. Each end-of-chapter question and problem has been solved independently by at least three PhD chemists. For the Sixth Edition the team included solutions manual author Don Carpenetti and two additional chemistry educators. Don compared his solutions to those from the reviewers and resolved any discrepancies. This process is designed to ensure clearly written problems and accurate answers in the appendices and solutions manual.

No matter how you use this book, we hope it becomes a valuable tool for you and helps you not only understand the principles of chemistry but also apply them to solving global problems, such as diagnosing and treating disease or making more efficient use of Earth's natural resources.

Changes to the Sixth Edition

Dear Instructor,

As authors of a textbook we are very often asked: "Why is a new edition necessary? Has the science changed that much since the previous edition?" Although chemistry is a vigorous and dynamic field, most basic concepts presented in an introductory course have not changed dramatically. However, two areas tightly intertwined in this text—pedagogy and context—have changed significantly, and those areas drive this new edition. Here are some of the most noteworthy changes we made throughout this edition:

- Adopters enthusiastically embraced the visualization pedagogy that was introduced in the Fifth Edition and then asked for additional tools to help them use this research-based pedagogy to assess student learning. The teaching tools accompanying the Sixth Edition include:

  - In-class activities, such as pre-made handouts, help you facilitate active learning, with a focus on visualization, in any size classroom.
  - Projected visualization questions help you assess students on their understanding and support the Particulate Review, Particulate Preview, and Visual Matrix problems in the book by providing color images that you can project in your class accompanied by questions that you can use on your exam or for in-class quizzes.
  - The new Interactive Instructor's Guide (IIG), an easily searchable online resource, contains all the teaching resources for the Sixth Edition. Instructors can search by chapter, phrase, topic, or learning objective to find activities, animations, simulations, and visualization questions to use in class.

- Based on her chemistry education research, Stacey Lowery Bretz evaluated and revised the art in the book and the media to be more pedagogically effective and address student misconceptions.
- The gases chapter, now Chapter 5, comes before thermochemistry (Chapter 6), which allows instructors to introduce pressure–volume work and its impact of the internal energy of gaseous systems after students have explored the behavior of gases and the inverse relationship between pressure and volume.
- End-of-chapter problems have been refined to better align with the text's Learning Outcomes and provide a more balanced selection in terms of level and concept coverage. We estimate that between 10%–15% of the end-of-chapter problems have been replaced or revised.
- Smartwork5 now offers more than 5000 problems, including 600 new to the Sixth Edition. New Smartwork5 problems include more end-of-chapter problems, algorithmic problems,

and pooled problems.
- Adaptive functionality in Smartwork5, powered by Knewton, has been continuously improved, resulting in more intuitive experiences for students as they work through personalized learning paths. It also offers the availability of better data for instructors to review their students' mastery of chosen learning objectives.
- Revised ChemTour animations, also found in the ebook and Smartwork5, are now easier to navigate and individual sections of each animation can now be easily viewed and assigned. ChemTours are available streaming in the ebook, in Smartwork5 questions, as remediation in adaptive assignments, and are in the IIG, which also includes discussion questions and activity ideas for each animation.
- Our new partnership with Squarecap classroom response system provides you with book-specific clicker questions in an easy-to-use system at a low cost to students.

Teaching and Learning Resources

Smartwork5

digital.wwnorton.com/chem6

Smartwork5 is the most intuitive online tutorial and homework management system available for general chemistry. The many question types, including graded molecular drawings, math and chemical equations, ranking tasks, and interactive figures, help students develop and apply their understanding of fundamental concepts in chemistry. Adaptive functionality, powered by Knewton, gives students personalized coaching, allowing them to reach mastery of assigned concepts at their own pace.

Every problem in Smartwork5 includes response-specific feedback and general hints often organized by the steps in COAST. Links to the ebook version of *Chemistry*, Sixth Edition, take students to the specific place in the text where the concept is explained. All problems in Smartwork5 use the same language and notation as the textbook.

Smartwork5 also features Tutorial Problems. If students ask for help in a Tutorial Problem, the system breaks the problem down into smaller steps, coaching them with hints, answer-specific feedback, and probing questions within each part. At any point in a Tutorial, a student can return to and answer the original problem.

Assigning, editing, and administering homework within Smartwork5 is easy. It's tablet compatible and integrates with the most common campus learning management systems. Smartwork5 allows the instructor to search for problems by text sections, learning objectives, question type, difficulty, and Bloom's taxonomy. Instructors can use premade assignment sets provided by Norton authors, modify those assignments, or create their own. Instructors can also make changes in the problems at the question level. All instructors have access to our WYSIWYG (What You See Is What You Get) authoring tools—the same ones Norton authors use. Those intuitive tools make it easy to modify existing problems or to develop new content that meets the specific needs of a course.

Wherever possible, Smartwork5 makes use of algorithmic variables so that students see slightly different versions of the same problem. Assignments are graded automatically, and Smartwork5 includes sophisticated yet flexible tools for managing class data. Instructors can use the class activity report to assess students' performance on specific problems within an assignment. Instructors can also review individual students' work on problems.

Smartwork5 for *Chemistry*, Sixth Edition, features the following problem types:

- End-of-Chapter Problems. These problems, which use algorithmic variables when appropriate, all have hints and answer-specific feedback to coach students through mastering single- and multiple-concept problems based on chapter content. They make use of all of Smartwork5's answer-entry tools.
- ChemTour Problems. Many of the ChemTour animations have been redesigned to make them easier than ever to navigate, making it simple to assign Smartwork5 questions on specific interactives.
- Visual and Graphing Problems. These problems challenge

students to identify chemical phenomena and to interpret graphs. They use Smartwork5's drag-and-drop functionality.
- Ranking Task Problems. These problems ask students to make comparative judgments between items in a set.
- Nomenclature Problems. New matching and multiple-choice problems help students master course vocabulary.
- Multistep Tutorials. These problems offer students who demonstrate a need for help a series of linked, step-by-step subproblems to work. They are based on the Concept Review problems at the end of each chapter.
- Math Review Problems. These problems can be used by students for practice or by instructors to diagnose the mathematical ability of their students.

Ebook

digital.wwnorton.com/chem6

An affordable and convenient alternative to the print text, Norton Ebooks let students access the entire book and much more: they can search, highlight, and take notes with ease. The Norton Ebook allows instructors to share their notes with students. The ebook can be viewed on most devices—laptop, tablet, even a public computer—and will stay synced between devices.

The online version of *Chemistry*, Sixth Edition, also provides students with one-click access to our approximately 130 simulations and animations.

The online ebook is available bundled with the print text and Smartwork5 at no extra cost, or it may be purchased bundled with Smartwork5 access.

Norton also offers a downloadable PDF version of the ebook.

Student Solutions Manual

by Don Carpenetti, Craven Community College

The Student Solutions Manual provides students with fully worked solutions to select end-of-chapter problems using the **COAST** four-step method (**C**ollect and **O**rganize, **A**nalyze, **S**olve, and **T**hink About It). The Student Solutions Manual contains several pieces of art for each chapter, designed to help students visualize ways to approach problems. This artwork is also used in the hints and feedback within Smartwork5.

Test Bank

by Chris Harmon, Humboldt State University, and Jamie Schneider, University of Wisconsin River Falls

Norton uses an innovative, evidence-based model to deliver high-quality and pedagogically effective quizzes and testing materials. Each chapter of the Test Bank is structured around an expanded list of student learning objectives and evaluates student knowledge on six distinct levels based on Bloom's Taxonomy: Remembering, Understanding, Applying, Analyzing, Evaluating, and Creating.

Questions are further classified by text section and difficulty, making it easy to construct tests and quizzes that are meaningful and diagnostic, according to each instructor's needs. New questions are marked and sortable, making it easy to find brand new problems to add to exams. More than 2500 questions are divided into multiple choice and short answer.

The Test Bank is available with ExamView Test Generator software, allowing instructors to effortlessly create, administer, and manage assessments. The convenient and intuitive test-making wizard makes it easy to create customized exams with no software learning curve. Other key features include the ability to create paper exams with algorithmically generated variables and export files directly to Blackboard, Canvas, Desire2Learn, and Moodle.

Projected Visualization Questions

by Chris Harmon, Humboldt State, and Jamie Schneider, University of Wisconsin River Falls

Stacey Lowery Bretz believes that you must include visualization questions on exams if you want students to take learning this skill seriously. To overcome the challenge of not being able to distribute four-color exams to her class, she includes several problems on her exams that require students to look at a particulate, macro, or symbolic image which is projected at the front of the room. Our new projected visualization problems allow instructors to use this approach to ask questions about full-color images on exams or in-class activities.

Instructor's Solutions Manual

by Don Carpenetti, Craven Community College

The Instructor's Solutions Manual provides instructors with fully worked solutions to every end-of-chapter Concept Review and Problem. Each solution uses the **COAST** four-step method (**C**ollect and **O**rganize, **A**nalyze, **S**olve, and **T**hink About It).

Interactive Instructor's Guide

iig.wwnorton.com/chem6/full

by Kevin Braun, Virginia Military Institute, Nicole Heldt, SUNY Canton, and Mohammed Shahin, Fullerton College

The Interactive Instructor's Guide will help instructors use our unique visualization pedagogy in class and for assessment by compiling the many valuable teaching resources available with *Chemistry*, Sixth Edition, in an easily searchable online format. In-class activities, backed by chemical education research and written by active learning experts, emphasize visualization and are designed to promote collaboration. New projected visualization problems, based on how Stacey Lowery Bretz gives her own exams, allow instructors to ask exam questions using full-color images. The ChemTours are also accompanied by new activity ideas, discussion questions, and clicker questions, making them easier than ever to use. All resources are searchable by chapter, keyword, or learning objective.

Clickers in Action: Increasing Student Participation in General Chemistry

by Margaret Asirvatham, University of Colorado, Boulder

An instructor-oriented resource providing information on implementing clickers in general chemistry courses, *Clickers in Action* contains more than 250 class-tested, lecture-ready questions, with histograms showing student responses, as well as insights and suggestions for implementation. Question types include macroscopic observation, symbolic representation, and atomic/molecular views of processes.

Downloadable Instructor's Resources

digital.wwnorton.com/chem6

This password-protected site for instructors includes:

- Stepwise Animations and classroom response questions. Developed by Jeffrey Macedone of Brigham Young University and his team, these animations, which use native PowerPoint functionality and textbook art, help instructors to "walk" students through nearly 100 chemical concepts and processes. Where appropriate, the slides contain two types of questions for students to answer in class: questions that ask them to predict what will happen next and why, and questions that ask them to apply knowledge gained from watching the animation. Self-contained notes help instructors adapt these materials to their own classrooms.
- Lecture PowerPoints.
- All ChemTours.
- Test Bank in PDF, Word, and ExamView Assessment Suite formats.
- Solutions manual in PDF and Word, so that instructors may edit solutions.
- All of the end-of-chapter Questions and Problems, available in Word along with the key equations.
- Photographs, drawn figures, and tables from the text, available in PowerPoint and JPEG format.
- Clicker questions, including those from *Clickers in Action.*
- Course cartridges. Available for the most common learning management systems, course cartridges include access to the

ChemTours and Stepwise Animations as well as links to the ebook and Smartwork5.

Acknowledgments

We begin by thanking the users and reviewers who provided the feedback necessary to make the Sixth Edition possible. In addition to written reviews, the comments we receive at meetings, in focus groups, in emails, and from office visits with the Norton sales, editorial, and marketing staff help us identify what works well and what needs to be improved. Those suggestions and critical feedback encouraged us to make the content, context, and pedagogy work better and maximize learning for students.

Our colleagues at W. W. Norton remain a constant source of inspiration and guidance. Their passion for providing accurate and reliable content sets a high standard that motivates us to create an exceptional and user-friendly set of resources for instructors and students. The people at W. W. Norton with whom we work most closely deserve much more praise than we can possibly express here. Our editor, Erik Fahlgren, continues to offer his wisdom, guidance, energy, creativity, and most impressively, an endless amount of patience, as he simultaneously leads and pushes us to meet deadlines. Erik's leadership is the single greatest reason for this book's completion, and our greatest thanks are far too humble an offering for his unwavering vision and commitment. He is the consummate professional and a valued friend.

We have enjoyed and benefited from the humor and wisdom of our developmental editor, John Murdzek. Carla Talmadge has been the project editor on many editions and we trust that she will help synchronize our words and images on every page. Thanks to our production manager, Ben Reynolds, who handled his first chemistry rodeo like a pro; copyeditor Marjorie Anderson who was punctual, accurate, and pleasant to work with; proofreader Chris Curioli whose work is always thorough and steady; Stephanie Romeo and Julie Tesser who helped us find just the right photos; Grace Tuttle who did a masterful job at creating and revising the teaching and learning resources for this edition; Cailin Barrett-Bressack for her work on Smartwork5 and the other media that help students learn and practice and instructors assess that learning; and to Stacy Loyal who continues to creatively market the book and work with the Norton team in the field.

This book has benefited greatly from the care and thought that many reviewers, listed here, gave to their readings of earlier drafts. We owe an extra-special thanks to Don Carpenetti for his dedicated and precise work on the solutions manual. He, along with Andy Ho and Sri Kamesh Narasimhan are the triple-check accuracy team who solved each problem and reviewed each solution for accuracy. We also greatly appreciate Thomas Berke, Kevin Boyd, Carmin Burrell, Mark Campbell, Gabriel Cook, Jim Davis, John Elliff, Matthew Hurst, Rebecca Laird, Edgar Lee, Brian Leskiw, Carol Martinez, Drew Meyer, James Nyachwaya, Julie Pigza, Wendy Schatzberg, Daniel Swart, and Jordan Vincent for checking the accuracy of the myriad facts that form the framework of our science.

We have used the U.S. system as well as the system recommended by the International Union of Pure and Applied Chemistry (IUPAC) to label the groups in this periodic table. The system used in the United States includes a letter and a number (1A, 2A, 3B, 4B, etc.), which is close to the system developed by Mendeleev. The IUPAC system uses numbers 1–18 and has been recommended by the American Chemical Society (ACS). Although we show both numbering systems here, we use the IUPAC system exclusively in the book.

Particles of Matter

Measurement and the Tools of Science

PARTICULATE REVIEW

Atoms and Molecules: What’s the Difference?

In Chapter 1 we explore how chemists classify different kinds of matter, from elements to compounds to mixtures. Hydrogen and helium were the first two elements formed after the universe began. Chemists use distinctively colored spheres to distinguish atoms of different elements in their drawings and models. For example, hydrogen is almost always depicted as white.

- How many of the following particles are shown in this image?
    - ○ Hydrogen atoms
    - ○ Hydrogen molecules
    - ○ Helium atoms
- Are molecules composed of atoms, or are atoms composed of molecules?

(Answers to Particulate Review questions are in the back of the book.)

PARTICULATE PREVIEW

Matter and Energy

The temperature in outer space is 2.73 K. The temperature of dry ice (carbon dioxide, CO_2) can be 192 K warmer, but still cold enough to keep ice cream frozen on a hot summer day. As you read Chapter 1, look for ideas that will help you answer these questions:

- Particulate images of CO_2 as it sublimes are shown here. Which two phases of matter are involved in sublimation?
- What features of the images helped you decide which two phases were involved?
- What is the role of energy in this transformation of matter? Is energy added or is energy produced?

Learning Outcomes

- LO1 Distinguish among pure substances, homogeneous mixtures, and heterogeneous mixtures, and between elements and compounds
- LO2 Describe the particles that make up elements and compounds and how the particulate composition of substances is reflected in their chemical formulas and molecular structures
- LO3 Distinguish between physical processes and chemical reactions, and between physical and chemical properties

Sample Exercise 1.1

- LO4 Use a systematic approach (COAST) to problem solving
- LO5 Describe the three states of matter and the transitions between them at the macroscopic and particulate levels

Sample Exercise 1.2

- LO6 Describe the scientific method
- LO7 Convert quantities from one system of units to another

Sample Exercises 1.3, 1.4, 1.9

- LO8 Express uncertain values with the appropriate number of significant figures

Sample Exercise 1.5

- LO9 Distinguish between exact and uncertain values, evaluate the precision and accuracy of experimental results, and identify outliers

Sample Exercises 1.6, 1.7, 1.8

1.1 How and Why

For thousands of years, we humans have sought to better understand the world around us. For most of that time we resorted to mythological explanations of natural phenomena. Many once believed, for example, that the Sun rose in the east and set in the west because it was carried across the sky by a god driving a chariot propelled by winged horses.

In recent times we have been able to move beyond such fanciful accounts of natural phenomena to explanations based on observation and scientific reasoning. Unfortunately, this movement toward rational explanations has not always been smooth. Consider, for example, the contributions of Galileo Galilei, the man Albert Einstein called the father of modern science. At the dawn of the 17th century, Galileo used advanced telescopes of his own design to observe the movement of the planets and their moons. He concluded that they, like Earth, revolved around the Sun. However, this view conflicted with a belief held by many religious leaders of his time that Earth was the center of the universe. In 1633 a religious tribunal forced Galileo to disavow his conclusion that Earth orbited the Sun and banned him (or anyone) from publishing the results of studies that called into question the Earth-centered view of the universe. The ban was not completely lifted until 1835—nearly 200 years after Galileo's death.

In the last century, advances in the design and performance of telescopes have led to the astounding discovery that we live in an expanding universe that probably began 13.8 billion years ago with an enormous release of energy. In this chapter and in later ones, we examine some of the data that led to the theory of the Big Bang and that also explain the formation of the elements that make up the universe, our planet, and ourselves.

Scientific investigations into the origin of the universe have stretched the human imagination and forced scientists to develop new models and new explanations of how and why things are the way they are. Frequently these efforts have involved observing and measuring large-scale phenomena, which we refer to as *macroscopic* phenomena. We seek to explain these macroscopic phenomena through *particulate* representations that show the structure of matter on the scale of atomic and even subatomic particles. Throughout this text, you will encounter many of these macroscopic–particulate connections. The authors of this book hope that your exploration of these connections will help you better understand how and why nature is the way it is.

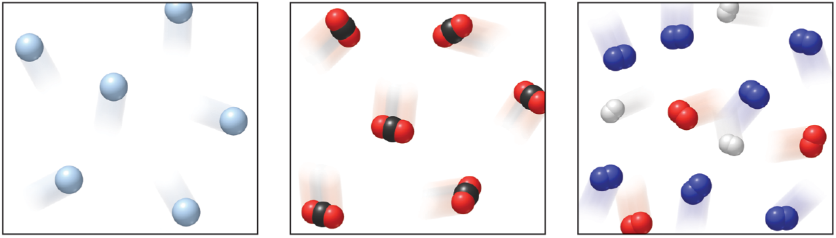
FIGURE 1.1 The two principal classes of matter are pure substances and mixtures. A pure substance may be a compound (such as water) or an element (such as gold). A mixture is homogeneous when the substances are distributed uniformly, as they are in vinegar (a mixture of mostly acetic acid and water). A mixture is heterogeneous when the substances are not distributed uniformly, that is, when solids are suspended in a liquid but may settle to the bottom of the container, as they do in some salad dressings.

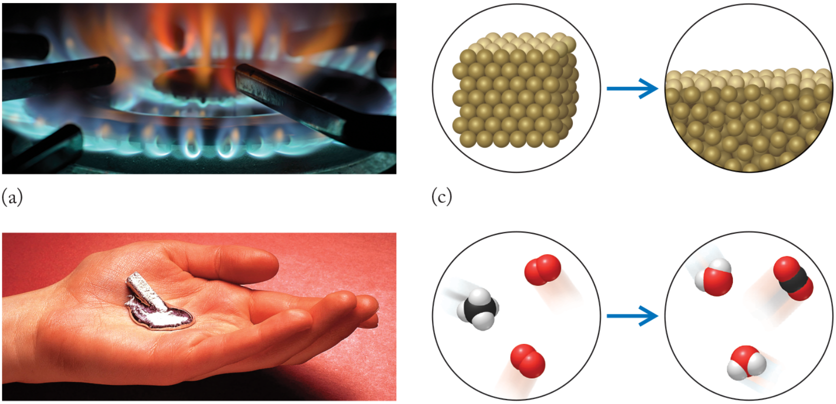


(a) Atoms of helium, an element

(b) Molecules of carbon dioxide, a compound

(c) Mixture of gases

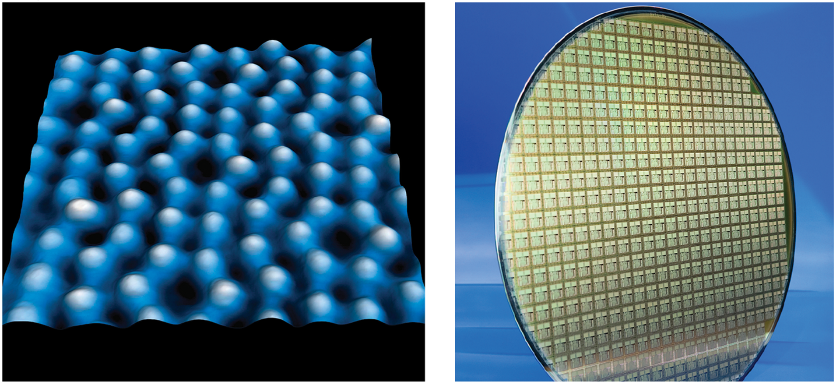
FIGURE 1.2 All matter is made up of either pure substances (of which there are relatively few in nature) or mixtures. (a) The element helium (He), the second most abundant element in the universe, is a pure substance. (b) The compound carbon dioxide (CO_2), the gas used in many fire extinguishers, is also a pure substance. (c) This homogeneous mixture contains three substances: nitrogen (N_2, blue), hydrogen (H_2, white), and oxygen (O_2, red).



(a) (c)

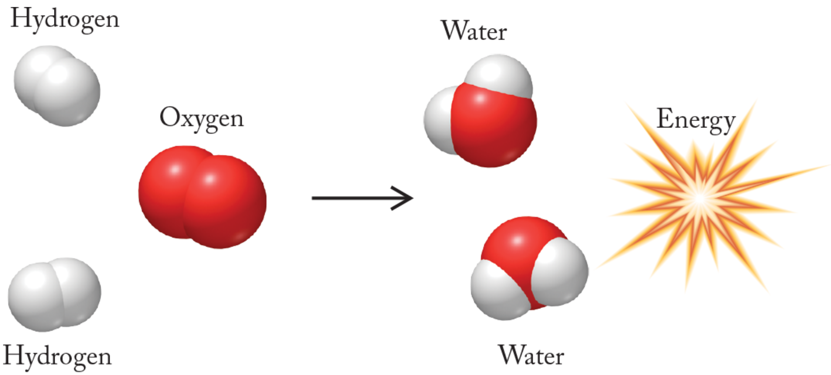
(b) (d)

FIGURE 1.3 Macroscopic and particulate representations of both a physical process and a chemical reaction.



(a) (b)

FIGURE 1.4 Since the 1980s, scientists have been able to image individual atoms by using an instrument called a scanning tunneling microscope (STM). (a) In this STM image of (b) a disk made of high-purity silicon, the fuzzy objects arranged in an array of hexagons are composed of six silicon atoms, which are colored blue to make them easier to see—keep in mind that atoms don't have colors!



$$2\,H_2(g) + O_2(g) \longrightarrow 2\,H_2O(g) + \text{Energy}$$

Reactants ⟶ Products

FIGURE 1.5 The reaction between hydrogen and oxygen is depicted with molecular models (white and red spheres) and in the form of a chemical equation. Energy is also a product of the reaction, meaning that energy is released when the water product is formed.

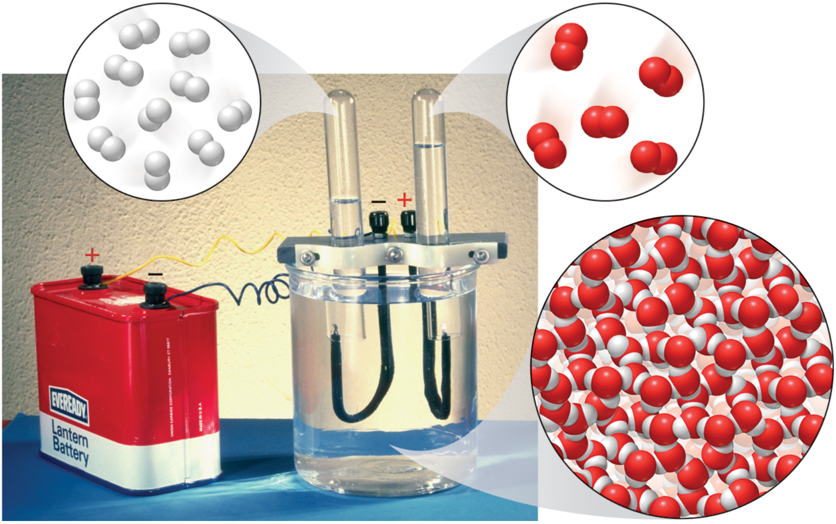


FIGURE 1.6 An electric current passed through water provides enough energy to decompose water into oxygen gas and hydrogen gas, both of which displace the water from the tops of their respective inverted test tubes. The ratio of the gases produced is always two molecules of hydrogen for every one molecule of oxygen, which is why the volume of H_2 gas produced is twice the volume of O_2 gas. These fixed proportions illustrate the law of

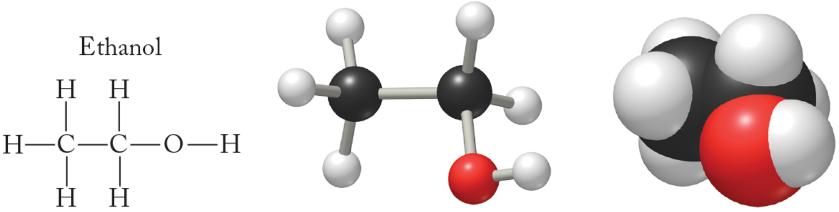
constant composition.



(a) Structural formula (b) Ball-and-stick model (c) Space-filling model

FIGURE 1.7 Three ways to represent the arrangement of atoms in a molecule of ethanol: (a) structural formula, (b) ball-and-stick model, (c) space-filling model. In both molecular models, white spheres represent hydrogen atoms, black spheres represent carbon atoms, and red spheres represent oxygen atoms.

1.2 Macroscopic and Particulate Views of Matter

According to a formula widely used in medicine, the ideal weight for adult males 176 centimeters (cm, or 69 inches) tall (the average height of American and Canadian men) is 69 kilograms (kg, or 152 pounds). On average, this body mass consists of 12 kg of fat and 57 kg of lean body mass, including bones, organs, muscles, and blood. These values are measures of the total *mass* of all the *matter* in the body. In general, mass is the quantity of matter in any object. Matter, in turn, is a term that applies to everything in the body (and in the universe) that has mass and occupies space. Chemistry is the study of the composition, structure, and properties of matter.

Classes of Matter

The different forms of matter are classified according to the scheme shown in **Figure 1.1**. We begin on the left with pure substances, which have a constant composition that does not vary from one sample to another. The composition of pure water does not vary, no matter what its source or how much of it there is. Like all pure substances, water cannot be separated into simpler substances by any physical process. A physical process is a transformation of a sample of matter that does not alter the chemical identities of any of the substances in the sample, such as a change in physical state from solid to liquid.

Pure substances are further classified as elements (**Figure 1.2a**) and compounds (**Figure 1.2b**). An element is a pure substance that cannot be broken down into simpler substances. The periodic table inside the front cover shows all 118 of the known elements. Only a few of them (including gold, silver, nitrogen, oxygen, and sulfur) occur in nature uncombined with other elements. Instead, most elements in nature are combined with other elements in the form of compounds, which are substances composed of two or more elements combined in fixed proportions. The elements in a compound can be separated from one another only by a chemical reaction: the transformation of one or more substances into one or more different substances. Compounds typically have properties that are very different from those of the elements of which they are composed. For example, common table salt (sodium chloride) has little in common with either sodium, which is a silver-gray metal that reacts violently when dropped in water, or chlorine, which is a toxic yellow-green gas.

CONCEPT TEST

Which photo in **Figure 1.3** depicts a physical process? Which photo depicts a chemical reaction? Use what you know about the difference between a physical process and a chemical reaction to match each photo to its corresponding particulate representation.

(Answers to Concept Tests are in the back of the book.)

A mixture (**Figure 1.2c**) is a form of matter that is composed of two or more substances that retain their own chemical identities. The substances in mixtures are not present in definite proportions. For example, the composition of circulating blood in a human body is constantly changing as it delivers substances involved in energy production and cell growth to the cells and carries away the waste products of life's biochemical processes. Thus, blood contains more oxygen and less carbon dioxide when it leaves our lungs than it does when it enters them. The substances in mixtures can be separated from one another by physical processes (Figure 1.1), such as those described in Section 1.3.

Mixtures can be further classified as homogeneous and heterogeneous (Figure 1.1). In a homogeneous mixture, the substances making up the mixture are uniformly distributed. This means that the first sip you take from a bottle of water has the same composition as the last. (Bottled water contains small quantities of dissolved substances that either occur naturally in the water or are added prior to bottling to give it an agreeable taste. Bottled drinking water is not *pure* water.) Homogeneous mixtures are also called solutions, a term that chemists apply to homogeneous mixtures of gases and solids, too, not just liquids. For example, a sample of filtered air is a solution of nitrogen, oxygen, argon, carbon dioxide, and other atmospheric gases, and a "gold" ring is actually a solid solution of mostly gold plus other metals such as silver, copper, and zinc.

The substances in a heterogeneous mixture are *not* distributed uniformly. One way to tell that a liquid mixture is heterogeneous is to look for a boundary between the liquids in it (such as the oil and water layers in the bottle of salad dressing in Figure 1.1). Such a boundary indicates that the substances do not dissolve in one another. Another sign that a liquid may be a heterogeneous mixture is that it is not clear (transparent). Light cannot pass through such liquids because it is scattered by tiny solid particles or liquid drops that are *suspended*, but not dissolved, in the surrounding liquid. Human blood, for example, is opaque because the blood cells that are suspended in it absorb and scatter light.

A Particulate View

Given that compounds are formed from elements, do elements consist of yet smaller particles? The answer is yes. Each element consists of atoms: particles of one type unique to that element. Civilizations as old as the ancient Greeks believed in atoms, though people then had no evidence that atoms existed. Today, however, we have compelling evidence in the form of images of atoms, such as those on the surface of a disk made of high-purity silicon used to make computer chips (**Figure 1.4**) that has been magnified over 100 million times by using a device called a scanning tunneling microscope.

Some elements, including helium and the others in column 18 of the periodic table, exist as free atoms; other elements exist as molecules. A molecule is an assembly of two or more atoms that are held together in a characteristic pattern by forces called chemical bonds. A molecule of an element contains two or more atoms of that element that are bonded together. For example, the air we breathe consists mostly of *diatomic* (two-atom) molecules of nitrogen gas, N_2, and oxygen gas, O_2. The subscripts in the chemical formulas of these two gases tell us that their molecules are each composed of two atoms of that element. Other elements also exist as diatomic molecules, including H_2 and elements in column 17 of the periodic table: F_2, Cl_2, Br_2, and I_2.

Most of the molecules in the universe, however, are compounds because they contain atoms of more than one element. The chemical formula of a molecular compound tells us the number of atoms of each element in one of its molecules. For example, the formula H_2O tells us that pure water is composed of molecules that each contain two hydrogen atoms and one oxygen atom (the subscript 1 is omitted), as shown in **Figure 1.5**.

The 2:1 ratio of hydrogen to oxygen atoms in molecules of H_2O also reflects the proportions of H_2 gas and O_2 gas that must react to form water. These gases *always* react with each other in the same proportion: two molecules of H_2 for every molecule of O_2 to form two molecules of H_2O. This relationship is illustrated in Figure 1.5 with models of the molecules involved and the chemical equation beneath them. In a chemical equation, chemical formulas represent the substances involved in a chemical reaction. The arrow in the middle of a chemical equation separates the formulas of the reactant(s) on the left from those of the product(s) on the right. In Figure 1.5, the *phase symbols* (*g*) and (ℓ) indicate that the reactants are gases and H_2O is a liquid, respectively. Solids are denoted by (*s*).

The reaction between hydrogen and oxygen also produces energy, which is generally defined as the capacity to do work. The reaction can be forced to run in reverse if enough energy is added to decompose water into hydrogen and oxygen (**Figure 1.6**). The reverse chemical reaction always produces two molecules of hydrogen gas for every one molecule of oxygen gas. This consistency illustrates the law of constant composition: every sample of a compound always contains the same elements combined in the same proportions.

CONCEPT TEST

A compound with the formula NO is present in the exhaust gases leaving a car's engine. As NO travels through the car's exhaust system, some of it decomposes into nitrogen gas and oxygen gas. What is the ratio of nitrogen molecules to oxygen molecules formed from the decomposition of NO?

(Answers to Concept Tests are in the back of the book.)

Chemical formulas provide information about the ratios of the elements in molecular compounds, but formulas do not tell us how the atoms of each element are bonded to one another within each molecule, nor do they tell us anything about the shapes of molecules. To communicate information about bonding and shape, we need to draw *structural formulas* such as the one for ethanol (C_2H_5OH) in **Figure 1.7a**, which uses straight lines to represent the chemical bonds that connect the carbon (C), hydrogen (H), and oxygen (O) atoms within the molecule.

Although a structural formula shows which atoms are connected by bonds, it does not necessarily show how those atoms are arranged in three-dimensional space. *Molecular models* provide this 3-D perspective. *Ball-and-stick* molecular models (**Figure 1.7b**) use spheres to represent atoms and sticks to represent chemical bonds.

The advantage of ball-and-stick models is that they show the correct angles between the bonds. However, the sizes of the spheres in these models may not be proportional to the sizes of the atoms they represent, and the atoms are spaced far enough apart to accommodate the stick bonds. (In real molecules, the atoms touch each other.) Both limitations are overcome with *space-filling* molecular models (**Figure 1.7c**), in which the spheres are drawn to scale and touch one another as atoms do in real molecules. One limitation of space-filling models is that the bond angles between atoms may be difficult to discern. An additional limitation of both the ball-and-stick and space-filling models is that atoms themselves do not have color. Representing oxygen atoms as red spheres and hydrogen atoms as white spheres is merely a convention used by chemists.

Not all compounds are composed of molecules. Many of them consist of positively and negatively charged particles called ions that are electrostatically attracted to one another. For example, the chemical formula of calcium chloride is $CaCl_2$, which means that this ionic compound contains two chloride (Cl^-) ions for every one calcium (Ca^{2+}) ion. Positive ions are called cations, whereas negative ions are called anions. Ions may consist of single atoms like Ca^{2+} and Cl^-, or they may contain two or more atoms bonded together that have an overall positive or negative charge, such as the hydroxide ion (OH^-).

Glossary

mass	the property that defines the quantity of matter in an object.
matter	anything that has mass and occupies space.
chemistry	the study of the composition, structure, and properties of matter, and of the energy consumed or given off during chemical reactions.
pure substance	

matter that has a constant composition and cannot be broken down into simpler matter by any physical process.

physical process

a transformation of a sample of matter, such as a change in its physical state, that does not alter the chemical identity of any substance in the sample.

element

a pure substance that cannot be separated into simpler substances.

compound

a pure substance that is composed of two or more elements combined in fixed proportions and that can be broken down into those elements by a chemical reaction.

chemical reaction

the transformation of one or more substances into different substances.

mixture

a combination of pure substances in variable proportions in which the individual substances retain their chemical identities and can be separated from one another by a physical process.

homogeneous mixture

a mixture in which the components are distributed uniformly throughout and have no visible boundaries or regions.

solution

another name for a homogeneous mixture; solutions are often liquids, but they may also be solids or gases.

heterogeneous mixture

a mixture in which the components are not distributed uniformly, so that the mixture contains distinct regions of different compositions.

atom

the smallest particle of an element that retains the element’s properties.

molecule

a collection of atoms chemically bonded together in characteristic proportions.

chemical bond

a force that holds two atoms or ions in a compound together.

chemical formula

notation for representing elements and compounds; consists of the symbols of the constituent elements, each followed by subscripts that identify the number of atoms of each element present.

chemical equation

notation in which chemical formulas express the identities and their coefficients express the quantities of substances involved in a chemical reaction.

energy

the capacity to do work.

law of constant composition

the principle that all samples of a compound contain the same elements combined in the same proportions.

ion

a particle consisting of one or more atoms that has a net positive or negative electrical charge.

cation

an ion with a positive charge.

anion

an ion with a negative charge.

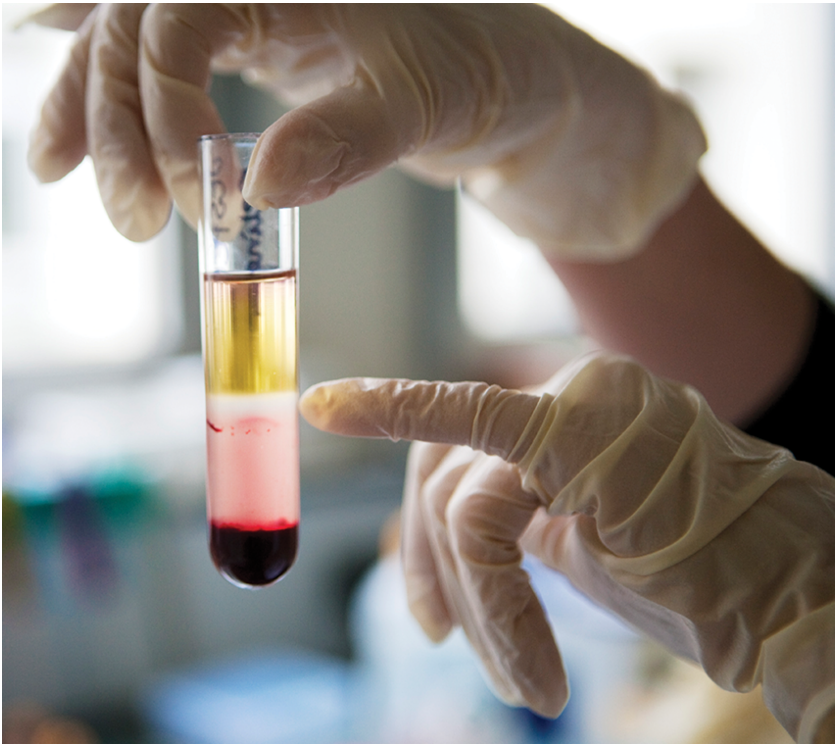


FIGURE 1.8 Separation of whole blood by centrifugation. The red blood cells at the bottom of the sample are separated from the upper layer of pale yellow plasma by a pale-red layer of white blood cells and platelets.

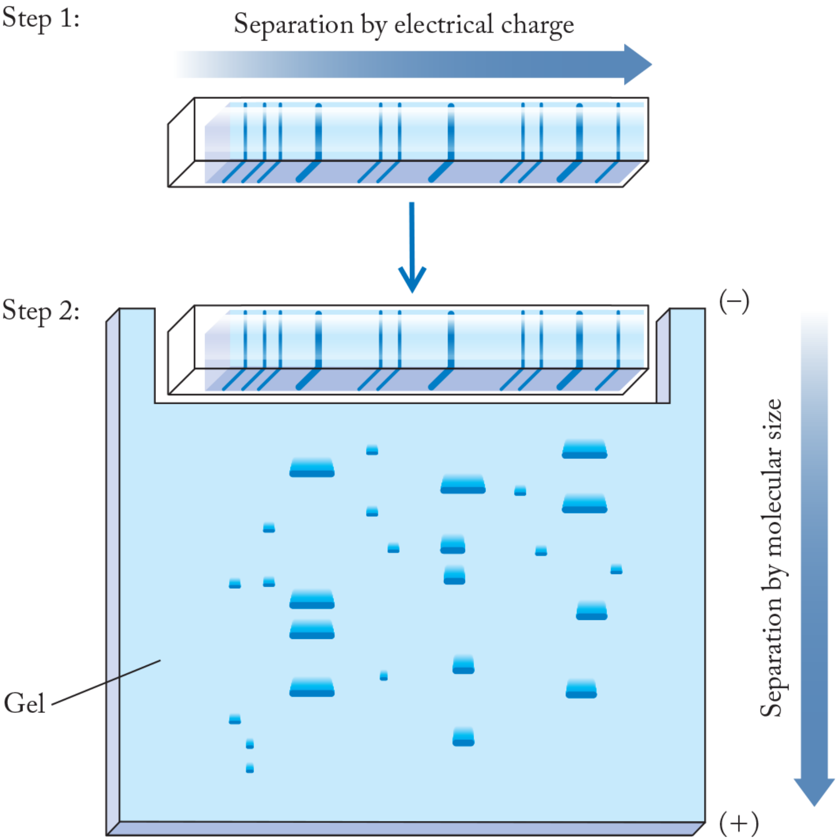

Step 1:
Separation by electrical charge
Step 2:

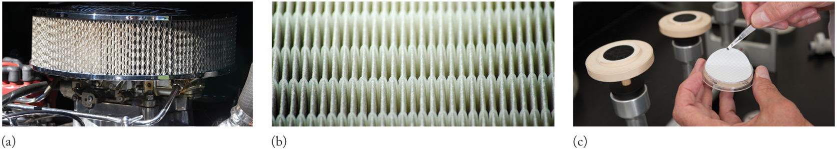
FIGURE 1.9 Separation of proteins by electrophoresis. In the first step, the proteins are separated based on whether they are positively or negatively charged—or have no net charge. In the second step, negatively charged proteins are separated mostly by molecular size: smaller molecules move faster than larger ones.



(a) (b) (c)

FIGURE 1.10 Filters are used to remove particles from gases such as (a) the air entering a car engine or (b) the air circulating through a hospital, and from liquids such as (c) the water being analyzed at a municipal water supply treatment plant. The pore size of the hospital filters must be very small to trap bacteria and viruses that are less than 1 micrometer (10^{-6} m) in diameter.

1.3 Mixtures and How to Separate Them

As noted in Section 1.2, mixtures can be separated into their component substances by physical processes. Consider, for example, how the components of human blood can be separated (**Figure 1.8**). Blood is a heterogeneous mixture of hundreds of different ions and molecules that are dissolved or suspended in a liquid called blood *plasma*. Plasma includes red blood cells (which carry oxygen from the lungs to our body's tissues), white blood cells (which play a key role in fighting infections), and platelets (which combine with clotting proteins to stop bleeding).

Each day, millions of blood samples are separated into their suspended and dissolved components for diagnostic purposes or to recover materials used to treat sick or injured patients. To separate their components, blood samples are placed in centrifuge tubes and subjected to forces about 1000 times the force of gravity. Centrifugation causes the large, dense red blood cells to settle to the bottom of the tubes. Above them is a layer of platelets and white blood cells, and above that layer is clear, yellow-colored plasma.

Once the plasma has been separated, other techniques are used to isolate blood proteins dissolved in the plasma. Identification of these proteins helps doctors diagnose diseases. One such protein isolation technique is two-dimensional electrophoresis, in which the proteins are separated in two steps (**Figure 1.9**): first by charge, and then by size. The first step works because protein molecules have different charges because of the presence of positively and negatively charged ionic groups in their molecular structures. In the second step, fractions from the first step are further separated in a process in which smaller molecules move more rapidly and migrate farther than larger ones.

Different techniques are used to separate solid particles from liquid and gas mixtures. Consider, for example, the use of filters to trap particles of dust suspended in the air entering an automobile engine (**Figure 1.10a**) or to remove bacteria from the air in hospitals to control the spread of infectious diseases (**Figure 1.10b**). A key parameter in designing these filters is their pore size, which must be small enough to trap the target particles or microbes, but not so small that enormous pressure would be required to force an adequate flow of air through them. Filtration is also used to separate particles suspended in liquids—a key step in treating the water that many of us drink (**Figure 1.10c**).

The components of a liquid mixture can also be separated by exploiting differences in their *volatilities*, that is, how easily they can be converted from liquids to gases. The most widely used of these techniques is distillation (**Figure 1.11**), which can be used to desalinate seawater because water is much more volatile than the sea salts dissolved in it. Distillation is also used to purify the water used in laboratories and other places where highly pure water is required. To prepare ultra high-purity water requires an additional separation step based on a technology called *ion exchange*, which can be used to remove essentially all the dissolved ions from water. During this process any dissolved cations in the water are replaced with H^+ ions, and any dissolved anions are replaced with OH^- ions. These two ions then combine to form additional molecules of water:

$$H^+(aq) + OH^-(aq) \rightarrow H_2O(\ell)$$

The phase symbol (*aq*) indicates that the ions are dissolved in water, that is, they are in an *aqueous* solution.

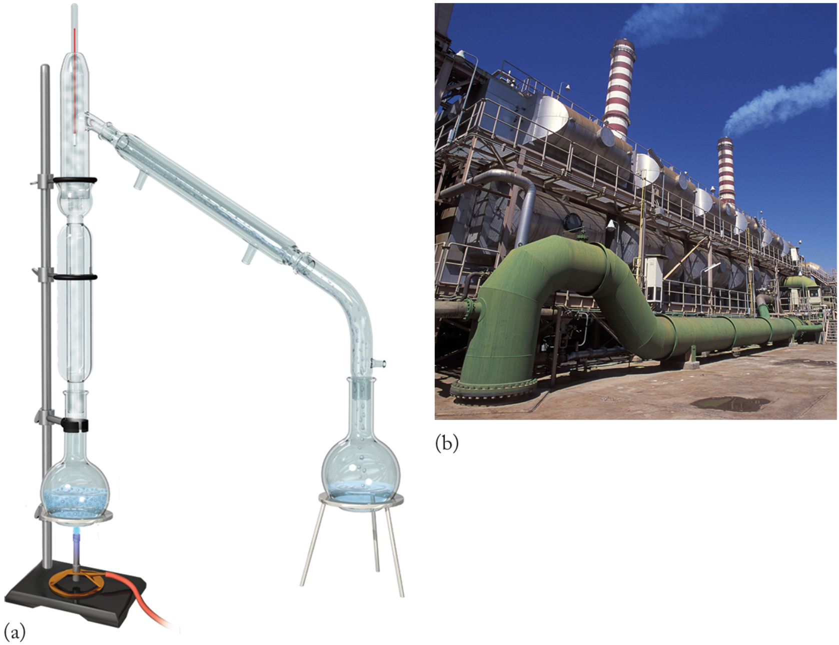


FIGURE 1.11 Distillation can be used to (a) purify compounds in the laboratory and (b) desalinate seawater for public consumption. This desalination plant is in Kuwait City.

1.4 A Framework for Solving Problems

Throughout this book we include questions and problems that test your understanding of chemical principles and that develop your problem-solving skills. Solving chemistry problems is like playing a musical instrument: the more you practice, the better you become.

In this section we present a framework for solving problems that we follow throughout the book. Each Sample Exercise is followed by a Practice Exercise that can be solved using a similar approach. We strongly encourage you to hone your problem-solving skills by working all the Practice Exercises as you read. You should find the approach described here useful in solving the exercises in this book as well as problems you encounter in other courses and other contexts.

We use the acronym COAST (**C**ollect and **O**rganize, **A**nalyze, **S**olve, and **T**hink about the answer) to represent the four steps in this approach. As you read about it here and use it later, keep in mind that COAST is merely a *framework* for solving problems, not a recipe. Use it as a guide to develop your own approach to solving problems.

Collect and Organize The first step in solving a problem is to decide how to use the given information. You should be able to identify the key concept of the problem and the key terms used to express that concept. You may find it useful to restate the problem in your own words. Visualizing the problem may also be helpful—drawing a sketch based on molecular models or an experimental setup, or even just closing your eyes and picturing the situation. Once you have a clear understanding of what is being asked, sort through the information and separate what is relevant from what is not. Then assemble the relevant information, including chemical equations, molecular models, definitions, and the values of constants.

Analyze The next step is to analyze the information you have assembled to determine how to use it to answer the problem. Sometimes you can work backward to create these links: Consider the answer first and think about how you might reach it from the information you've assembled. This approach might mean finding some intermediate quantity to use in a later step. If the problem requires a numerical answer, frequently the units of the initial values and the final answer can help you identify how they are connected and which equations and conversion factors should be used. Also, when possible, try to estimate the value of your answer before solving the problem.

Some Sample Exercises in this book involve performing a single-step calculation or answering a question based on a single concept. These exercises don't require assembling and sorting through a lot of information and equations, so we may combine the Collect, Organize, and Analyze steps before solving the problem.

Solve The solution to a problem that tests your understanding of a concept often flows directly from the Analyze step. To solve quantitative problems, you will need to set up and use the conversion factors and equations you have assembled to calculate the correct answer with appropriate units. Also, be sure that calculated answers contain the appropriate number of significant figures. (We discuss conversion factors in Section 1.9 and significant figures in Section 1.10.)

Think About It Does your answer make sense? Is this value about what you estimated it would be? Are the units correct? Is the number of significant figures appropriate? Finally, could you solve another problem, perhaps drawn from another context but based on the same concept?

The COAST approach should help you solve problems in a logical way and avoid pitfalls such as grabbing an equation that seems to have the right variables and just plugging in initial values or resorting to trial and error. As you study each step in a Sample Exercise, be sure to ask yourself these questions: *What* is done in this step? *How* is it done? *Why* is it done? With answers to these questions in mind, you will be ready to solve the Practice Exercises and end-of-chapter Questions and Problems in a systematic way.

$$d = \frac{m}{V} \tag{1.1}$$

1.5 Properties of Matter

Our senses provide a constant stream of information about the world around us. Subconsciously, we process this information to confirm that “all is well”—or, if it’s not, to take appropriate action. For example, the normal components of the air we breathe are odorless, so when we smell something unusual as we enter a room or step outside, we know we are inhaling a gas not normally present in the air, and we respond accordingly.

Pure substances have distinctive properties. Some substances burn, whereas others put out fires. Some solid substances are shiny, whereas others are dull. Some are brittle, whereas others are malleable. These and other properties do not vary from one sample of a given pure substance to the next. Consider gold, for example: its color (very distinctive), its hardness (soft for a metal), its malleability (it can be hammered into very thin sheets called gold leaf), and its melting temperature (1064°C) all apply to any sample of pure gold. These characteristics are examples of intensive properties: properties that characterize matter independent of the quantity of it present in a sample. On the other hand, an object made of gold, such as an ingot, has a length, width, mass, and volume. These properties, which depend on how much of the substance is present, are extensive properties.

CONCEPT TEST

Which of these properties of a sample of pure iron is intensive? (a) mass; (b) hardness; (c) volume

(Answers to Concept Tests are in the back of the book.)

Properties may be categorized as physical or chemical. The physical properties of a pure substance can be observed or measured without changing the substance into another substance. The intensive properties of gold are all physical properties, as is its density (***d***)—the ratio of the mass (*m*) of an object to its volume (*V*):

As we saw in Figure 1.5, hydrogen combines with oxygen in a chemical reaction that produces water and energy. This reaction is an example of combustion (burning), and H_2 is the fuel. High flammability is a chemical property of hydrogen. Like any other chemical property, flammability can be determined only by reacting one substance with another one and finding that one or more other substances are produced. A substance's chemical reactivity, including the rates of its reactions, the identities of other substances with which it reacts, and the products they form, define the chemical properties of the substance.

SAMPLE EXERCISE 1.1 Distinguishing Physical and Chemical Properties LO3

Which of the following properties of gold are chemical and which are physical?

1. Gold metal, which is insoluble in water, can be made soluble by reacting it with a mixture of nitric and hydrochloric acids known as aqua regia.
2. Gold melts at 1064°C.
3. Gold can be hammered into sheets so thin that light passes through them.
4. Gold metal can be recovered from gold ore by treating the ore with a solution containing cyanide, which reacts with and dissolves gold.

Collect, Organize, and Analyze Chemical properties describe how a substance reacts with other substances, whereas physical properties can be observed or measured without changing one substance into another. Properties (a) and (d) involve reactions that chemically change gold metal (which does not dissolve in water) into compounds of gold that do dissolve in water. Properties (b) and (c) describe physical changes that do not change the identity of the element: molten gold and gold leaf are still gold.

Solve Properties (a) and (d) are chemical properties, whereas (b) and (c) are physical properties.

Think About It When possible, we fall back on our experiences and observations. We know jewelry made of gold does not dissolve in water. Therefore, dissolving gold metal requires a change in its chemical identity: it can no longer be elemental gold. On the other hand, physical processes such as melting do not alter the chemical identity of the gold. Gold can be melted and then cooled to produce solid gold again.

Practice Exercise Which of the following properties of water are chemical and which are physical?

1. Water normally freezes at 0.0°C.
2. Water does not burn.
3. A cork floats on water, but a piece of copper sinks.
4. During digestion, starch reacts with water to form sugar.

(Answers to Practice Exercises are in the back of the book.)

Glossary

intensive property
a property that is independent of the amount of substance present.

extensive property
a property that varies with the quantity of the substance present.

physical property
a property of a substance that can be observed without changing it into another substance.

chemical property

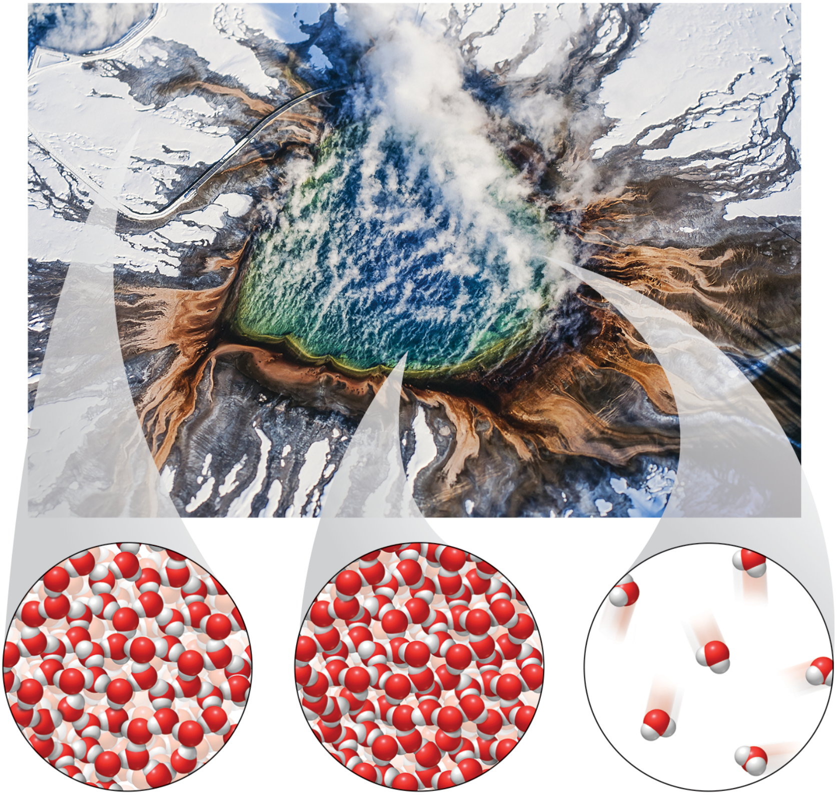
a property of a substance that can be observed only by reacting it to form another substance.

density (*d*)

the ratio of the mass (*m*) of an object to its volume (*V*).

Learning Objectives

- Distinguish between physical processes and chemical reactions, and between physical and chemical properties **Return to Sample Exercise 1.1**



(a) Solid (b) Liquid (c) Gas

FIGURE 1.12 Macroscopic and particulate views of the three states of water in this winter photograph of a hot spring in Yellowstone National Park: (a) solid (ice), (b) liquid (water: in the case of the hot spring, it is a solution of compounds in liquid water), and (c) gas (water vapor). Water vapor is invisible, but the mist above the spring consists of tiny drops of liquid water that form as water vapor condenses in the frigid air. The rich colors near the edges of the spring are produced by thermophiles, tiny organisms that thrive in extremely hot water.

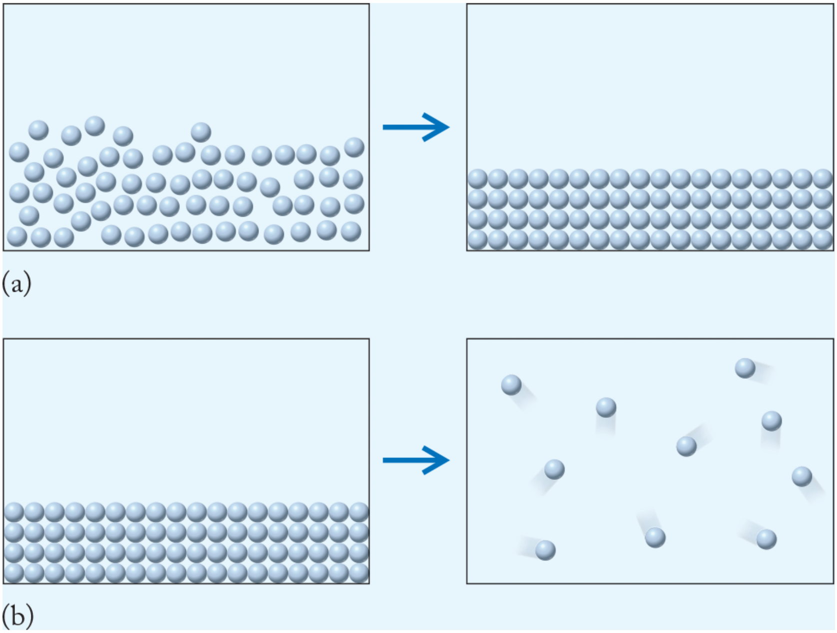

FIGURE 1.14 Changes in the physical state of matter.

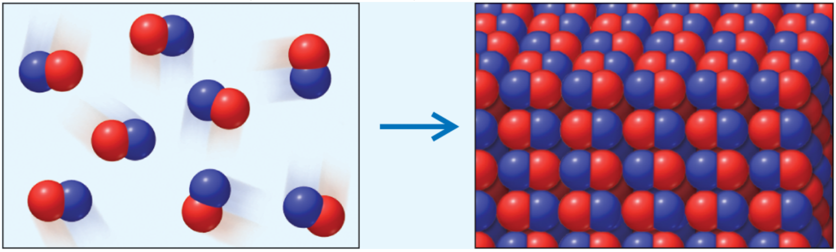

FIGURE 1.15A change in the physical state of matter.

1.6 States of Matter

Matter typically exists in one of three phases or physical states—namely, solid, liquid, or gas (**Figure 1.12**), which have the following characteristic properties:

- A solid has a definite volume and shape.
- A liquid has a definite volume but not a definite shape.
- A gas (or *vapor*) has neither a definite volume nor a definite shape. Rather, it expands to occupy the entire volume and shape of its container.

- Unlike solids, liquids and gases are fluids, which means they are free to flow.
- Unlike a solid or a liquid, a gas is compressible, which means it can be squeezed into a smaller volume if its container is not rigid and pressure is applied to it.

The differences between solids, liquids, and gases can be understood if we consider the three states on the particulate level. As shown in Figure 1.12a, each H_2O molecule in ice is surrounded by other H_2O molecules and is locked in place in a rigid three-dimensional lattice (array) of molecules. A molecule in this structure may vibrate, but it cannot move past the other molecules that surround it. In liquid water (Figure 1.12b), the H_2O molecules flow past one another, but they are still near one another, even though their nearest neighbors change over time. The H_2O molecules in water vapor (Figure 1.12c) are widely separated by empty space, so the volume of the molecules themselves is much smaller than the total volume occupied by the vapor. This separation accounts for the compressibility of gases. Molecules in the gas phase move freely throughout the space occupied by the vapor.

We can transform water from one physical state to another by heating or cooling it (**Figure 1.13**). Ice forms on a pond when the temperature drops in the winter and the water freezes. This process is reversed when warmer temperatures return in the spring and the ice melts. The heat of the Sun may vaporize liquid water during the daytime, but colder temperatures at night may cause the water vapor to condense as dew.

Some solids change directly into gases with no intervening liquid phase. For example, snow may be converted to water vapor on a sunny but cold winter day even though the air temperature remains well below freezing. This transformation of solid directly to vapor is called sublimation. The reverse process, in which a gas (water vapor) is transformed directly into a solid (frost) without ever being a liquid, is called deposition.

CONCEPT TEST

Is energy absorbed by a solid or released from it as it sublimes?

(Answers to Concept Tests are in the back of the book.)

SAMPLE EXERCISE 1.2 Distinguishing between Particulate Views of the Different States of Matter LO5

Which physical state is represented in each box of **Figure 1.14**? (The particles could be atoms or molecules.) What change of state does each arrow indicate? What would the changes of state be if both arrows pointed in the opposite direction?

Collect, Organize, and Analyze We need to look for patterns among the particles in each box:

- An ordered arrangement of particles with little space between the particles represents a solid.
- A less-ordered arrangement of particles with little space between the particles represents a liquid.
- Particles widely separated from one another represent a gas.

Solve The particles in the left box in Figure 1.14a are close together but have a disordered arrangement, so they represent a liquid. The particles in the box on the right are ordered and are close together, so they represent a solid. The arrow represents a liquid turning into a solid, so the physical process is freezing. An arrow in the opposite direction would represent melting.

The particles in the box on the left in Figure 1.14b represent a solid because they are ordered, and are close together. Those to the right are widely separated from one another, so they represent a gas. The arrow represents a solid turning into a gas, so the physical process is sublimation. The reverse process—a gas becoming a solid—would be deposition.

Think About It The particles represented in Figure 1.14a are close together, which is consistent with how particles are distributed in solids and liquids such as ice and water (Figure 1.12). On the other hand, the particles in gases, as shown in the right panel of Figure 1.14b, are widely separated.

Practice Exercise (a) What physical state is represented by the particles in each box of **Figure 1.15**, and which change of state is represented? (b) Which change of state would be represented if the arrow pointed in the opposite direction?

(Answers to Practice Exercises are in the back of the book.)

Glossary

solid

a form of matter that has a definite volume and shape.

liquid

a form of matter that occupies a definite volume but flows to assume the shape of its container.

gas

a form of matter that has neither definite volume nor shape and that expands to fill its container; also called *vapor*.

sublimation

transformation of a solid directly into a vapor (gas).

deposition

transformation of a vapor (gas) directly into a solid.

Learning Objectives

- Describe the three states of matter and the transitions between them at the macroscopic and particulate levels **Return to Sample Exercise 1.2**

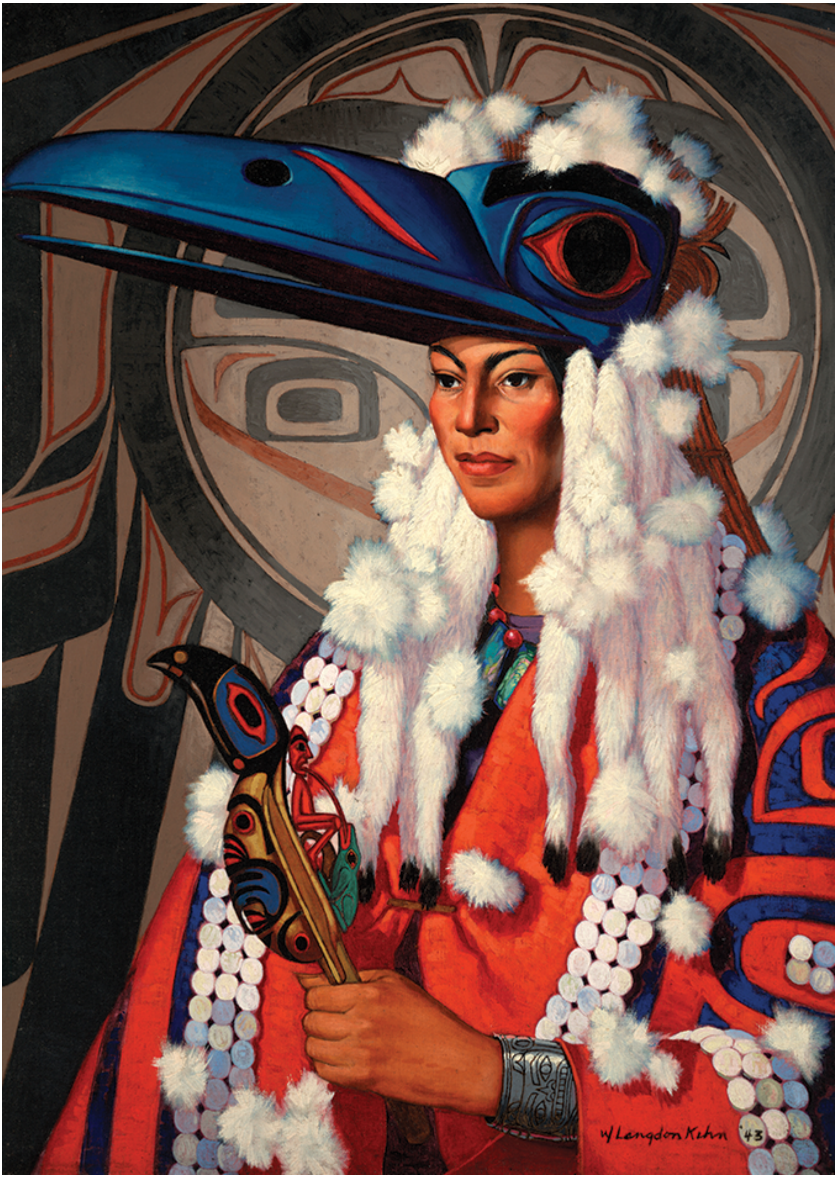

FIGURE 1.16 For centuries, cultures have passed on creation stories in which a supreme being is responsible for creating the Sun, the Moon, and Earth and its inhabitants. According to a creation myth of the indigenous peoples of coastal British Columbia, such as the Bellacoola woman depicted here, a deity in the form of a raven was responsible for releasing the Sun into the sky.

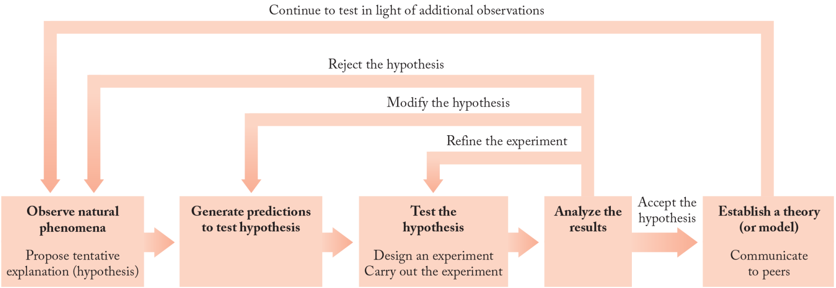

Continue to test in light of additional observations
Reject the hypothesis
Modify the hypothesis
Refine the experiment
Observe natural phenomena
Propose tentative explanation (hypothesis)
Generate predictions to test hypothesis
Test the hypothesis
Design an experiment
Carry out the experiment
Analyze the results
Accept the hypothesis
Establish a theory (or model)
Communicate to peers

FIGURE 1.17 In the scientific method, observations lead to a tentative explanation, or hypothesis, which leads to more observations and testing, which may lead to the formulation of a succinct, comprehensive explanation called a theory. This process is rarely linear: it often involves looping back, as the results of one test lead to additional tests and a revised hypothesis. Science is a dynamic and self-correcting process.

FIGURE 1.18 The Hubble Space Telescope is named in honor of American astronomer Edwin Hubble.

1.7 The Scientific Method: Starting Off with a Bang

In Sections 1.5 and 1.6, we examined the properties and states of matter. Here in Section 1.7 and in Section 1.11, we examine the origins of matter and a theory of how the universe came into being.

The ancient Greeks believed that at the beginning of time there was no matter, only a vast emptiness they called Chaos, and that from that emptiness emerged Gaia (also known as Mother Earth), the first supreme being, who gave birth to Uranus (Father Sky). Other cultures and religions have described creation in similar terms of supernatural beings creating ordered worlds out of vast emptiness. The opening verses of the book of Genesis, for example, describe darkness “without form and void” from which God created the heavens and Earth. Similar stories are part of indigenous cultures of Asia, Africa, and the Americas (**Figure 1.16**). Today we have the technology to take a different approach to explaining how the universe was formed and what physical forces control it. Our approach is based on the scientific method of inquiry (**Figure 1.17**).

This approach evolved in the late Renaissance, during a time when economic and social stability gave people an opportunity to study nature and question old beliefs. By the early 17th century, the English philosopher Francis Bacon (1561–1626) had published his *Novum Organum* (*New Organ* or *New Instrument*) in which he described how humans could acquire knowledge and understanding of the natural world through observation, experimentation, and reflection. In the process, he described how observations of a natural phenomenon could lead to a tentative explanation, or hypothesis, of what caused the phenomenon. Developing a hypothesis and devising experiments to test its validity are creative aspects of science. Further testing and observation may support a hypothesis, but unexpected results that don’t support it are also valuable because they may result in modifications to the hypothesis that enable it to explain *all* experimental results. However, experimental results that do support a hypothesis can never “prove” it; the best that scientists can say is that no experiment or observation has yet to contradict the hypothesis.

One measure of the validity of a hypothesis is that it enables scientists to predict accurately the results of *future* experiments and observations. Ultimately, a hypothesis that withstands the tests of many experiments over time and explains the results of further observation and experimentation may be elevated to the rank of a scientific theory or model. Although *theory* in everyday conversation is often used as a synonym for “speculation,” it is used by scientists to refer to an explanatory framework that can be used to test hypotheses empirically.

What are some of the ways the scientific method helped formulate the theory of the origin of the universe that has come to be called the Big Bang theory? In the early 20th century, American astronomer Edwin Hubble (1889–1953; **Figure 1.18**) and others used increasingly powerful telescopes to discover that the universe contains billions of galaxies, each containing many billions of stars. They also discovered that (1) these other galaxies were moving away from us and (2) the speeds with which these galaxies were receding was proportional to the distances from us—the farthest galaxies were moving away the fastest.

From these observations, Belgian priest and astronomer Georges-Henri Lemaître (1894–1966) proposed in 1927 that the universe we know today formed with an enormous release of energy that quickly transformed into a rapidly expanding, unimaginably hot cloud of matter in accordance with Einstein’s formula,

$$E = mc^2$$

where E is energy, m is the equivalent mass of matter, and c is the speed of light. To understand Lemaître’s proposal, consider what we would see if the motion of the matter in the universe had somehow been recorded since the beginning of time and we were able to play the recording in reverse. The other galaxies would move toward ours (and toward one another), with those farthest away closing in the fastest. Eventually, all the matter in the universe would approach the same point at the same time. During this compression, the universe would become tremendously dense and hot. At the very beginning, then, the universe would be squeezed into an infinitesimally small space with an inconceivably high temperature. At such a temperature, the distinction between matter and energy would become blurred. Indeed, at the very beginning there would be no matter, only energy. Now, if we were to play this recording in the forward direction, we would see an instantaneous release of an enormous quantity of energy in an event called the Big Bang.

Lemaître’s explanation of how the universe began has been the subject of extensive testing—and controversy—since it was first proposed. Indeed, the term *Big Bang* was first used by British astronomer Sir Fred Hoyle (1915–2001) to poke fun at the idea. However, the results of many experiments and observations conducted since the 1920s support what is now described as the Big Bang theory. We use the term *theory* because this comprehensive explanation of natural phenomena has been validated by the results of extensive experimentation and observation and has also been used to accurately *predict* the results of *other* experiments and observations. In Section 1.11 we return to the Big Bang theory and examine a few of the experiments that have tested its validity.

CONCEPT TEST

If the volume of the universe is expanding and if the mass of the universe is not changing, is the density of the universe (a) increasing, (b) decreasing, or (c) remaining the same?

(Answers to Concept Tests are in the back of the book.)

Glossary

scientific method

an approach to acquiring knowledge based on observation of phenomena, development of a testable hypothesis, and additional experiments that test the validity of the hypothesis.

hypothesis

a tentative and testable explanation for an observation or a series of observations.

scientific theory (model)

a general explanation of a widely observed phenomenon that has been extensively tested and validated.

scientific theory (model)

a general explanation of a widely observed phenomenon that has been extensively tested and validated.

1.8 SI Units

The rise of scientific inquiry in the 17th and 18th centuries brought about a heightened awareness of the need for accurate measurements and for expressing the results of those measurements in ways that others, including scientists in other countries, could understand. Standardization of the units of measurement was essential.

In 1791 French scientists proposed a standard unit of length, which they called the meter (m) after the Greek *metron*, which means “measure.” They based the length of the meter on 1/10,000,000 of the distance along an imaginary line running from the North Pole to the equator. By 1794, hard work by teams of surveyors had established the length of the meter that is still in use today.

These French scientists also settled on a decimal-based system for designating lengths that are multiples or fractions of a meter (**Table 1.1**). They chose Greek prefixes for lengths much greater than 1 meter, such as *deka*- and *kilo*- for lengths of 10 meters (1 dekameter) and 1000 meters (1 kilometer). Then they chose Latin prefixes for lengths much smaller than a meter, such as *centi*- and *milli*- for lengths of 1/100 of a meter (1 centimeter) and 1/1000 of a meter (1 millimeter).

TABLE 1.1 Commonly Used Prefixes for SI Units

PREFIX	**Symbol**	**VALUE**	Exponential
zetta	**Z**	1,000,000,000,000,000,000,000	10^{21}
exa	**E**	1,000,000,000,000,000,000	10^{18}
peta	**P**	1,000,000,000,000,000	10^{15}
tera	**T**	1,000,000,000,000	10^{12}
giga	**G**	1,000,000,000	10^{9}
mega	**M**	1,000,000	10^{6}
kilo	**k**	1000	10^{3}
hecto	**h**	100	10^{2}

deka	da	10^{1}	10
deci	d	10^{-1}	0.1
centi	c	10^{-2}	0.01
milli	m	10^{-3}	0.001
micro	μ	10^{-6}	0.000001
nano	n	10^{-9}	0.000000001
pico	p	10^{-12}	0.000000000001
femto	f	10^{-15}	0.000000000000001
atto	a	10^{-18}	0.000000000000000001
zepto	z	10^{-21}	0.000000000000000000001

Eventually these decimal prefixes carried over to the names of standard units for other dimensions. In July 1799 a platinum rod 1 meter long and a platinum block having a mass of 1 kilogram (1000 grams) were placed in the French National Archives to serve as the legal standards for length and mass. These objects served as references for the metric system for expressing measured quantities.

Since 1960, scientists have, by international agreement, used a modern version of the French metric system: the *Système International d'Unités*, commonly abbreviated SI. **Table 1.2** lists the seven *SI base units*; many other SI units are derived from them. For example, a common SI unit for volume, the cubic meter (m^3), is derived from the base unit for length, the meter. The common SI unit for speed, meters per second (m/s), is derived from the base units for both length and time. **Table 1.3** lists some of these derived units and their equivalents in the U.S. Customary (USC) units. They include the volume corresponding to 1 cubic decimeter (a cube 1/10 meter on each side), which we call a liter (L).

TABLE 1.2 SI Base Units[a]

Quantity or Dimension	Unit Name	Abbreviation
Mass	kilogram	kg
Length	meter	m
Temperature	kelvin	K
Time	second	s
Electrical current	ampere	A
Amount of a substance	mole	mol
Luminous intensity	candela	cd

Various combinations of base and derived SI units are used to express the densities of materials, that is, their mass-to-volume ratios. The selection of units depends on how dense the material is. For example, the densities of gases are often expressed in grams/liter (g/L) so that the density values are close to one. Liquids, on the other hand, are many hundreds of times denser than gases, so their densities are often expressed in g/cm^3, which is equivalent to g/mL. Solids have densities that are comparable to or greater than those of most liquids, so their values are usually expressed in g/cm^3, too (**Table 1.4**).

TABLE 1.3 SI Units and Their U.S. Customary Unit Equivalents

Quantity or Dimension	Equivalent Units
Mass	1 kg = 2.205 pounds (lb); 1 lb = 0.4536 kg = 453.6 g
	1 g = 0.03527 ounce (oz); 1 oz = 28.35 g
Length (distance)	1 m = 1.094 yards (yd); 1 yd = 0.9144 m (exactly)
	1 m = 39.37 inches (in); 1 foot (ft) = 0.3048 m (exactly)
	1 in = 2.54 cm (exactly)
	1 km = 0.6214 miles (mi); 1 mi = 1.609 km
Volume	1 m^3 = 35.31 ft^3; 1 ft^3 = 0.02832 m^3
	1 m^3 = 1000 liters (L) (exactly)
	1 L = 0.2642 gallon (gal); 1 gal = 3.785 L
	1 L = 1.057 quarts (qt); 1 qt = 0.9464 L

Modern science requires that the length of the meter, as well as the dimensions of other SI units, be defined by quantities that are much more constant than the length of a platinum rod in Paris. Two such quantities are the speed of light (*c*) and time. In 1983, 1 meter was redefined as the distance traveled in 1/299,792,458 of a second by the light emitted from a helium–neon laser. This modern definition of the meter is consistent with the one adopted in France in 1794.

TABLE 1.4 Densities of Common Materials

ITEM	DENSITY (AT 20°C)
Solids	g/cm^3
Aluminum	2.70
Copper	8.96

1.9 Unit Conversions and Dimensional Analysis

Throughout this book we will often need to convert measurements and quantities from one unit to another. Sometimes this will require choosing the appropriate prefix, such as expressing the distance between Vancouver, BC, and Seattle, WA, in kilometers instead of meters. Other times we will need to convert a value from one unit system to another, such as converting a gasoline price per liter to an equivalent price per U.S. gallon.

To do these calculations and many others, we use an approach sometimes called the *unit factor method* but more often called *dimensional analysis*. The approach makes use of conversion factors, which are fractions in which the numerators and denominators have different units but represent equivalent quantities. This equivalency means that multiplying a quantity by a conversion factor is equal to multiplying by 1. The intrinsic value that the quantity represents does not change; it is simply expressed in different units.

The key to using conversion factors is to set them up correctly with the appropriate units in the numerator and denominator. For example, the odometer of a car traveling between the airports serving Vancouver and Seattle records the distance as 241 km. What is that distance in miles? To find out we turn the following equivalency from Table 1.3

$$1\ \text{km} = 0.6214\ \text{mi}$$

into the following conversion factor,

and multiply the distance in kilometers by it:

We obtain a value with the desired units (in this case, miles) because those units are in the numerator of the conversion factor, whereas the units in the denominator (in this case, kilometers) of the conversion factor cancel out the units of the initial value itself. The general form of the equation for converting a value from one unit to another is

Most conversion factors, such as the one for converting kilometers to miles, also have a “1” in the numerator or denominator. All these ones are *exactly* one; there is no uncertainty in their value, which is a topic we explore in Section 1.10.

SAMPLE EXERCISE 1.3 Converting Units LO7

The masses of diamonds are usually expressed in carats (1 gram = 5 carats exactly). The Star of Africa (**Figure 1.19**) is one of the world’s largest diamonds, having a mass of 530.02 carats. What is its mass in grams? In kilograms? In ounces?

Collect and Organize We have a mass value expressed in carats, and we want to convert it into grams (g), kilograms (kg), and ounces (oz). The problem states there are exactly 5 carats in 1 gram. From Table 1.1 we know that there are exactly 1000 grams in 1 kilogram, and from Table 1.3 that there are 0.03527 ounces in 1 gram.

Analyze We can use the above unit equivalencies to write conversion factors that enable us to convert carats into grams:

grams into kilograms:

and grams into ounces:

Solve We use the above three conversion factors to convert the diamond’s mass from carats into grams:

grams into kilograms:

and grams into ounces:

Think About It The calculated masses may seem unusually large for a diamond, and they are in comparison to those of the ~1 carat diamonds in many engagement rings. The Star of Africa has an estimated value of U.S. $1 billion.

Practice Exercise The Eiffel Tower in Paris is 324 m tall. What is this height, which includes a 24-m television antenna that did not exist when the tower was built in 1889, in kilometers and in centimeters?

(Answers to Practice Exercises are in the back of the book.)

SAMPLE EXERCISE 1.4 Multistep Conversions of U.S. Customary to SI Units LO7

On April 12, 1934, a wind gust of 231 miles per hour was recorded at the summit of Mount Washington in New Hampshire (**Figure 1.20**). What is this wind speed in meters per second?

Collect and Organize Speed is given in the USC units of miles per hour, and we need to convert it to meters per second. Table 1.3 contains the equivalency 1 km = 0.6214 mi, and we know from Table 1.1 that the *kilo*- prefix means 1000. We will also need two unit-of-time equivalencies: 1 hour = 60 minutes and 1 minute = 60 seconds.

Analyze The unit conversion patterns are

mi → km → m

in the numerator, and

h → min → s

in the denominator.

Solve We use the unit equivalencies described above as conversion factors corresponding to the conversion patterns we have identified. We arrange them so that their numerators and denominators cancel out the initial and intermediate units:

Think About It The calculated value is reasonable because the product of the numerator values is 1000, and the product of the denominator values is (~2/3 × 60 × 60), or about 2400. Therefore, the calculated value should be near (1000/2400), or a little less than half the initial value, which it is.

Practice Exercise Light travels through exactly 1 meter of outer space in 1/299,792,458 of a second. How many kilometers does it travel in one year (a so-called light-year)?

(Answers to Practice Exercises are in the back of the book.)

Glossary

conversion factor

a fraction in which the numerator is equivalent to the denominator, even though they are expressed in different units, making the value of the fraction one.

$$Z = \frac{|x_i - \overline{x}|}{s} = \frac{|3.107 - 2.562|}{0.1915} = 2.846$$

$$Z = \frac{|x_i - \overline{x}|}{s} = \frac{|35.8 - 36.38|}{0.38} = 1.5$$

1.10 Evaluating and Expressing Experimental Results

Although scientific measurements can be expressed in different units, they all have one thing in common: there is a limit to how accurate they can be. Nobody is perfect, and no analytical method is perfect either. The accuracy of every method has an inherent limit, so we need ways to express experimental results that reflect these limits in their certainty.

Significant Figures

One way to express how well we know a measured value is by using the appropriate number of significant figures, which are all the certain digits in a measured value *plus one estimated digit*. Suppose we determine the mass of a newly minted penny on the two laboratory scales shown in **Figure 1.21**. The upper one determines the masses of objects to the nearest 0.01 gram (g), whereas the lower one determines the mass of objects to the nearest 0.0001 g. According to the upper scale, our penny has a mass of 2.50 g; according to the lower scale, though, it has a mass of 2.4987 g. The mass obtained from the top scale has three significant figures: the 2, 5, and 0 are considered *significant*, which means we are confident in their values. The mass obtained using the bottom scale has five significant figures (2, 4, 9, 8, and 7). The mass of the penny can be determined with greater certainty with the bottom scale.

Scientific Notation

Now imagine that an aspirin tablet is placed on the lower scale in Figure 1.21, and the display reads 0.0180 g. How many significant figures are in this measurement? You might be tempted to say five because that is the number of digits displayed. However, the first two zeros are not considered significant because they serve only to set the location of the decimal point. These two zeros function the way exponents do when we use scientific notation to express values. Expressing 0.0180 g in scientific notation gives us 1.80×10^{-2} g. Only three of the digits (1, 8, and 0) in the decimal part indicate how precisely we know the value; the "-2" in the exponent does not. (See Appendix 1 for a review of how to express values using scientific notation.) The following guidelines will help you determine whether zeros (highlighted in green) are significant:

1. Zeros at the beginning of a value, as in **0.0**592, are *never* significant. In this example, they just set the decimal place.
2. Zeros at the end of a value and after a decimal point, as in 3.**00** × 10^8, are *always* significant.
3. Zeros at the end of a value that contains no decimal point, as in 96,5**00**, may or may not be significant. If the zeros are there only to set the decimal place, then we should use scientific notation to indicate clearly that the value has only three significant figures: 9.65 × 10^4. Another approach to expressing the significance of ending zeroes in a value is to add a decimal point after them. For example, expressing the length of race sometimes called the “Olympic mile” as 1500. meters instead of 1500 meters makes it clear the value is known to more than two significant figures. In practice, this guideline is frequently not followed.
4. Zeros between nonzero digits, as in 1**0**1.3, are *always* significant.

CONCEPT TEST

How many significant figures are there in the values used as examples in guidelines 1, 2, and 4?

(Answers to Concept Tests are in the back of the book.)

Significant Figures in Calculations

How are significant figures used to express the results of calculations involving measured quantities? Suppose we suspect that a small nugget of yellow metal is pure gold. We could test our suspicion by determining the mass and volume of the nugget and then calculating its density. If the calculated density matches that of gold (19.3 g/mL), chances are good that the nugget is pure gold because few minerals are that dense. We find that the mass of the nugget is 4.72 g and its volume is 0.25 mL. What is the density of the nugget, expressed with the appropriate number of significant figures?

Using Equation 1.1 to calculate the density (*d*) from the mass (*m*) and volume (*V*) produces the following result:

This density value appears to be slightly less than that of pure gold, but how well do we know the result? The mass value is known to three significant figures, but the volume value is known only to two. At this point we need to apply the *weak-link principle*, which is based on the idea that a chain is only as strong as its weakest link. In calculations involving measured values, this principle means that we can know the answer to a calculation only as well as we know the least well-known measurement. In calculations involving multiplication or division, the weak link has the fewest significant figures. In this example, the weak link is the volume, 0.25 mL. Because it has only two significant figures, our final answer should be reported with only two significant figures. We must convert 18.88 to a number with two significant figures. We do this by a process called *rounding off*.

Rounding off a value means dropping the insignificant digits [all digits to the right of the last significant (first uncertain) digit] and then rounding that last significant digit either up or down. If the first digit in the string of insignificant digits dropped is greater than 5, we round up; if it is less than 5, we round down. If it is 5 and there is at least one nonzero digit to the right of it, we round up. For example, rounding 45.4501 to three significant figures makes it 45.5 (we rounded up because there was a nonzero digit to the right of the second 5).

If there are no nonzero digits to the right of the 5, then we need a tie-breaking rule for rounding down or up. A good rule to follow is to round the last significant digit to the nearest even number. For example, rounding 45.45 (or 45.450) to three significant figures makes either value 45.4, because the 4 in the tenths place is the nearest even number. However, we round off 45.55 (or 45.550) to 45.6, because the 6 in the tenths place is the nearest even number.

An important rule to remember is that you round off *only at the end* *of a calculation*—never on intermediate results. Otherwise, "rounding errors" can creep into calculations. Reasonable guidelines to follow are to carry at least one digit to the right of the last significant digit through all intermediate steps in a multistep calculation or simply to store all intermediate values in your calculator's memory until you have the final answer.

In the case of our gold nugget, the density value resulting from our calculation, 18.88 g/mL, must be rounded to two significant figures. Because the first insignificant digit to be dropped (shown in red) is greater than 5, we round up the blue 8 to 9:

18.88 g/mL = 19 g/mL

The density of pure gold (i.e., 19.3 g/mL) expressed to two significant figures is also 19 g/mL, so the nugget could be pure gold.

The weak-link principle for significant figures also applies to calculations involving addition and subtraction. To illustrate, consider how the volume of a gold nugget might be measured. One approach is to measure the volume of water the nugget displaces. Suppose we add 50.0 mL of water to a 100 mL graduated cylinder, as shown in **Figure 1.22**. The cylinder is graduated in milliliters, but the space between the graduations allows us to estimate the volumes of samples to the nearest tenth of a milliliter. For example, the meniscus of the water in Figure 1.22 is aligned exactly with the 50 mL graduation. We may record the volume of water as 50.0 mL because we can read the "50" part of this value directly from the cylinder, and we can estimate that the next digit is "0." An estimated final digit in a measured value is still considered significant.

Then we place the nugget in the graduated cylinder, being careful not to splash any water out. The level of the water is now about halfway between the 58 and 59 mL graduations, so we estimate the volume of the combined sample to be 58.5 mL. Taking the difference of the two estimated values, we have the volume of our nugget:

The result has only two significant figures because the initial and final volumes are known to the nearest tenth of a milliliter. Therefore, we can report the difference between them to only the nearest tenth of a milliliter. When measured numbers are added or subtracted, the result is reported with the same number of significant digits to the right of the decimal as the measured number with the fewest digits to the right of the decimal.

Next, suppose the average mass of a recently minted penny is 2.50 g and a roll of pennies contains 50 of them. We use the upper scale from Figure 1.21 to determine the mass of a roll of pennies. Using the tare feature to correct for the mass of the wrapper, we find that the mass of pennies in the roll is 122.53 g. Dividing this value by the average mass of a penny and canceling out the grams units in the numerator and denominator, we get

If we were measuring uncountable substances, rounding off to 49.0 would be appropriate (because under these circumstances, the measured value of 2.50 g/penny would be the weak link in the calculation). However, because we use only whole numbers to count items, we round to 49 and conclude that the roll contains 49 pennies. We must add one penny to make the roll complete.

Suppose the penny we add is one we know has a mass of 2.5007 g because we determined its mass on the lower scale in Figure 1.21. What is the mass of all 50 pennies to the appropriate number of significant figures? Adding the mass of the 50th penny to the mass of the other 49, we have

The mass of the first 49 pennies is known to two decimal places, whereas the mass of the 50th is known to four decimal places. By the weak-link principle, then, we can know the sum of the two numbers to only two decimal places. This makes the last two digits in the sum, shown in red, not significant, so we must round off the mass to 125.03 g.

SAMPLE EXERCISE 1.5 Using Significant Figures in Calculations
LO8

The volume of a nugget of a shiny yellow mineral with a mass of 30.01 g is determined by the method of water displacement (see Figure 1.22). A 100 mL graduated cylinder contains 56.3 mL of water before the nugget is added and 62.6 mL after it is added. Is the nugget made of gold ($d = 19.3$ g/mL)?

Collect and Organize We are given the mass of a nugget and water displacement data that can be used to calculate its volume. Density is mass divided by volume.

Analyze The volume of the nugget is the difference between 62.6 mL and 56.3 mL, or about 6 mL. The ratio of the mass (30.01 g) to volume (~6 mL) is about 5 g/mL, which is much less than the density of gold.

Solve

We know the volume of the nugget (6.3 mL) to two significant figures, so we can report its density to only two significant figures, too. As a result, we must round off the result to 4.8 g/mL. The density of gold is 19.3 g/mL, so the nugget cannot be pure gold.

Think About It The weak link in defining the certainty in this calculation is the volume of the irregularly shaped sample, which was calculated from the difference between two measured values that each had three significant figures, but the difference between them had only two. Our rough estimate in the Analyze step strongly suggested that the nugget was unlikely to be pure gold and our calculation in the Solve step confirmed that.

Practice Exercise Express the result of the following calculation to the appropriate number of significant figures:

Note: None of the starting values are exact numbers.

(Answers to Practice Exercises are in the back of the book.)

CONCEPT TEST

The distances between the opposite surfaces of a cube of metal were determined using a micrometer (**Figure 1.23**) and found to be 2.534, 2.537, and 2.529 cm. These values were multiplied together to calculate the volume of the cube, which was then divided into the mass of the cube, 135.080 g, to calculate its density. Was the volume of the cube or its mass the weak link in calculating its density?

(Answers to Concept Tests are in the back of the book.)

Measurements always have some degree of uncertainty, which limits the number of significant figures we can use to report any measurement. Some values are known exactly, however, such as 12 eggs in a dozen and 60 seconds in a minute. Because these values are definitions, there is no uncertainty in them and they are not considered when determining significant figures in the answer to a mathematical calculation in which they appear.

SAMPLE EXERCISE 1.6 Distinguishing Exact from Uncertain Values LO9

Which of the following data for the Washington Monument in Washington, DC, are exact numbers and which are not?

1. The monument is made of 36,491 white marble blocks.
2. The monument is 169 m tall.
3. There are 893 steps to the top.
4. The mass of its aluminum apex is 2.8 kg.
5. The area of its foundation is 1487 m^2.

Collect, Organize, and Analyze One way to distinguish exact from inexact values is to answer the question, “Which quantities can be counted?” Values that can be counted are exact.

Solve (a) The number of marble blocks and (c) the number of stairs are quantities we can count, so they are exact numbers. The other three quantities are based on measurements of (b) length, (d) mass, and (e) area and therefore are not exact.

Think About It The “you can count them” property of exact numbers works in this exercise and in most others even when it takes a long time (such as counting the hairs on a dog) or if help is needed in visualizing the objects (such as using a microscope). These examples raise a good point: Is there uncertainty in the counting process itself? Can you think of a famous example in the history of American politics of an uncertain counting process?

Practice Exercise Which of the following statistics associated with the Golden Gate Bridge in San Francisco, CA, are exact numbers and which have some uncertainty?

1. The roadway is six lanes wide.
2. The width of the bridge is 27.4 m.
3. The bridge has a mass of 3.808×10^8 kg.
4. The length of the bridge is 2740 m.
5. The Pay-by-Plate toll for a car traveling south increased to $7.75 on July 7, 2017.

(Answers to Practice Exercises are in the back of the book.)

Precision and Accuracy

Two terms—precision and accuracy—are used to describe how well we know a measured quantity or a value calculated from a measured quantity. Precision indicates how well the results of repeated measurements or analyses agree with each other, whereas accuracy reflects how close the results are to the true (or accepted) value of a quantity (**Figure 1.24**). The accuracy of a scale, for example, can be checked by measuring objects of known mass. Similarly, a thermometer can be calibrated by measuring the temperature at which a substance changes state. For example, ice melts to liquid water at 0.0°C, and an accurate thermometer dipped into a mixture of ice and liquid water reads 0.0°C. A measurement that is validated by calibration with an accepted standard material is considered accurate.

Another way to check the accuracy of measurements is to periodically analyze *control samples*, which contain known quantities of substances of interest. Control samples are used in clinical chemistry labs to ensure the accuracy of routine analyses of blood serum and urine samples. One substance that is included in comprehensive blood tests is creatinine, a product of protein metabolism that doctors use to monitor patients' kidney function. Suppose that a control sample known to contain 0.681 milligrams of creatinine per deciliter of sample is analyzed after every ten patient samples, and that the results of five control sample analyses are 0.685, 0.676, 0.669, 0.688, and 0.692 mg/dL. How precise (repeatable) are these results, and do they mean that the analyses of the control sample (and those subsequently conducted on the real samples) are accurate?

A widely used method for expressing the precision of data such as these involves calculating the average of all the values and then calculating how much each value deviates from the average. To calculate the average, we sum the five control sample results and divide by the number of values (5):

We can write a general equation to represent this calculation for any number of measurements (n) of any parameter x. Individual results are identified by the generic symbol x_i, where i can be any integer from 1 to n, the number of measurements made. The capital Greek sigma (Σ) with an i subscript, $\Sigma_i(x_i)$, represents the *sum* of all the individual x_i values. This kind of average is called the mean or arithmetic mean, and it is represented by the symbol $\bar{x}$:

To evaluate the precision of the five analyses of the control sample, we first calculate how much each of the values, x_i, deviates from the mean value $\bar{x}$: $(x_i - \bar{x})$. Next, we square each deviation $(x_i - \bar{x})^2$ and then sum all the squared values. Next, we divide the sum by

$(n - 1)$, and finally we take the square root of the quotient. The results of these calculations are shown in **Table 1.5**. The result is called the standard deviation (s) of the control sample values. Equation 1.3 combines the above steps for calculating s into a single equation:

The standard deviation is sometimes reported with the mean value, using a ± sign to indicate that the uncertainty in the mean value spans the range from the mean plus the standard deviation to the mean minus the standard deviation. This expression is 0.6820 ± 0.0094 mg/dL for the five creatinine control samples, where the s value is rounded off to match the last decimal place of the mean. The smaller the value of s, the more tightly clustered the measurements are around the mean and the more precise the data are.

Now that we have evaluated the precision of the control sample data, we should evaluate how accurate they are—that is, how well they agree with 0.681 mg/dL, the actual creatinine value of the control sample. The mean of the five values is within 0.001 mg/dL of the actual value, so the results certainly seem accurate, but there is also a way to quantitatively express the certainty that they are accurate. It involves calculating the confidence interval, which is a range of values around a calculated mean (0.682 mg/dL in this case) that probably contains the true mean value, μ. Once we have calculated the size of this range, we can determine whether the actual creatinine value is within it. If it is, then the analyses are probably accurate.

TABLE 1.5 Calculating the Standard Deviation of the Control Sample Creatinine Values

X_i (mg/dL)	$X_i - \bar{x}$	$(X_i - \bar{x})^2$	$s = \sqrt{\frac{\sum_i (x_i - \bar{x})^2}{n - 1}}$
0.685	0.003	0.000009	
0.676	−0.006	0.000036	
0.669	−0.013	0.000169	
0.688	0.006	0.000036	
0.692	0.010	0.000100	
		0.000350	

To calculate the confidence interval, we use a statistical tool called the *t*-distribution and the following equation:

TABLE 1.6 Values of *t*

	CONFIDENCE LEVEL (%)		
$(n-1)$	90	95	99
3	2.353	3.182	5.841
4	2.132	2.776	4.604
5	2.015	2.571	4.032
10	1.812	2.228	3.169
20	1.725	2.086	2.845
∞	1.645	1.960	2.576

A table of *t* values is in Appendix 1. **Table 1.6** contains a portion of it. The values are arranged based on two parameters: the number of values in a set of data (actually, $n-1$) and the confidence level we wish to use in our decision making. A commonly used confidence level in chemical analysis is 95%. Using it means that the chances are 95% that the range we calculate using Equation 1.4 will contain the true mean value of, in this case, the amount of creatinine in our control sample. Using the 95% value for ($n-1=5-1=4$) in Table 1.6, which is 2.776, and the mean and standard deviation values calculated above:

Thus, we can say with 95% certainty that the true mean of our control sample data is between 0.670 and 0.694 mg/dL. Because this range includes the known concentration of the sample, 0.681 mg/dL, we may conclude that the results of analyses of the control samples (and, importantly, analyses of patient samples) are accurate.

SAMPLE EXERCISE 1.7 Evaluating the Precision of Analytical Results LO9

A group of students collects a sample of water from a river near their campus and shares it with five other groups of students. All six groups of students determine the concentration of dissolved oxygen in the sample. The results of their analyses are 9.2, 8.6, 9.0, 9.3, 9.1, and 8.9 mg O_2/L. What are the mean, standard deviation, and 95% confidence interval of these results?

Collect and Organize We are asked to calculate the mean, standard deviation, and 95% confidence interval of the results of six analyses of the same sample. Equations 1.2, 1.3, and 1.4 can be used to calculate the three statistical parameters we seek.

Analyze There are 6 values, so $n - 1 = 5$, and the appropriate t value (Table 1.6) to use in Equation 1.4 is 2.571. Mean and standard deviation functions are also included in many programmable calculators and in computer worksheet applications such as Microsoft Excel.

Solve

1. Calculating the mean:

$$\bar{x} = \frac{\sum_i (x_i)}{n} = \left(\frac{9.2 + 8.6 + 9.0 + 9.3 + 9.1 + 8.9}{6}\right) \text{mg/L} = \frac{54.1}{6} = 9.02 \text{ mg/L}$$

2. To calculate the standard deviation, we set up a data table like the one in Table 1.5:

x_i	$\bar{x}$	$x_i - \bar{x}$	$(x_i - \bar{x})^2$
9.2	9.02	0.18	0.0324
8.6	9.02	−0.42	0.1764
9.0	9.02	−0.02	0.0004
9.3	9.02	0.28	0.0784
9.1	9.02	0.08	0.0064
8.9	9.02	−0.12	0.0144

The sum of the $(x_i - \bar{x})^2$ values is 0.3084 and

$$s = \sqrt{\frac{\sum_i (x_i - \bar{x})^2}{n - 1}} = 0.25$$

3. Using Equation 1.4 to calculate the 95% confidence interval:

$$\mu = \bar{x} \pm \frac{ts}{\sqrt{n}} = \left(9.02 \pm \frac{2.571 \times 0.25}{\sqrt{6}}\right) \text{mg/L} = (9.02 \pm 0.26)\ \text{mg/L}$$

Think About It Did you notice that the six data points used in these calculations each contained two significant figures (each was known to the nearest tenth of a mg/L), yet we expressed the mean with three significant figures (to the hundredths place)? This was appropriate because we knew the sum of the six results (54.1) to three significant figures and dividing this value by an exact number (six values) meant the quotient could be reported with three significant figures: 9.02. This increase in significant figures—and in the students' confidence in knowing the actual concentration of dissolved oxygen in the river—illustrates the importance of replicating analyses: doing so gives us more certainty about the true value of an experimental value than a single determination of it.

Practice Exercise Analyses of a sample of Dead Sea water produced these results for the concentration of sodium ions: 35.8, 36.6, 36.3, 36.8, and 36.4 mg/L. What are the mean, standard deviation, and 95% confidence interval of these results?

(Answers to Practice Exercises are in the back of the book.)

There is an assumption built into calculating means, standard deviations, and confidence intervals, which is that the variability in the data is random. *Random* means that data points are as likely to be above the mean value as below it and that there is a greater probability of values close to the mean than far away from it. This is called a *normal* distribution of the data points (it is also called a Gaussian distribution). Large numbers of such data produce a distribution profile called a bell curve. **Figure 1.25** shows such a curve, based on a study conducted by the U.S. Centers for Disease Control and Prevention on the average weights of Americans of different ages. The data in the figure are for the weights of 19-year-old males and have a mean of 175 pounds (79 kg) and a standard deviation of 41 pounds (19 kg). In randomly distributed data, 68% of the values—represented by the area under the curve highlighted in orange—are within 1 standard deviation of the mean.

The concept of a normal distribution raises the question of how to handle outliers, that is, individual values that are much farther away from the mean than any of the other values. There may be a temptation to simply ignore such a value, but unless there is a valid reason for doing so, such as accidentally leaving out a step in an analytical procedure, it is unethical to disregard a value just because it is unexpected or not like the others.

Suppose a college freshman discovers a long-forgotten childhood piggy bank full of pennies and, being short of cash, decides to pack them into rolls of 50 to deposit them at a bank. To avoid having to count out hundreds of pennies, the student decides to weigh them out on a scale in a general chemistry lab that can weigh up to 300 grams to the nearest 0.001 g. The student separately weighs ten pennies from the piggy bank to determine their average mass, intending to multiply the average by 50 to calculate how many to weigh out and then pack into each roll. The results of the ten measurements are listed in **Table 1.7** from lowest value to highest value.

TABLE 1.7 Masses in Grams of Ten Circulated Pennies

2.486
2.495
2.500
2.502
2.502
2.505
2.506
2.507
2.515
3.107

The results reveal that nine of the ten masses are quite close to 2.5 grams, but the tenth is considerably heavier. Was there an error in the measurement, or is there something unusual about that tenth penny? To answer questions such as these—and the broader one of whether an unusually high or low value is statistically different enough from the others in a set of data to be labeled an outlier—we analyze the data by using *Grubbs' test of a single outlier*, or Grubbs' test. In this test, the absolute difference between the suspected outlier and the mean of a set of data is divided by the standard deviation of the data set. The result is a statistical parameter that has the symbol Z:

If this calculated Z value is greater than the reference Z value (**Table 1.8**) for a given number of data points and a confidence level—usually 95%—then the suspect data point is an outlier and can be discarded.

To apply Grubbs' test to the mass of the tenth and heaviest penny, we first calculate the mean and standard deviation of the masses of all ten pennies. These values are 2.562 ± 0.1915 g. We use them in Equation 1.5 to calculate Z:

TABLE 1.8 Reference Z Values for Grubbs' Test of a Single Outlier

	CONFIDENCE LEVEL (%)	
n	95	99
3	1.155	1.155
4	1.481	1.496
5	1.715	1.764
6	1.887	1.973
7	2.020	2.139
8	2.126	2.274
9	2.215	2.387
10	2.290	2.482
11	2.355	2.564
12	2.412	2.636

Next, we check the reference Z values in Table 1.8 for $n = 10$ data points, and we find that our calculated Z value is greater than both 2.290 and 2.482—the Z values above which we can conclude with 95% and 99% confidence, respectively, that the 3.107 g data point is an outlier. Stated another way, the probability that this data point *is not* an outlier is less than 1%. Note that Grubbs' test can be used *only once* to identify *only one* outlier in a set of data.

The tenth penny probably weighed much more than the others because U.S. pennies minted since 1983 weigh 2.50 grams new, but those minted before 1983 weighed 3.11 grams new. The older pennies are 95% copper and 5% zinc, whereas the newer pennies are 97.5% zinc and are coated with a thin layer of copper. (Copper is about 25% more dense than zinc.) Thus, a pre-1983 penny in a population of post-1983 pennies is an outlier based on its mass *and* based on its chemical composition.

CONCEPT TEST

Calculate the mean mass of one penny in a roll of pennies that contains exactly half pre-1983 pennies. One synonym for *mean* is "average." Would the mass of any penny in this roll equal the average mass?

(Answers to Concept Tests are in the back of the book.)

SAMPLE EXERCISE 1.8 Testing Whether a Data Point Should Be Considered an Outlier LO9

Use Grubbs' test to determine whether the lowest value in the set of sodium ion concentration data from Practice Exercise 1.7 should be considered an outlier at the 95% confidence level.

Collect, Organize, and Analyze We want to determine whether the lowest value in the following set of five results is an outlier: 35.8, 36.6, 36.3, 36.8, and 36.4 mg/L. Grubbs' test (Equation 1.5) is used to determine whether a data point should be deemed an outlier. If the resulting Z value is equal to or greater than the reference Z values for $n = 5$ in Table 1.8, the suspect value is an outlier.

Solve Using the statistics functions of a programmable calculator, we find the mean and standard deviation of the data set to be 36.38 ± 0.38 mg/L. We calculate the value of Z by using Equation 1.5:

This calculated Z value is less than 1.71, which is the reference Z value for $n = 5$ at the 95% confidence level (Table 1.8). Therefore, the lowest value is *not* an outlier, and it should be included with the other four values in any analysis of the data.

Think About It Although the lowest value may have appeared to be considerably lower than the others in the data set, Grubbs' test tells us that it is not *significantly* lower at the 95% confidence level.

Practice Exercise Duplicate determinations of the cholesterol concentration in a blood serum sample produce the following results: 181 mg/dL and 215 mg/dL. The patient's doctor is concerned about the difference between the two results because values above 200 mg/dL are considered "borderline high," so she orders a third cholesterol test. The result is 185 mg/dL. Should the doctor ignore the 215 mg/dL value?

(Answers to Practice Exercises are in the back of the book.)

Glossary

significant figures

all the certain digits in a measured value plus one estimated digit; the greater the number of significant figures, the greater the certainty with which the value is known.

precision

agreement between the results of multiple measurements that were carried out in the same way.

accuracy

agreement between one or more experimental values and the true (or accepted) value.

mean (arithmetic mean, $\bar{x}$)

an average calculated by summing a set of related values and dividing the sum by the number of values in the set.

mean (arithmetic mean, $\bar{x}$)

an average calculated by summing a set of related values and dividing the sum by the number of values in the set.

standard deviation (s)

a measure of the amount of variation, or dispersion, in a set of related values. The lowercase Greek letter sigma (σ) is also used as the symbol for standard deviation.

confidence interval

a range of values that has a specified probability of containing the true value of a measurement.

outlier

a data point that is distant from the other observations.

Grubbs' test

a statistical test used to detect an outlier in a set of data.

Learning Objectives

- Express uncertain values with the appropriate number of significant figures **Return to Sample Exercise 1.5**

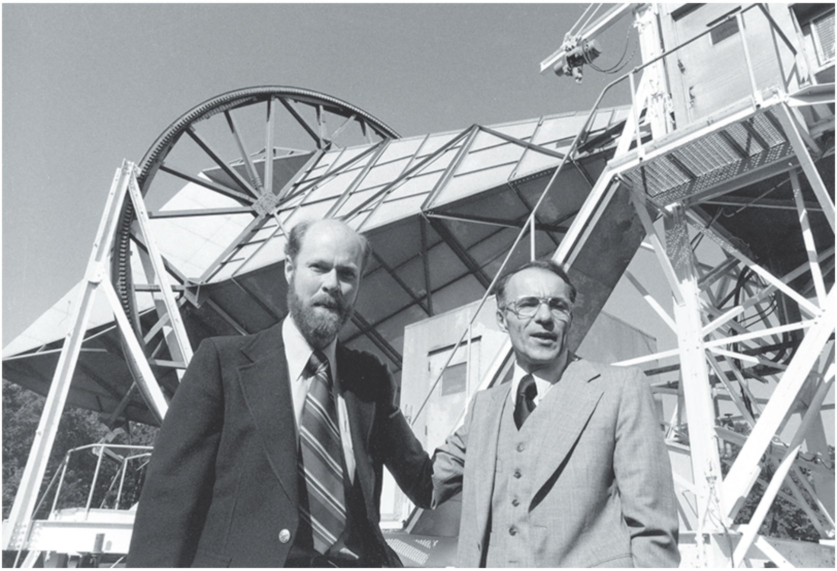

FIGURE 1.29 In 1965 Robert Wilson (left) and Arno Penzias discovered the microwave echo of the Big Bang while tuning this highly sensitive "horn" antenna at Bell Labs in Holmdel, NJ.

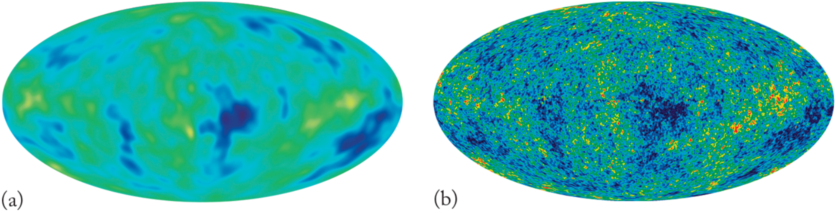

FIGURE 1.30 (a) Map of the cosmic microwave background released in 1992. It is a 360-degree image of the sky made by collecting microwave signals for a year from the microwave telescopes of the *COBE* satellite. (b) Higher-resolution image based on measurements made in 2012 by the *WMAP* satellite. Red regions are up to 200 μK warmer than the average interstellar temperature of 2.73 K, and blue regions are up to 200 μK colder than 2.73 K.

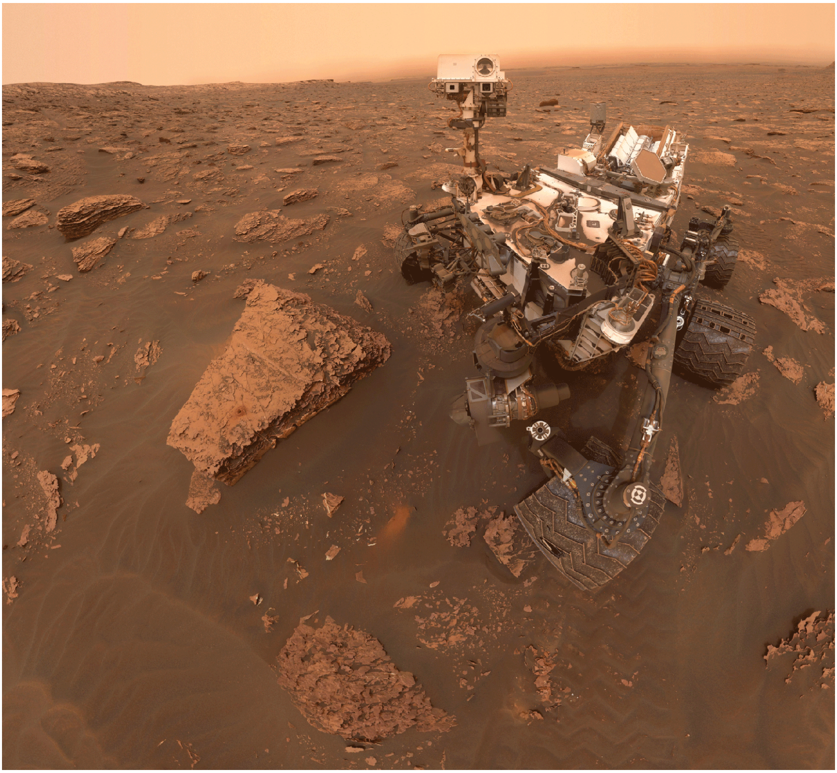

FIGURE 1.31 In late March 2018, NASA celebrated *Curiosity*'s 2000th Martian day (sol) of exploration by releasing this selfie taken by the rover with Mount Sharp in the background.

1.11 Testing a Theory: The Big Bang Revisited

If all the matter in the universe started as a dense cloud of very hot gas accompanied by an enormous release of energy (the Big Bang), and if the universe has been expanding ever since, then the universe must have been cooling throughout time because gases cool as they expand. This is the principle behind the operation of refrigerators and air conditioners—and behind one of the most important experiments testing the validity of the Big Bang theory.

Temperature Scales

If the universe is still expanding and cooling, some warmth must be left over from the Big Bang. By the 1950s, some scientists predicted that the leftover warmth should be enough to give interstellar space a temperature of 2.73 K, where K indicates a temperature value on the Kelvin scale.

Several temperature scales are in use today. In the United States the Fahrenheit scale is still the most popular. In the rest of the world and in science, temperatures are most often expressed in degrees Celsius or on the Kelvin scale. The Fahrenheit and Celsius scales differ in two ways, as shown in **Figure 1.26**. First, their zero points are different. Zero degrees Celsius (0°C) is the temperature at which water freezes under normal conditions, but that temperature is 32 degrees on the Fahrenheit scale (32°F). The other difference is the size of the temperature change corresponding to 1 degree. The difference between the freezing and boiling points of water is $212 - 32 = 180$ degrees on the Fahrenheit scale but only $100 - 0 = 100$ degrees on the Celsius scale. This difference means that a Fahrenheit degree is 100/180, or 5/9, as large as a Celsius degree.

To convert temperatures from Fahrenheit into Celsius, we need to account for the differences in zero point and in degree size. Equation 1.6 does both:

The SI unit of temperature (Table 1.2) is the kelvin (K). The zero point on the Kelvin scale is not related to the freezing of a substance; rather, it is the coldest temperature—called absolute zero (0 K)—that can theoretically exist. It is equivalent to −273.15°C. No one has ever been able to chill matter to absolute zero, but scientists have cooled samples to less than 10^{-9} K, so they have come very close.

The zero point on the Kelvin scale differs from that on the Celsius scale, but the size of 1 degree is the same on the two scales. For this reason, the conversion from a Celsius temperature to a Kelvin temperature is simply a matter of adding 273.15 to the Celsius value:

SAMPLE EXERCISE 1.9 Temperature Conversions LO7

The temperature of interstellar space is 2.73 K. What is this temperature on the Celsius scale and on the Fahrenheit scale?

Collect and Organize We are given the temperature of interstellar space and want to convert it to other scales. Equation 1.6 relates Celsius and Fahrenheit temperatures; Equation 1.7 relates Kelvin and Celsius temperatures.

Analyze We can first use Equation 1.7 to convert 2.73 K into an equivalent Celsius temperature and then use Equation 1.6 to calculate an equivalent Fahrenheit temperature. The value in degrees Celsius should be close to absolute zero (about -273°C). The temperature on the Fahrenheit scale, though, should be a little less than twice the value of the temperature on the Celsius scale (around -500°F), because 1°F is about half the size of 1°C.

Solve To convert from kelvins to degrees Celsius, we have

To convert degrees Celsius to degrees Fahrenheit, we rearrange Equation 1.6 to solve for degrees Fahrenheit:

Multiplying both sides by 9 and dividing both by 5 gives us

The value 32°F is a definition, so it does not affect the number of significant figures in the answer. The number that determines the accuracy to which we can know this value is -270.42°C.

Think About It The calculated Celsius value of -270.42°C makes sense because it represents a temperature only a few degrees above absolute zero, just as we estimated. The Fahrenheit value is within 10% of our estimate, so it is reasonable, too.

Practice Exercise The temperature of the Moon's surface varies from −233°C at night to 123°C during the day. What are these temperatures on the Kelvin and Fahrenheit scales?

(Answers to Practice Exercises are in the back of the book.)

An Echo of the Big Bang

By the early 1960s, Princeton University physicist Robert Dicke (1916–1997; **Figure 1.27**) had suggested the presence of residual energy left over from the Big Bang, and he was eager to test this hypothesis. He proposed building an antenna that could detect microwave energy reaching Earth from outer space. Why did he pick microwaves? Even matter as cold as 2.73 K emits a "glow" (an energy signature), but not a glow you can see or feel, like the infrared rays emitted by any warm object, including humans (**Figure 1.28**). Dicke wanted to build a microwave antenna because the glow from a 2.73 K object takes the form of microwaves.

Dicke's microwave detector was never built because of events that occurred just a short distance from Princeton. By the early 1960s, the United States had launched *Echo* and *Telstar*, the first communication satellites. These satellites were reflective spheres designed to bounce microwave signals to receivers on Earth. An antenna designed to receive these microwave signals had been built at Bell Laboratories in Holmdel, NJ (**Figure 1.29**). Two Bell Labs scientists, Robert W. Wilson (born 1936) and Arno A. Penzias (born 1933), were working to improve the antenna's reception when they encountered a problem. They found that no matter where they directed their antenna, it picked up a constant background microwave signal much like the hissing sound radios make when tuned between stations. They thought the signal was due to a flaw in the antenna or in one of the instruments connected to it, but extensive testing failed to detect such a flaw.

Then Wilson and Penzias learned of Dicke's prediction that a microwave echo of the Big Bang penetrated the universe, and they realized the cosmic significance of what they had thought was a problem with their satellite communication system. Others realized it, too, and in 1978 Wilson and Penzias shared the Nobel Prize in Physics for discovering the cosmic microwave background. Dicke did not share in the prize, even though he had accurately predicted what Wilson and Penzias discovered by accident.

Major discoveries in science almost always lead to new questions, new experiments, and new discoveries. The discovery of cosmic microwaves was no exception. It supported the Big Bang theory, but it also seemed to find a problem with it: the Bell Labs antenna picked up the same microwave signal no matter where in the sky it was pointed. In other words, the cosmic microwaves appeared to be uniformly distributed throughout the universe. This uniformity in the afterglow from the Big Bang troubled scientists because they knew there had to have been at least some heterogeneity in the density of the expanding universe to eventually allow clusters of matter to assemble and grow, leading to the formation of galaxies containing the first generation of stars.

Scientists doing work related to Dicke's proposed that, if such clustering had occurred, a record of it should exist as subtle differences in the cosmic background radiation. Unfortunately, a microwave antenna in New Jersey—or any other place on Earth—could not detect such slight variations in signals because too many other sources of microwaves interfere with such measurements. Detecting these tiny variations would require launching a radio antenna into space.

In late 1989 the United States launched such an antenna in the form of the *Cosmic Background Explorer* (*COBE*) satellite. After many months of collecting data and many more months of analyzing it, scientists released the results in 1992. The image in **Figure 1.30a** appeared on the front pages of newspapers and magazines around the world. This was a major news story because the predicted heterogeneity had been found, providing additional support for the Big Bang theory. At a news conference, the lead scientist on the

COBE project called the map a "fossil of creation."

COBE's measurements, and those obtained over the next two decades by a satellite with even higher resolving power (**Figure 1.30b**), support the theory that the universe had undergone an uneven expansion and cooling. The blobs and ripples in the images in Figure 1.30 indicate that galaxy "seed clusters" formed early in the history of the universe. Cosmologists believe these ripples are a record of the next stage after the Big Bang in the creation of matter. This stage is examined in Chapter 2, where we discuss how some elements may have formed just after the Big Bang and how others continue to be formed by the nuclear reactions that fuel our Sun and all the stars in the universe.

CONCEPT TEST

When Lemaître first proposed how the universe might have formed following a cosmic release of energy, would it have been more appropriate to call his explanation a hypothesis or a theory? Why?

(Answers to Concept Tests are in the back of the book.)

SAMPLE EXERCISE 1.10 Integrating Concepts: Driving around Mars

In press conferences about the Martian rover *Curiosity* (**Figure 1.31**), scientists and engineers have expressed distances in SI and USC units and temperatures in K, °C, and °F in response to questions from journalists from different countries. After one early drive, they said *Curiosity* had stopped 8.0 ft away from an interesting football-shaped rock. *Curiosity*'s wheels are 50 cm in diameter, and the rover moves at a speed of 200 m/sol, where 1 sol = 1 Martian day = 24.65 h.

1. How many minutes would it take the rover to move to within 1.0 ft of the rock?
2. How many rotations of the wheels would be required to move that distance?
3. The rover landed in a valley about 15 miles away from the

base of Mt. Sharp. How far is that in kilometers?

4. The distance from the base to the peak of Mt. Sharp is 5.5 km; the distance from the base to the peak of Mt. Everest on Earth is 15,000 ft. Which mountain is taller?
5. One night *Curiosity* recorded a temperature reported as $-132°F$. If the daytime temperature was 263 K, what was the day/night temperature range in °C?

Collect, Organize, and Analyze We are given a series of measurements and are asked questions that require us to convert units of time, distance, speed, and temperature. The needed conversion factors are available on the inside back cover of the book or provided in the problem, including the rover's speed (200 m/sol) and the length of a Martian day (1 sol = 24.65 h).

Solve

1. The time to travel to within 1.0 ft of the rock is

$$(8.0 - 1.0)\ \cancel{\text{ft}} \times \frac{12\ \cancel{\text{in}}}{1\ \cancel{\text{ft}}} \times \frac{2.54\ \cancel{\text{cm}}}{1\ \cancel{\text{in}}} \times \frac{1\ \cancel{\text{m}}}{100\ \cancel{\text{cm}}} \times \frac{1\ \cancel{\text{sol}}}{200\ \cancel{\text{m}}} \times \frac{24.65\ \cancel{\text{h}}}{1\ \cancel{\text{sol}}} \times \frac{60\ \text{min}}{1\ \cancel{\text{h}}} = 16\ \text{min}$$

2. The diameter of the wheel is 50 cm, or

$$50\ \cancel{\text{cm}} \times \frac{1\ \cancel{\text{in}}}{2.54\ \cancel{\text{cm}}} \times \frac{1\ \text{ft}}{12\ \cancel{\text{in}}} = 1.64\ \text{ft}$$

and its circumference is

$\pi \times d = 3.1416 \times 1.64\ \text{ft} = 5.15\ \text{ft}$

The wheel has 7.0 ft to travel, so it requires

$$7.0\ \cancel{\text{ft}} \times \frac{1\ \text{revolution}}{5.15\ \cancel{\text{ft}}} = 1.4\ \text{revolutions}$$

3. $$15\ \cancel{\text{mi}} \times \frac{1.6093\ \text{km}}{1\ \cancel{\text{mi}}} = 24\ \text{km}$$

4. $$\text{Mt. Sharp: } 5.5\ \cancel{\text{km}} \times \frac{1\ \text{mi}}{1.6093\ \cancel{\text{km}}} = 3.4\ \text{mi}$$
$$\text{Mt. Everest: } 15{,}000\ \cancel{\text{ft}} \times \frac{1\ \text{mi}}{5280\ \cancel{\text{ft}}} = 2.8\ \text{mi}$$

Mt. Sharp is $(3.4 - 2.8) = 0.6$ miles higher than Mt. Everest.

5. $$°\text{C} = \frac{5}{9}(-132°\text{F} - 32°\text{F}) = -91.1°\text{C}$$

The high temperature that day was 263 K:

$°\text{C} = \text{K} - 273.15 = 263 - 273.15 = -10.15 = -10°\text{C}$

The temperature differential on the surface that day was

$-10°\text{C} - (-91.1°\text{C}) = 81°\text{C}$

Think About It Two of the reported starting values—the diameter (50 cm) of *Curiosity*'s wheels and its speed (200 m/sol)—ended with zeros and had no decimal points. This created ambiguity in how well these values are known and forced us to guess their certainties based on (1) the likely precision with which the components of *Curiosity* must have been fabricated and (2) the ability of the Jet Propulsion Laboratory engineers to control its speed. In both cases we assumed the values were known to two significant figures and used that many to express the results of the calculations in parts (a) and (b).

Glossary

kelvin (K)

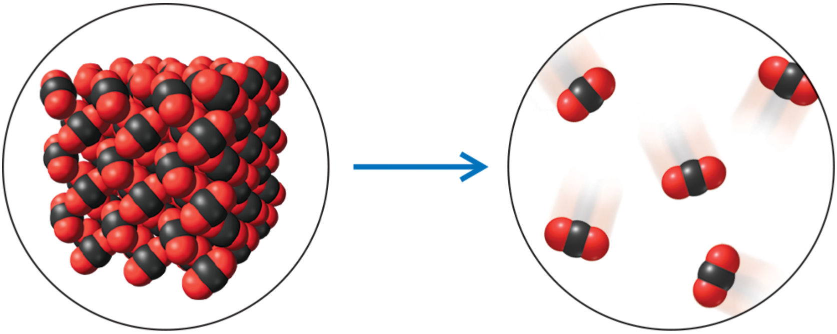
the SI unit of temperature.

absolute zero (0 K)

the zero point on the Kelvin temperature scale; theoretically the lowest temperature possible.

Learning Objectives

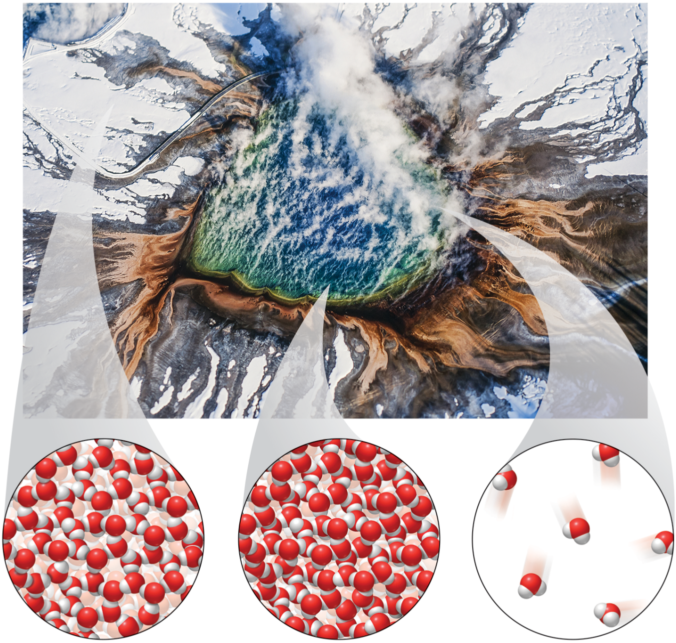
- Convert quantities from one system of units to another
  Return to Sample Exercises 1.3, 1.4, 1.9



SUMMARY

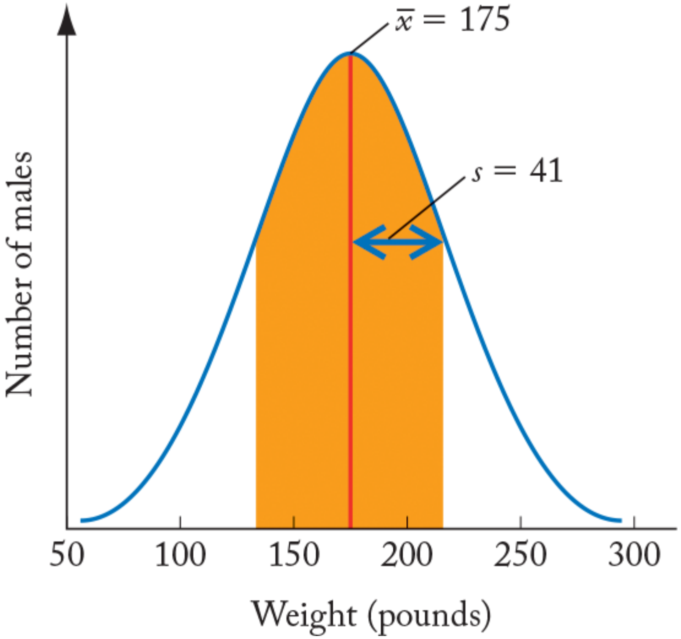
- LO1 Matter exists as pure substances, which may be either elements or compounds, and as mixtures. Mixtures may be homogeneous (these mixtures are also called solutions) or heterogeneous. (Section 1.2)
- LO2 All matter consists of particles: atoms, molecules (combinations of atoms held together by chemical bonds), or ions (atoms or combinations of atoms that have a net negative or positive electrical charge). Chemical formulas are used to describe polyatomic forms of elements, such as H_2, and the elemental composition of compounds, such as H_2O. Chemical equations describe the proportions of the substances involved in a chemical reaction. Space-filling and ball-and-stick models are used to show the three-dimensional arrangement of the atoms in molecules. (Section 1.2)

- LO3 Matter undergoes physical processes, which do not change its chemical identity, and chemical reactions, which transform matter into different substances. Matter is described and defined in terms of its physical properties and chemical properties. Physical properties may be used to separate mixtures into pure substances. (Sections 1.1, 1.2, 1.3, and 1.5)
- LO4 The COAST framework used in this book to solve problems has four components: Collect and Organize information and ideas; Analyze the information to determine how it can be used to obtain the answer; Solve the answer to the problem (often the math-intensive step); and Think About It, where you consider the answer's reasonableness, including its value and units. (Section 1.4)



(a) Solid (b) Liquid (c) Gas

- LO5 The physical properties of the different states of matter are linked to the arrangement and mobility of the particles in them. For example, the particles in solids and liquids are packed close together, which make these states of matter nearly incompressible. Gases, however, are compressible because their particles are far apart. (Section 1.6)
- LO6 The scientific method is the approach we use to acquire knowledge through observation, testable hypotheses, and experimentation. An extensively tested and well-validated hypothesis becomes accepted as a scientific theory or model. (Sections 1.7 and 1.11)
- LO7 Dimensional analysis uses conversion factors (fractions in which the numerators and denominators have different units but represent the same quantity) to convert a value from one unit into another unit. (Section 1.9)
- LO8 The limit of how well we know an uncertain value is expressed by the number of significant figures used to express the value. (Sections 1.8 and 1.10)



- LO9 There are inherent uncertainties in all measured values, whereas other values, such as the number of eggs in a carton, are known exactly because they can be counted. The precision of measured values refers to how little variability there is between repeated measurements. The accuracy of a measurement, such as weighing an object on a scale, refers to how close the measured value is to the actual mass of the object. The standard deviation and confidence interval of a set of measurements provide measures of the uncertainty surrounding the average or arithmetic mean of the data set. An outlier in a data set may be identified by using the Grubbs' test. (Section 1.10)

PARTICULATE PREVIEW WRAP-UP

Sublimation is the process by which a solid changes directly into a gas. The image on the left is a solid because it consists of tightly packed and ordered molecules, whereas the image on the right is a gas because there is space between the molecules and they are spread out to fill the circle. Energy must be added to convert a solid into a gas.

PROBLEM-SOLVING SUMMARY

Type of Problem	Concepts & Skills	Sample Exercises	Key Equations
Distinguishing physical properties from chemical properties	Chemical properties can be determined only by reacting it with another substance; physical properties can be determined without altering the substance's composition.	1.1	
Recognizing physical states of matter	Particles in a solid are ordered; particles in a liquid are randomly arranged but close together; particles in a gas are separated by space and fill the volume of their container.	1.2	
Using dimensional analysis to convert units	Convert values from one set of units to another by multiplying by conversion factors set up so that the original units cancel.	1.3, 1.4	
Calculating density, mass, and volume		1.5	$d = \frac{m}{V}$ (1.1)
Applying significant figures in calculations	Apply the weak-link principle in expressing the results of calculations that involve uncertain values: the results are known only as well as the least well-known value used in the calculation.	1.5	
Distinguishing exact from uncertain values	Quantities that are counted are exact values. Measured quantities or conversion factors that are not exact values are inherently uncertain.	1.6	
Calculating mean, standard deviation, and confidence interval values		1.7	$\bar{x} = \frac{\sum_i(x_i)}{n}$ (1.2) $s = \sqrt{\frac{\sum_i(x_i - \bar{x})^2}{n-1}}$ (1.3) $\mu = \bar{x} \pm \frac{t\,s}{\sqrt{n}}$ (1.4)
Using Grubbs' test to identify an outlier	Calculate the value of Z for suspected outlier x_i: $Z = \frac{\lvert x_i - \bar{x}\rvert}{s}$ (1.5) If the calculated Z value is greater than the appropriate reference Z value in Table 1.8, then x_i is an outlier.	1.8	
Converting temperatures		1.9	$°C = \frac{5}{9}(°F - 32)$ (1.6) $K = °C + 273.15$ (1.7)

VISUAL PROBLEMS

(Answers to boldface end-of-chapter questions and problems are in the back of the book.)

For each image in Figure P1.1, identify what class of matter is depicted (an element, a compound, a homogeneous mixture, or a heterogeneous mixture) and identify the physical state(s).

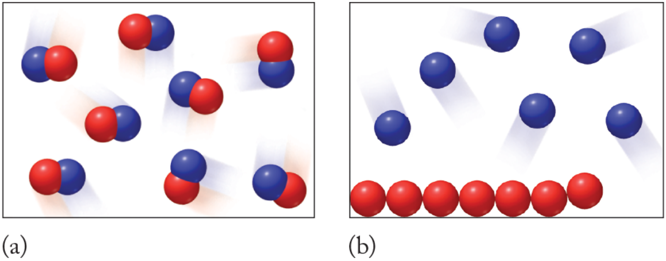


FIGURE P1.1

For each image in Figure P1.2, identify what class of matter is depicted (an element, a compound, a homogeneous mixture, or a heterogeneous mixture) and identify the physical state(s).

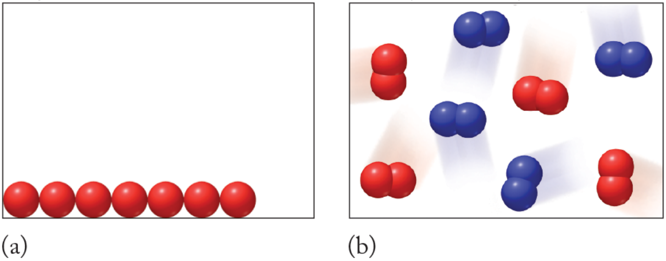

FIGURE P1.2

Which of the following statements best describes the change depicted in Figure P1.3?

1. A mixture of two gaseous elements undergoes a chemical reaction, forming a gaseous compound.
2. A mixture of two gaseous elements undergoes a chemical reaction, forming a solid compound.
3. A mixture of two gaseous elements undergoes deposition.
4. A mixture of two gaseous elements condenses.

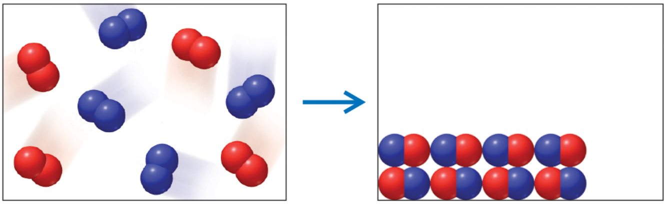

FIGURE P1.3

Which of the following statements best describes the change depicted in Figure P1.4?

1. A mixture of two gaseous elements is cooled to a temperature at which one of them condenses.
2. A mixture of two gaseous compounds is heated to a temperature at which one of them decomposes.
3. A mixture of two gaseous elements undergoes deposition.
4. A mixture of two gaseous elements reacts together to form two compounds, one of which is a liquid.

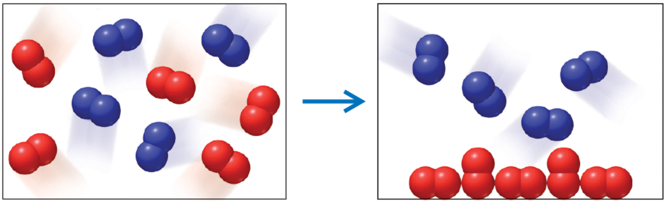

FIGURE P1.4

Suppose the CO_2 represented by the molecules in the box on the left in Figure P1.5 is cooled from room temperature to 180 K. Draw the particulate image of the CO_2 that would be present at that temperature in the box on the right. *Hint*: The normal sublimation point of CO_2 is 195 K.

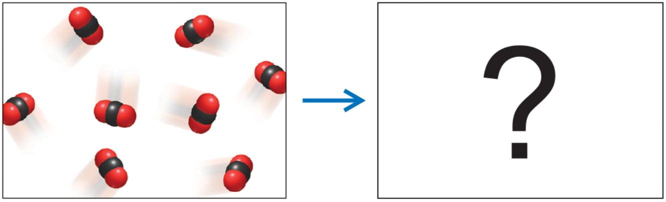

FIGURE P1.5

Suppose the temperature of the mixture of substances represented by the molecules in the box on the left in Figure P1.6 was reduced from 298 K to 50 K. Draw the particulate image of the mixture that would be present at 50 K in the box on the right. *Hint*: The colors used to represent the atoms of different elements are shown on the last page of the book.

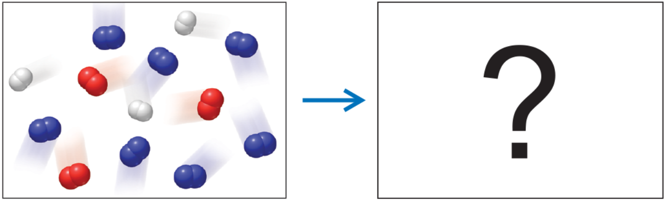

FIGURE P1.6

What are the chemical formulas of the three compounds with the molecular structures shown in Figure P1.7?

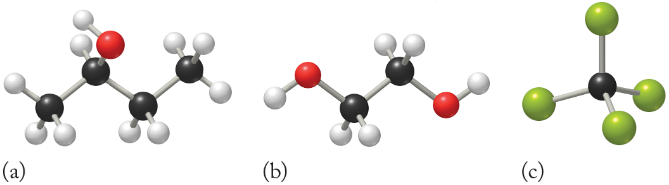

FIGURE P1.7

What are the chemical formulas of the three compounds with the molecular structures shown in Figure P1.8?

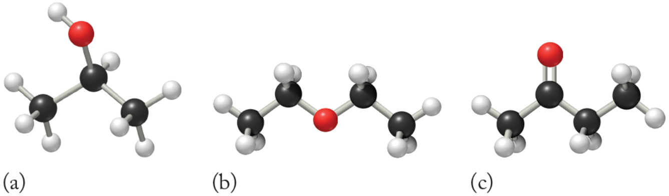

FIGURE P1.8

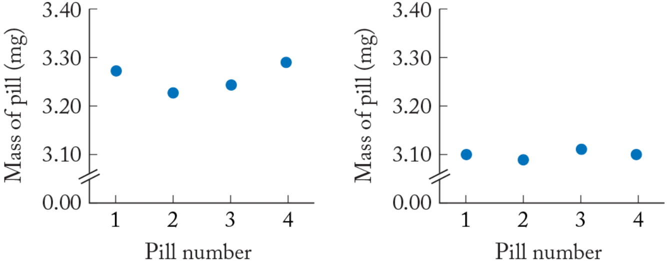
A pharmaceutical company checks the quality control process involved in manufacturing pills of one of its medicines by taking the mass of two samples of four pills each. Figure P1.9

shows graphs of the masses of the pills in each of the two samples. The pill is supposed to weigh 3.25 mg. Label each sample as both precise and accurate, precise but not accurate, accurate but not precise, or neither precise nor accurate.

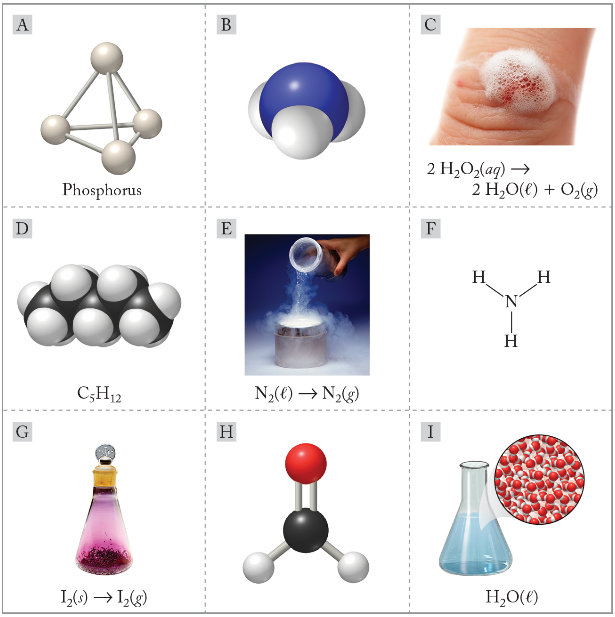


Sample A Sample B

FIGURE P1.9

Use representations [A] through [I] in Figure P1.10 to answer questions (a)–(f).

1. Which figures, if any, depict a chemical reaction?
2. Which two representations depict the same compound?
3. Which representations, if any, depict a physical process? Name the change(s).
4. List the molecules that are elements.
5. What is the formula of the compound that consists of three elements?
6. Which molecule contains the most atoms?



A
Phosphorus
B
C
2 $H_2O_2(aq) \rightarrow$ 2 $H_2O(\ell) + O_2(g)$
D
C_5H_{12}
E
$N_2(\ell) \rightarrow N_2(g)$
F
H H N H
G
$I_2(s) \rightarrow I_2(g)$
H
I
$H_2O(\ell)$

FIGURE P1.10

QUESTIONS AND PROBLEMS

Matter

Concept Review

Which of the following are homogeneous mixtures? (a) a gold wedding ring; (b) sweat; (c) bottled drinking water; (d) human blood; (e) compressed air in a scuba tank

Which of the following is a pure substance? (a) sweat; (b) blood; (c) air; (d) sucrose (table sugar); (e) milk

Which of the following is an element? (a) Cl_2; (b) H_2O; (c) HCl; (d) NaCl

Which of the following is *not* an element? (a) I_2; (b) O_3; (c) ClF; (d) S_8

Which of the following is a homogeneous mixture? (a) filtered water; (b) chicken noodle soup; (c) clouds; (d) trail mix snack; (e) fruit salad

Which of the following is a heterogeneous mixture? (a) air; (b) a sports drink (e.g., Gatorade); (c) muddy river water; (d) brass; (e) table salt (sodium chloride)

Composition of the Atmosphere Over 99% of the molecules in Earth's atmosphere are nitrogen and oxygen. What are their chemical formulas?

The first four elements in column 17 of the periodic table exist as diatomic molecules. What are their chemical formulas?

Among the compounds formed by nitrogen and oxygen are three that consist of molecules with (a) two atoms of nitrogen and one of oxygen, (b) two atoms of oxygen and one of nitrogen, and (c) one atom of each element. What are the chemical formulas of these compounds?

Among the multitude of compounds formed by carbon and hydrogen are three composed of molecules with (a) two atoms each of carbon and hydrogen, (b) six atoms each of carbon and hydrogen, and (c) one atom of carbon and four of hydrogen. What are the chemical formulas of these compounds?

Acid Rain In one of the reactions in the atmosphere that contributes to the formation of acid rain, molecules of water (H_2O) vapor and sulfur trioxide (SO_3) gas combine, forming a molecule of liquid sulfuric acid (H_2SO_4). Write a chemical equation describing this reaction (including the physical states of the reactants and product).

When dinitrogen pentoxide (N_2O_5) gas dissolves in water, molecules of N_2O_5 and H_2O combine, forming two molecules of nitric acid (HNO_3). Write a chemical equation describing this reaction (including the physical states of the reactants and product).

Which of the following describe physical properties and which describe chemical properties of the element sodium?

1. Its density is greater than that of kerosene and less than that of water.
2. It has a lower melting point than that of most metals.
3. It is an excellent conductor of heat and electricity.
4. It is soft and can be easily cut with a knife.
5. Freshly cut sodium is shiny, but it rapidly tarnishes in contact with air.
6. It reacts very vigorously with water to form hydrogen gas (H_2) and sodium hydroxide (NaOH).

Which of the following describe physical properties and which describe chemical properties of hydrogen gas (H_2)?

1. At room temperature, its density is less than that of any other gas.
2. It reacts vigorously with oxygen (O_2) to form water.
3. Liquefied H_2 boils at a very low temperature (-253°C).
4. H_2 gas does not conduct electricity.

Which of the following describe physical properties and which describe chemical properties of water?

1. Most, but not all, kinds of wood float in water.
2. Water has a remarkably high boiling point for a compound whose molecules consist of only three atoms, two of which are hydrogen.
3. Evaporation of the water in perspiration cools the skin.
4. A process called electrolysis can convert liquid water into hydrogen gas and oxygen gas.
5. Ice is less dense than liquid water.
6. Water is denser than gasoline.

Which of the following describe physical properties and which describe chemical properties of methane (the principal component of natural gas)?

1. Methane is lighter (less dense) than air.
2. Methane has a higher fuel value (energy produced per gram) than any other fossil fuel.
3. Methane can be liquefied for transport by ship if it is cooled to 109 K.
4. Liquefied methane is over 300 times denser than methane gas at its boiling point.
5. Leaking natural gas has caused explosions that destroyed peoples’ homes.
6. Methane is colorless and odorless.

Which of the following are examples of chemical properties of formaldehyde (CH_2O)?

1. It has a characteristic acrid smell.
2. It is soluble in water.
3. It burns in air.
4. It is a gas at room temperature.
5. It is colorless.
6. Formaldehyde is used to synthesize many other compounds.

Which of the following is an example of a physical property of silver (Ag)?

1. Silverware slowly tarnishes over time.
2. Tarnished silverware can be restored to a shiny metallic finish if placed in a boiling hot aqueous solution of baking soda that also contains aluminum foil.
3. Silver coins in pirate treasure turn black when left in the sea for a few centuries.
4. Silver sinks in seawater.
5. Silver is an excellent conductor of electricity.
6. Silver is soft for a metal, though not as soft as gold.

Which of the following can be separated by filtration? (a) sugar dissolved in coffee; (b) sand and water; (c) octane from the other components in gasoline; (d) alcohol dissolved in water; (e) water vapor from the other gases in humid air

Would filtration be a suitable way to separate dissolved proteins from blood plasma? Explain why or why not.

Examine Figure 1.12. In which physical state do particles have the greatest freedom of motion—solid, liquid, or gas? In which state do they have the least freedom of motion?

A pot of water on a stove is heated to a rapid boil. Identify the gas inside the bubbles that form in the boiling water.

A brief winter storm leaves a dusting of snow on the ground. During the sunny but very cold day after the storm, the snow disappears even though the air temperature never gets above freezing. If the snow didn't melt, where did it go?

What is in the space between the particles that make up a gas?

Can an extensive property be used to identify a substance? Explain why or why not.

Which of these properties of water are intensive and which are extensive?

1. The density of water at room temperature and pressure.
2. The temperature at which water freezes.
3. The mass of water in your body.
4. The mass of one molecule of water.
5. The rate at which water is flowing over Niagara Falls.

The Scientific Method: Starting Off with a Bang

Concept Review

What kinds of information are needed to formulate a hypothesis?

How does a hypothesis become a theory?

Is it possible to disprove a scientific hypothesis?

Is it possible to prove a theory?

Compare the meaning of the word *theory* as it is used in science with its use in normal conversation.

Why was the belief that matter consists of atoms considered a philosophy in ancient Greece, but a theory by the early 1800s?

Unit Conversions and Dimensional Analysis

Concept Review

Describe in general terms how the SI and USC systems of units differ.

Suggest two reasons why SI units are so widely used in science.

Problems

Note: The physical properties of the elements are listed in Appendix 3.

What is the mass of a magnesium block that measures 2.5 cm × 3.5 cm × 1.5 cm?

What is the mass of an osmium block that measures 6.5 cm × 9.0 cm × 3.25 cm? Do you think you could lift it with one hand?

Write the conversion factor(s) for each of the following unit conversions: (a) picoseconds (ps) to femtoseconds (fs); (b) kilograms (kg) to milligrams (mg); (c) the mass of a block of titanium in kilograms (kg) to its volume in cubic meters (m^3)

A single strand of natural silk may be as long as 4.0 km. What is this length in meters?

There are ten steps from the sidewalk up to the front door of a student's apartment. Each tread is 12.5 cm deep and 15.5 cm above the previous one. What is the distance diagonally from the bottom of the steps to the top in meters?

An Olympic-sized swimming pool is 50.00 m long and 25.0 m wide, and it must have a water depth of at least 2.0 m. What is the minimum volume of water in such a pool in cubic meters?

Boston Marathon To qualify to run in the 2019 Boston Marathon, a distance of 42.195 km, an 18-year-old woman had to have completed another marathon in 3 hours and 30 minutes or less. To qualify, what must this woman's average speed have been in meters per second?

Olympic Mile The length of a track race known as the "Olympic mile" is actually 1500. m. What percentage of a USC mile (5280. feet) is an Olympic mile?

If a wheelchair-marathon racer moving at 8.28 m/s expends energy at a rate of 665 Calories per hour, how much energy in Calories would be required to complete a marathon race (42.195 km) at this pace?

Nearest Star At a distance of 4.3 light-years, Proxima Centauri is the nearest star to our solar system. What is the distance to Proxima Centauri in kilometers?

What volume of gold would be equal in mass to a piece of copper with a volume of 125 cm^3?

A small hot-air balloon is filled with 1.00×10^6 L of air ($d = 1.20$ g/L). As the air in the balloon is heated, it expands to 1.09×10^6 L. What is the density of the heated air in the balloon?

What is the volume of 1.00 kg of mercury?

A student wonders whether a piece of jewelry is made of pure silver. She determines that its mass is 3.17 g. She then drops it into a 10 mL graduated cylinder partially filled with water and determines that its volume is 0.3 mL. Could the jewelry be made of pure silver?

The Density of Blood The average density of human blood is 1.06 g/mL. What is the mass of blood in an adult with a blood volume of 5.5 L? Express your answer in (a) grams and (b) ounces.

The Density of Earth Earth has a mass of 5.98×10^{24} kg and a volume of 1.08×10^{12} km^3. What is the average density of our planet in units of grams per cubic centimeter?

Evaluating and Expressing Experimental Results

Concept Review

How many suspect data points can be identified from a data set by using Grubbs' test?

Which confidence interval is the largest for a given *n* value: 50%, 90%, or 95%?

The concentration of ammonia in an aquarium tank is determined each day for a week. When calculating the variability in the results, which will be larger: (a) standard deviation; (b) 95% confidence interval? Explain your selection.

During the analysis of a data set, if an outlier could not be found at the 95% confidence level, (a) could there be an outlier at the 90% confidence level? (b) Could there be an outlier at the 99% confidence level?

Problems

Which of these measured values has the fewest number of significant figures? (a) 545; (b) 6.4×10^{-3}; (c) 6.50; (d) 1.346×10^2

Which of these uncertain values has the greatest number of significant figures? (a) 545; (b) 6.4×10^{-3}; (c) 6.50; (d) 1.346×10^2

Which of these uncertain values has the fewest number of significant figures? (a) 1/545; (b) $1/(6.4 \times 10^{-3})$; (c) 1/6.50; (d) $1/(1.346 \times 10^2)$

Which of these uncertain values has the greatest number of significant figures? (a) 1/545; (b) $1/(6.4 \times 10^{-3})$; (c) 1/6.50; (d) $1/(1.346 \times 10^2)$

Which of these uncertain values has four significant figures? (a) 0.0592; (b) 0.08206; (c) 8.314; (d) 5420; (e) 5.4×10^3

Which of these uncertain values has only three significant figures? (a) 7.02; (b) 6.452; (c) 6.02×10^{23}; (d) 302; (e) 12.77

Perform each of the following calculations, and express the answer with the correct number of significant figures (only the highlighted values are exact):

$0.6274\ 1. \times 1.00 \times 10^3/[2.205 \times (2.54)^3] =$
$6 \times 10\ 2.^{-18} \times (1.00 \times 10^3) \times 12 =$
$(4.00\ 3. \times 58.69)/(6.02 \times 10^{23} \times 6.84) =$
$[(26.0\ 4. \times 60.0)/43.53]/(1.000 \times 10^4) =$

Perform each of the following calculations, and express the answer with the correct number of significant figures (only the highlighted values are exact):

$[(12 \times 1.\ 60.0) + 55.3]/(5.000 \times 10^3) =$
$(2.00\ 2. \times 183.9)/[(6.02 \times 10^{23}) \times (1.61 \times 10^{-8})^3] =$
$0.816\ 1\ 3./[2.205 \times (2.54)^3] =$
$(9.00\ 4. \times 60.0) + (50.0 \times 60.0) + (3.00 \times 10^1) =$

Perform each of the following calculations, and express the answer with the correct number of significant figures and units (only the highlighted values are exact):

1. $[0.066\ \text{cm}^3 \times (6.67 \times 10^5\ \text{g/cm}^3)]/(2.838 - 2.211)\ \text{mL} =$
2. $(7.6\ \text{g} + 7.8\ \text{g} + 8.1\ \text{g} + 7.9\ \text{g} + 8.0\ \text{g})/5 =$
3. $(273 + 37.4)\ \text{K} \times (1.3806 \times 10^{-23}\ \text{J/K}) =$

$$\sqrt{\frac{3\left(\frac{8.314\ \text{kg}\cdot\text{m}^2}{\text{s}^2\cdot\text{mol}\cdot\text{K}}\right)(273.15\ \text{K})}{0.0320\ \frac{\text{kg}}{\text{mol}}}} =$$

Perform each of the following calculations, and express the answer with the correct number of significant figures and units (only the highlighted values are exact):

1. $(43\ \text{mg} + 38\ \text{mg} + 39\ \text{mg} + 37\ \text{mg} + 40\ \text{mg} + 41\ \text{mg})/6 =$

$$(364.5\ \text{nm})\left(\frac{3^2}{3^2 - 2^2}\right) =$$

$$(2.998 \times 10^8\ \text{m/s})/[(656\ \text{nm}) \times \left(\frac{10^{-9}\ \text{m}}{1\ \text{nm}}\right)] =$$

$(6.626 \times 10^{-34}\ \text{kg}\cdot\text{m}^2/\text{s})/[(9.109 \times 10^{-31}\ \text{kg}) \times (2.998 \times 10^8\ \text{m/s})] =$

The widths of copper lines in printed circuit boards must be close to a design value. Three manufacturers were asked to prepare circuit boards with copper lines that are 0.500 μm (micrometers) wide (1 μm = 1×10^{-6} m). Each manufacturer's quality control department reported the following line widths on five sample circuit boards (given in micrometers):

Widths of Copper Lines (μm)

Manufacturer 1	Manufacturer 2	Manufacturer 3
0.512	0.514	0.500
0.508	0.513	0.501
0.516	0.514	0.502
0.504	0.514	0.502
0.513	0.512	0.501

1. What is the mean and standard deviation of the data provided by each manufacturer?
2. For which of the three sets of data does the 95% confidence interval include 0.500 μm?
3. Which of the data sets fit the description "precise and accurate," and which is "precise but not accurate"?

Diabetes Test Glucose concentrations in the blood above 110 mg/dL can be an early indication of several medical conditions, including diabetes. Suppose analyses of a series of blood samples from a patient at risk of diabetes produce these results: 106, 99, 109, 108, and 105 mg/dL.

1. What are the mean and the standard deviation of the data?
2. Patients with blood glucose levels above 120 mg/dL are considered diabetic. Is this value within the 95% confidence interval of these data?

Use Grubbs' test to decide whether the value 3.41 should be considered an outlier in the following data set from analyses of portions of the same sample conducted by six groups of students: 3.15, 3.03, 3.09, 3.11, 3.12, and 3.41.

Use Grubbs' test to decide whether any one of the values in this set of replicate measurements should be considered an outlier: 61, 75, 64, 65, 64, and 66.

Testing a Theory: The Big Bang Revisited

Concept Review

What is meant by an *absolute* temperature scale?

Can a temperature in °C ever have the same value in °F?

Problems

Silver and gold melt at 962°C and 1064°C, respectively. Convert these two temperatures to the Kelvin scale.

Radiator Coolant The coolant in an automobile radiator freezes at −39°C and boils at 110°C. What are these temperatures on the Fahrenheit scale?

Critical Temperature The discovery of new “high temperature” superconducting materials in the mid-1980s spurred a race to prepare the material with the highest superconducting temperature. The *critical temperatures* (T_c)—the temperatures at which the material becomes superconducting—of three such materials are −93.0 K, −250.0°C, and −231.1°F. Convert these temperatures into a single temperature scale, and determine which superconductor has the highest T_c value.

As air is cooled, which gas condenses first: N_2, He, or H_2O?

Liquid helium boils at 4.2 K. What is the boiling point of He in °C?

Liquid hydrogen boils at −253°C. What is the boiling point of H_2 on the Kelvin scale?

A person has a fever of 102.5°F. What is this temperature in °C?

Physiological temperature, or body temperature, is 37.0°C. What is this temperature in °F?

Record Low The lowest temperature measured on Earth is −128.6°F, recorded at Vostok, Antarctica, in July 1983. What is this temperature on the Celsius and Kelvin scales?

Record High The highest temperature ever recorded in the United States is 134°F at Greenland Ranch, Death Valley, CA, on July 13, 1913. What is this temperature on the Celsius and Kelvin scales?

Additional Problems

Sodium chloride (NaCl) contains 1.54 g of Cl^- ions for every 1.00 g of Na^+ ions. Which of the following mixtures would react to produce sodium chloride with no sodium or chlorine left over?

1. 11.0 g of sodium and 17.0 g of chlorine
2. 6.5 g of sodium and 10.0 g of chlorine
3. 6.5 g of sodium and 12.0 g of chlorine
4. 6.5 g of sodium and 8.0 g of chlorine

Your laboratory instructor has given you two shiny, light gray metal cylinders. Your assignment is to determine which one is made of aluminum ($d = 2.699$ g/mL) and which one is made of titanium ($d = 4.54$ g/mL). The mass of each cylinder was determined on a scale to five significant figures. The volume was determined by immersing the cylinders in a graduated cylinder as shown in Figure P1.92. The initial volume of water was 25.0 mL in each graduated cylinder. The following data were collected:

	Mass (g)	Diameter (cm)	Height (cm)
Cylinder A	[illegible]	[illegible]	[illegible]
Cylinder B	[illegible]	[illegible]	[illegible]

1. Calculate the volume of each cylinder by using the dimensions of the cylinder only.
2. Calculate the volume from the water displacement method.
3. Which volume measurement allows for the greater number of significant figures in the calculated densities?
4. Express the density of each cylinder to the appropriate number of significant figures.

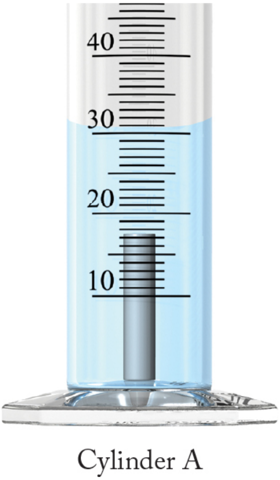


FIGURE P1.92

Manufacturers of trail mix must control the distribution of the items in their products. Deviations of more than 2% outside specifications cause supply problems and downtime in the factory. A favorite trail mix is designed to contain 67% peanuts and 33% raisins. Bags of trail mix were sampled from the assembly line on different days. The bags were opened, and the contents counted, with the following results:

Bag	Peanuts	Raisins
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]

1. Calculate the mean and standard deviation in the percentage of peanuts and percentage of raisins in the four samples.
2. Do the 90% confidence intervals for these percentages include the target composition values: 67% peanuts and 33% raisins?

Gasoline and water do not mix. Regular grade (87 octane) gasoline has a lower density (0.73 g/mL) than water (1.00 g/mL).

A 100 mL graduated cylinder with an inside diameter of 3.2 cm contains 34.0 g of gasoline and 34.0 g of water. What is the combined height of the two liquid layers in the cylinder? The volume of a cylinder is $\pi r^2 h$, where r is the radius and h is the height.

At a natural history museum, a child was heard stating that dinosaur bones on display at the museum were 68,000,002 years old. When asked about this unusual age value, the child explained that during a visit two years earlier a tour guide had said the bones were 68 million years old. How would you explain to the child the meaning (and certainty) of a value such as 68 million years?

Ms. Goodson's geology classes are popular because of their end-of-the-year field trips. Some last several days, but all involve exactly eight hours of hiking per day. On one three-day trip the class's average hiking speeds were 1.6 mi/h, 1.4 mi/h, and 1.7 mi/h each day. What was the length of their trip in miles and kilometers?

Toothpaste Chemistry Many popular brands of toothpaste contain about 1.00 mg of fluoride per gram of toothpaste. The fluoride compound that is most often used in toothpaste is sodium fluoride, NaF, which is 45% fluoride by mass. How many milligrams of NaF are in a 178-gram tube of toothpaste?

Test for HIV Tests called ELISAs (enzyme-linked immunosorbent assays) detect and quantify substances such as HIV antibodies in biological samples. A "sandwich" assay traps the HIV antibody between two other molecules. The trapping event causes a detector molecule to change color. To make a sandwich assay for HIV, you need the following components: one plate to which the molecules are attached; a 0.550-mg sample of the recognition molecule that "recognizes" the HIV antibody; 1.200 mg of the capture molecule that "captures" the HIV antibody in a sandwich; and 0.450 mg of the detector molecule that produces a visible color when the HIV antibody is captured. You need to make 96 plates for an assay. You are given the following quantities of material: 100.00 mg of the recognition molecule; 100.00 mg of the capture molecule; and 50.00 mg of the detector molecule.

1. Do you have sufficient material to make 96 plates?
2. If you do, how much of each material is left after 96 sandwich assays are assembled? If you do not have sufficient material to make 96 assays, how many assays can you assemble?

Vitamin C Some people believe that large doses of vitamin C can cure the common cold. One commercial over-the-counter product consists of 500.0-mg tablets that are 20% by mass vitamin C. How many tablets are needed for a 1.00-g dose of vitamin C?

Patient Data Measurements of a patient's temperature are routinely done several times a day in hospitals. Digital thermometers are used, and it is important to evaluate new thermometers and select the best ones. The accuracy of these thermometers is checked by immersing them in liquids of known temperature. Such liquids include an ice–water mixture at 0.0°C and boiling water at 100.0°C at exactly 1 atmosphere pressure (boiling point varies with atmospheric pressure). Suppose the data shown in the following table were obtained on three available thermometers and you were asked to choose the "best" one of the three. Which would you choose? Explain your choice.

Thermometer	Measured Temperature of Ice Water, °C	Measured Temperature of Boiling Water, °C
A	0.8	99.9
B	0.2	99.8
C	0.3	100.3

Glossary

matter

anything that has mass and occupies space.

pure substance

matter that has a constant composition and cannot be broken down into simpler matter by any physical process.

element

a pure substance that cannot be separated into simpler substances.

compound

a pure substance that is composed of two or more elements combined in fixed proportions and that can be broken down into those elements by a chemical reaction.

mixture

a combination of pure substances in variable proportions in which the individual substances retain their chemical identities and can be separated from one another by a physical process.

homogeneous mixture

a mixture in which the components are distributed uniformly throughout and have no visible boundaries or regions.

solution

another name for a homogeneous mixture; solutions are often liquids, but they may also be solids or gases.

heterogeneous mixture

a mixture in which the components are not distributed uniformly, so that the mixture contains distinct regions of different compositions.

atom

the smallest particle of an element that retains the element’s properties.

molecule

a collection of atoms chemically bonded together in characteristic proportions.

chemical bond

a force that holds two atoms or ions in a compound together.

ion

a particle consisting of one or more atoms that has a net positive or negative electrical charge.

chemical formula

notation for representing elements and compounds; consists of the symbols of the constituent elements, each followed by subscripts that identify the number of atoms of each element present.

chemical equation

notation in which chemical formulas express the identities and their coefficients express the quantities of substances involved in a chemical reaction.

chemical reaction

the transformation of one or more substances into different substances.

chemical reaction

the transformation of one or more substances into different substances.

physical process

a transformation of a sample of matter, such as a change in its physical state, that does not alter the chemical identity of any substance in the sample.

physical property

a property of a substance that can be observed without changing it into another substance.

chemical property

a property of a substance that can be observed only by reacting it to form another substance.

solid

a form of matter that has a definite volume and shape.

liquid

a form of matter that occupies a definite volume but flows to assume the shape of its container.

gas

a form of matter that has neither definite volume nor shape and that expands to fill its container; also called *vapor*.

scientific method

an approach to acquiring knowledge based on observation of phenomena, development of a testable hypothesis, and additional experiments that test the validity of the hypothesis.

hypothesis

a tentative and testable explanation for an observation or a series of observations.

scientific theory (model)

a general explanation of a widely observed phenomenon that has been extensively tested and validated.

scientific theory (model)

a general explanation of a widely observed phenomenon that has been extensively tested and validated.

conversion factor

a fraction in which the numerator is equivalent to the denominator, even though they are expressed in different units, making the value of the fraction one.

significant figures

all the certain digits in a measured value plus one estimated digit; the greater the number of significant figures, the greater the certainty with which the value is known.

precision

agreement between the results of multiple measurements that were carried out in the same way.

accuracy

agreement between one or more experimental values and the true (or accepted) value.

confidence interval

a range of values that has a specified probability of containing the true value of a measurement.

outlier

a data point that is distant from the other observations.

Grubbs' test

a statistical test used to detect an outlier in a set of data.

standard deviation (s)

a measure of the amount of variation, or dispersion, in a set of related values. The lowercase Greek letter sigma (σ) is also used as the symbol for standard deviation.

mean (arithmetic mean, $\bar{x}$)

an average calculated by summing a set of related values and dividing the sum by the number of values in the set.

BABY TEETH A young child proudly holds a tooth that has just fallen out. A landmark study involving baby teeth showed that children living hundreds, even thousands, of miles away from atomic bomb test sites in the 1950s were exposed to and accumulated radioactive nuclides (radionuclides) produced during the tests.

Atoms, Ions, and Molecules

Matter Starts Here

PARTICULATE REVIEW

Elements versus Compounds

In Chapter 2 we begin to explore the structure of atoms and to discuss why they form the molecules and ions they do. All pure substances can be classified as either elements or compounds.

- Write the chemical formula for each substance shown here.
- Identify each substance as either an element or a compound.

  (Review Section 1.2 if you need help.)

(Answers to Particulate Review questions are in the back of the book.)

PARTICULATE PREVIEW

Ionic versus Molecular Compounds

Some compounds, such as NaCl, are composed of negatively and positively charged ions. Others are composed of molecules that contain the atoms of different elements held together by shared pairs of electrons called covalent bonds. As you read Chapter 2, look for ideas that will help you answer these questions:

- Which of the compounds represented here consist of different atoms bonded together and which consist of different ions bonded together?
- Which compound(s) are molecular? Which compound(s) are ionic?
- What features of these particulate images helped you make these distinctions?

Learning Outcomes

- LO1 Explain how the experiments of Thomson, Millikan, and Rutherford contributed to our understanding of atomic structure
- LO2 Use the symbol of a nuclide to describe the composition of its nucleus: the number of protons, the number of neutrons, and the total number of nucleons

  Sample Exercises 2.1, 2.2

- LO3 Relate the natural abundance values of the stable isotopes of an element to the element's average atomic masses

  Sample Exercise 2.3

- LO4 Describe the development of the periodic table and use it to predict the chemical properties of elements

  Sample Exercise 2.4

- LO5 Distinguish between ionic and molecular compounds and explain how the law of multiple proportions is connected to the formulas of common molecular compounds

Sample Exercises 2.5 and 2.6

- LO6 Relate the names and formulas of common molecular and ionic compounds

Sample Exercises 2.7, 2.8, 2.9, 2.10, 2.11

- LO7 Distinguish between organic compounds and other molecular compounds and among the classes of organic compounds
- LO8 Describe the origin of the elements

FIGURE 2.1 (a) Teeth collected in the Baby Tooth Survey and the information card used to record important data regarding the teeth; (b) a button given to children who donated their teeth.

2.1 Atoms in Baby Teeth

In 1958 a group of physicians, scientists, and other concerned citizens in St. Louis, MO, began a project that would last for more than a decade—and alter the course of world events. Their project was known as the Baby Tooth Survey (**Figure 2.1**). It would eventually involve the analyses of more than 300,000 baby teeth collected from dentists' offices and young families in and around St. Louis, and it would inspire similar studies in other regions of the United States, Canada, and Europe.

The founders of the Baby Tooth Survey were worried about the effects of fallout from the hundreds of tests of nuclear weapons that had taken place in Earth's atmosphere since the end of World War II. They knew that the products of these tests included atoms exhibiting radioactivity, the spontaneous emission of high-energy radiation and particles. They also knew that radioactive fallout posed serious risks to human health. Their goal was to determine the impact of atmospheric nuclear testing on everyday citizens by measuring the concentration of strontium-90, a radioactive form of the element strontium that does not occur in nature, in the teeth of young children.

The Baby Tooth Survey focused on strontium-90 because of its radioactivity *and* because of its chemistry. Look at the periodic table of the elements on the inside front cover of this book and find Sr, the symbol for strontium. It is just below the one for calcium, Ca. Elements in the same column of the periodic table have similar chemical properties. Sometimes they can even substitute for each other in the compounds they form. This is the case for Sr^{2+} and Ca^{2+} ions, which have the same $2+$ charge, as do all the ions formed by the elements in the second column. Thus, ions of strontium-90 can accumulate in the rapidly growing, calcium-rich teeth and bones of young children. The baby teeth lost by the children of St. Louis provided convenient, noninvasive biomarkers of their exposure to radioactive fallout.

The results of the survey grabbed worldwide attention. They showed that radioactivity from strontium-90 in the teeth of children born in the 1950s and 60s was 100 times greater than in baby teeth that formed before the dawn of the nuclear age in 1945, and that the amount of strontium-90 correlated with the frequency of atomic bomb testing. Early results from the Baby Tooth Survey, coupled with other data on the incidence of childhood cancer, helped persuade U.S. President John F. Kennedy to negotiate a treaty with the Soviet Union and other nuclear powers to end atmospheric testing of nuclear weapons in 1963.

In this chapter we explore the structure and composition of atoms, including the subatomic particles that cause radioactivity and the subatomic particles that are responsible for ionic charges. We begin with the discoveries made in the late 19th and early 20th centuries that led to our understanding of atomic structure and that helped explain the chemical properties of the elements, including their tendencies to form ions. We end the chapter by exploring how hydrogen and helium formed just after the Big Bang, and we explain how other elements have continued to form both in the cores of giant stars and in celestial explosions called supernovas. These are the atoms that make up the entire universe, including all the matter in our world and in our bodies.

Glossary

radioactivity

the spontaneous emission of high-energy radiation and particles by materials.

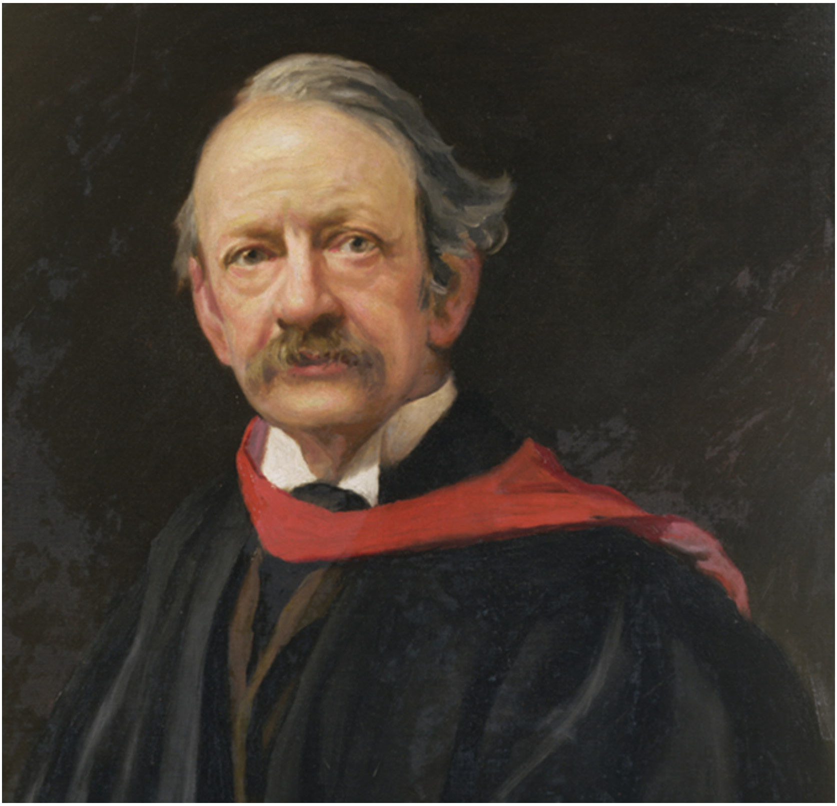

FIGURE 2.2 J. J. Thomson (1856–1940) discovered electrons in 1897 by using a cathode-ray tube, but he was not sure where electrons fit into the structure of atoms.

(c) The modern view of Rutherford's model of the gold atom includes electrons that surround (d) the nucleus, which is about 1/10,000 the overall size of the atom. The scales have units of picometers (1 pm $= 10^{-12}$ m). The nucleus would be too small to see if drawn to scale in (c) and (d). If an atom were the size of the Rose Bowl (an oval stadium about 212 m across in the narrow direction), the nucleus of the atom would be the size of a dime at midfield.

2.2 Discovering the Structure of Atoms

By the end of the 19th century, many scientists had realized that atoms were not the smallest particles of matter, but rather consisted of even smaller *subatomic* particles. This realization came in part from the research of the British scientist Joseph John (J. J.) Thomson (1856–1940; **Figure 2.2**). However, not even Thomson himself recognized the fundamental importance of his work for the future of science and technology.

Electrons

Figure 2.3 shows the apparatus Thomson used in his experiments. It is called a cathode-ray tube (CRT), and it consists of a glass tube from which most of the air has been removed. Electrodes within the tube are attached to the poles of a high-voltage power supply. One electrode, called the cathode, is connected to the negative terminal of the power supply, whereas the other electrode, called the anode, is connected to the positive terminal. When these connections are made, electricity passes through the glass tube in the form of a beam of cathode rays emitted by the cathode. Cathode rays are invisible to the naked eye, but when the end of the CRT opposite the cathode is coated with a phosphorescent material, a glowing spot appears where the beam hits it.

Thomson found that cathode-ray beams were deflected by magnetic fields (Figure 2.3a) and by electric fields (Figure 2.3b). The directions of these deflections established that cathode rays were not rays of energy, but rather consisted of negatively charged particles. By adjusting the strengths of the electric and magnetic fields, Thomson was able to balance out the deflections (Figure 2.3c). From the strengths of the two opposing fields, he calculated the mass-to-charge (m/e) ratio of the particles. Thomson and others observed that these particles always behaved the same way and always had the same mass-to-charge ratio, no matter what cathode material was used. This observation established that the particles in the cathode rays, which are now known as electrons, were fundamental particles present in all forms of matter.

Millikan Oil-Drop Experiment

In 1909 the American physicist Robert Millikan (1868–1953) advanced Thomson's work by quantifying the charge on the electron. Thomson had already calculated the mass-to-charge ratio of the electron; so, if Millikan could measure the charge of the electron, then he could determine its mass. **Figure 2.4** shows the components of Millikan's experimental setup. In it, high-energy X-rays remove electrons from molecules found in air in the lower of two connected chambers. As oil drops fall from the upper chamber into the lower one, they collide with the electrons removed from the air molecules and pick up their negative charge. Millikan measured the mass of the drops in the absence of an electric field, when their rate of fall was governed by gravity. He then repeated the experiment in the presence of an electric field, adjusting the field strength to make the drops fall at different rates and even suspending some of them in midair. From the strength of the electric field and the rate of fall, he calculated the charge on a drop. By measuring the charges on hundreds of drops, Millikan determined that the charge on each drop was a whole-number multiple of a minimum charge. He concluded that this minimum charge had to be the charge on one electron. Millikan's value was within 1% of the modern value: 1.602×10^{-19} C. (The coulomb, abbreviated C, is the SI unit for electric charge.) Knowing Thomson's value of m/e for the electron, Millikan calculated the mass of the electron: 9.109×10^{-28} g.

The discovery of the electron raised the possibility of other subatomic particles. Scientists in the 1890s knew that matter was electrically neutral, but they did not know how the electrons and the positive charges were arranged at the atomic level. Thomson proposed a *plum-pudding model* in which the atom was a diffuse sphere of positive charge with negatively charged electrons embedded in the sphere, like raisins in an English plum pudding (or blueberries in a muffin; **Figure 2.5**). Thomson's model did not last long. Its demise was linked to another scientific discovery in the 1890s: radioactivity.

CONCEPT TEST

Why did Thomson's discovery of the electron lead others to propose that a positive particle might exist within the atom?

(Answers to Concept Tests are in the back of the book.)

Radioactivity

In 1896 the French physicist Henri Becquerel (1852–1908) discovered that a mineral then called *pitchblende* (now known as *uraninite*; **Figure 2.6**), the principal natural source of the element uranium, produces radiation that can be detected on photographic plates. Becquerel and his contemporaries initially thought that this radiation consisted of the X-rays that had just been discovered by the German scientist Wilhelm Conrad Röntgen (1845–1923).[1] However, additional experiments by Becquerel, by the French wife-and-husband team of Marie Skłodowska Curie (1867–1934; **Figure 2.7**) and Pierre Curie (1859–1906), and by the British scientist Ernest Rutherford (1871–1937) showed that this radiation contained particles as well as rays. The scientists had discovered radioactivity.

In studying the particles emitted by pitchblende, Rutherford found that one type, which he named beta (β) particles, penetrated solid materials better than the second type, which he named alpha (α) particles. The degree to which β particles were deflected in a magnetic field allowed their mass-to-charge ratio to be calculated, and the results matched the electron mass-to-charge ratio determined by J. J. Thomson. These data established that β particles were simply high-energy electrons.

Rutherford discovered that α particles were deflected by an electric field or a magnetic field in the opposite direction from β particles. He concluded, therefore, that α particles were positively charged. The β particle (electron) was assigned a relative charge of $1-$, whereas the corresponding charge of an α particle was $2+$. In addition, α particles had nearly the same mass as an atom of helium, meaning they were over 10^3 times more massive than β particles.

The experiment that disproved Thomson's plum-pudding model was directed by Rutherford and carried out by two of his students at Manchester University: Hans Geiger (1882–1945; for whom the Geiger counter was named) and Ernest Marsden (1889–1970). Geiger and Marsden bombarded a thin foil of gold with a beam of α particles emitted from a radioactive source (**Figure 2.8a**). They then measured how many particles were deflected and to what extent. Rutherford's hypothesis was that if Thomson's model were correct, most of the α particles would pass straight through the diffuse positive spheres of gold atoms (each atom a "pudding" like the one shown in Figure 2.5), but a few of the particles would interact with the electrons (the "raisins") embedded in these spheres and be deflected slightly (**Figure 2.8b**).

Instead, Geiger and Marsden observed something quite unexpected. Although most of the α particles did indeed pass directly through the gold, about 1 in every 8000 particles was deflected from the foil through an average angle of 90 degrees. Even more surprising, a very few (about 1 out of 100,000) bounced back in the direction from which the α particles came (**Figure 2.8c**). Rutherford described his amazement at the result: "It is about as incredible as if you had fired a 15-inch shell at a piece of tissue paper and it came back and hit you." (The largest guns on British battleships in those days fired 15-inch-diameter shells.)

Rutherford Experiment

The results of the gold-foil experiments ended the short life of the plum-pudding model because the model could not account for the large angles of deflection. Rutherford concluded that those deflections occurred because the α particles occasionally encountered small, yet massive, regions of highly positive charge. Rutherford determined that the region of positive charge was only about 1/10,000 of the overall size of a gold atom. His model of the atom became the basis for our current understanding of atomic structure. It incorporates the assumption that an atom consists of a massive, but tiny, positively charged nucleus surrounded by a diffuse cloud of negatively charged electrons.

Protons and Neutrons

In the decade following the gold-foil experiments, Rutherford and others observed that bombarding elements with α particles could change, or *transmute*, these elements into other elements. They also discovered that hydrogen nuclei were sometimes produced during transmutation reactions. By 1920, agreement was growing that hydrogen nuclei, which Rutherford called protons (from the Greek *protos*, meaning “first”), were part of all nuclei. For example, to account for both the mass and charge of an α particle, Rutherford assumed it was made of four protons, two of which had combined with two electrons to form two electrically neutral particles that he called neutrons. Repeated attempts to produce neutrons by neutralizing protons with electrons were unsuccessful. In 1932, however, one of Rutherford’s students, James Chadwick (1891–1974), discovered and characterized neutrons. With the discovery of neutrons, the current model of atomic structure was complete, as illustrated for the gold atom in **Figure 2.9**.

Table 2.1 summarizes the properties of neutrons, protons, and electrons. For convenience, the masses of these tiny particles are expressed in unified atomic mass units (u). These units are also called daltons (Da). One u is exactly 1/12 the mass of a carbon atom that has six protons and six neutrons in its nucleus. As you can see from the data in Table 2.1, the masses of the neutron and the proton are nearly the same and very close to 1 u. If you compare the u values in the table with the masses of the particles in grams, you will see that these particles are tiny indeed: 1 u is only 1.66054×10^{-24} g.

The unit name “dalton” honors the English chemist John Dalton (1766–1844), who published the first table of atomic masses in 1803. Dalton is also remembered for his *atomic theory*, published in 1808, in which he proposed that:

1. Each element consists of tiny, indestructible particles called atoms.
2. All atoms of an element are identical, and they are different from the atoms of any other element.
3. Atoms combine in simple ratios of whole numbers to form compounds. (We explore this point further in Section 2.6.)
4. Atoms are not changed, created, or destroyed in chemical reactions; a reaction only changes the arrangement in which the atoms are bound.

TABLE 2.1 Properties of Subatomic Particles

[illegible]	[illegible]	
[illegible]	[illegible] Atomic Mass Units (u)	
$^{1}_{0}n$	[illegible] $\times 10^{-24}$	
$^{1}_{1}p$	[illegible] $\times 10^{[illegible]}$	
$^{0}_{-1}e$	[illegible] $\times 10^{[illegible]}$	< 0

Today, we know that Dalton's descriptions of atoms were not entirely correct: In Section 2.3 we reveal that all atoms of an element are *not quite* identical, and in Section 2.9 we describe how atoms are not indestructible and *can* change in nuclear reactions (although they never change in chemical reactions). But Dalton's atomic theory was revolutionary for its time, and it set the theoretical foundations for the chemistry that followed, including the experiments of Thomson, Millikan, and Rutherford.

Glossary

cathode rays	streams of electrons emitted by the cathode in a partially evacuated tube.
electron	a subatomic particle that has a negative charge and little mass.
beta (β) particle	

a radioactive emission equivalent to a high-energy electron.

alpha (α) particle

a radioactive emission with a charge of 2+ and a mass equivalent to that of a helium nucleus.

nucleus

the positively charged center of an atom that contains nearly all the atom’s mass.

proton

a positively charged subatomic particle present in the nucleus of an atom.

neutron

an electrically neutral (uncharged) subatomic particle found in the nucleus of an atom.

unified atomic mass units (u)

the unit used to express the relative masses of atoms and subatomic particles; it is exactly 1/12 the mass of one atom of carbon with six protons and six neutrons in its nucleus.

dalton (Da)

a unit of mass identical to 1 unified atomic mass unit (u); thus, 1 Da = 1 u.

Endnotes

- Röntgen discovered X-rays in experiments with a cathode-ray tube much like the apparatus used by J. J. Thomson. After encasing the tube in a black carton, Röntgen discovered that invisible rays escaped the carton and were detected by a photographic plate. Because he knew so little about these rays, he called them X-rays. Return to reference 1

- The *coulomb* (C) is the SI unit of electric charge. When a current of 1 ampere (see Table 1.2) passes through a conductor for 1 second, the quantity of electric charge that moves past any point in the conductor is 1 C.Return to reference a

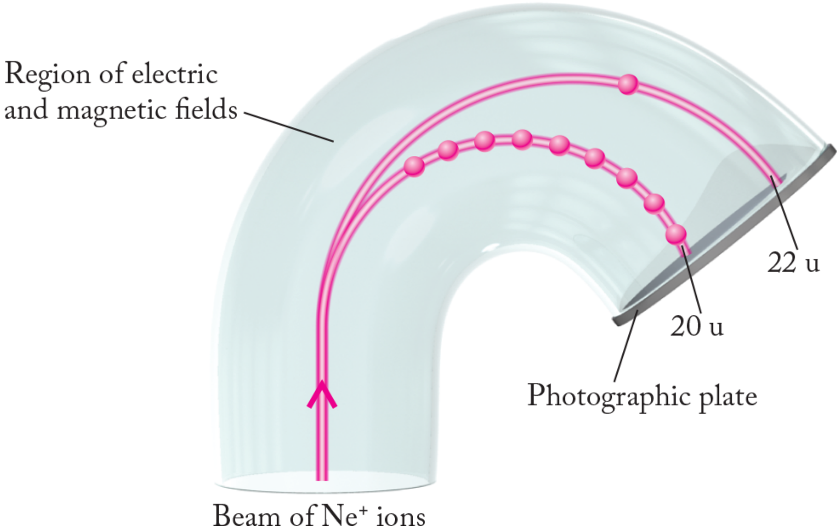

FIGURE 2.10 Aston's positive-ray analyzer. A beam of positively charged ions of neon gas is passed through a focusing slit into a region of electric and magnetic fields. The ions are separated according to mass: those with a mass of 20 u—90% of the sample—hit the detector at one spot, and those with a mass of 22 u—the remaining 10%—hit the detector at a different spot. Aston's positive-ray analyzer was the forerunner of the modern mass spectrometer.

$^{A}_{Z}\text{X}$ $^{20}_{10}\text{Ne}$ $^{22}_{10}\text{Ne}$

$^{87}_{38}\text{X}$ $^{90}_{40}\text{X}$ $^{234}_{90}\text{X}$

2.3 Isotopes

While Thomson investigated the properties of cathode rays in 1897, other scientists designed and built devices to produce beams of *positively* charged particles. One of Thomson's former students, Francis W. Aston (1877–1945), built modified cathode-ray tubes that were evacuated except for small quantities of *fill gases* such as neon. With these tubes he detected conventional beams of cathode rays, but he also detected secondary beams of positively charged particles. Charge was not the only thing different about the particles in these secondary beams. Whereas cathode rays are streams of electrons that all have the same mass and charge regardless of the cathode material or fill gas, the masses of the particles composing Aston's positive rays did depend on the identity of the fill gas. Aston's positively charged particles were not individual protons, but rather atoms of the fill gas that had lost electrons to form positively charged ions.

Aston used his positive-ray analyzer (**Figure 2.10**) to pass positively charged beams of particles through a magnetic field. Each particle in the beam was deflected along a path determined by the particle's mass: the greater the mass, the smaller the deflection. Using the purest sample of neon gas available, Aston determined that most of the particles had a mass of 20 u, but about 1 in 10 had a mass of 22 u.

Since the time of John Dalton, scientists had believed that each element was composed of identical atoms, each having the same mass. Aston's research contradicted this long-held idea. To explain his data, Aston proposed that neon consists of two kinds of atoms, or isotopes. Both isotopes of neon had the same number of protons (10) in the nucleus, but one isotope had 10 neutrons in its nucleus, giving it a mass of 20 u, whereas the other isotope had 12 neutrons in its nucleus, giving it a mass of 22 u.

Aston's work showed that each element is in fact composed of atoms each having the *same number of protons* in its nucleus, but not necessarily the same number of neutrons, and therefore not necessarily the same mass. The number of protons is called the atomic number (Z) of an atom and identifies it as an atom of a particular element. For example, all atoms of neon have 10 protons in each of their nuclei. The total number of nucleons (neutrons and protons) in the nucleus of an atom defines its mass number (A). Thus, isotopes of a given element all have the *same atomic number*, Z, but *different mass numbers*, A. A neutral atom has the same number of electrons as protons in its nucleus. The modern periodic table of the elements (inside the front cover of this book) displays the 118 known elements in order of atomic number.

An atom with a specific combination of neutrons and protons is called a nuclide. The general symbol for identifying a nuclide is

where X represents the one- or two-letter symbol for the element. For example, the two isotopes of neon identified by Aston have the symbols:

Because Z and X provide the same information—each by itself identifies the element—the subscript Z is frequently omitted. The isotope symbol is then simply written as ${}^{A}\mathrm{X}$ (e.g., ${}^{20}\mathrm{Ne}$ and ${}^{22}\mathrm{Ne}$ for Aston's isotopes). This same information—mass number and element name—may also be spelled out. For example, the names of the two isotopes of neon that Aston discovered may be written as neon-20 and neon-22.

CONCEPT TEST

The radioactive atoms measured in the Baby Tooth Survey were strontium-90. Only one of the nuclides below is an isotope of strontium. Which one is it and why?

(Answers to Concept Tests are in the back of the book.)

SAMPLE EXERCISE 2.1 Writing Nuclide Symbols LO2

Write symbols in the form ${}^{A}_{Z}\mathrm{X}$ for the nuclides that have (a) 6 protons and 6 neutrons, (b) 11 protons and 12 neutrons, and (c) 92 protons and 143 neutrons.

Collect, Organize, and Analyze We know the number of protons and neutrons in the nucleus of each nuclide. We need to write symbols in the ${}^{A}_{Z}\mathrm{X}$ form, where Z is the atomic number, A is the mass number, and X is the symbol of the element. The number of protons in the nucleus of an atom defines its atomic number (Z) and defines which element it is (X). The sum of the nucleons (protons plus neutrons) is the mass number (*A*).

Solve

1. This nuclide has six protons, so $Z = 6$. It must be an isotope of carbon. Six protons plus six neutrons give the isotope a mass number of 12, which makes it carbon-12, ${}^{12}_{6}\mathrm{C}$.
2. This nuclide has 11 protons, which means $Z = 11$, so it must be an isotope of sodium. Eleven protons and 12 neutrons give the isotope a mass number of 23, so the isotope is sodium-23, ${}^{23}_{11}\mathrm{Na}$.
3. This nuclide has 92 protons, so $Z = 92$, which makes it an isotope of uranium. The mass number is $92 + 143 = 235$. This isotope is uranium-235, ${}^{235}_{92}\mathrm{U}$.

Think About It In working through this exercise, did you use the periodic table of the elements? Once you identify the number of protons in a nucleus (its atomic number), finding a symbol and identifying the element it represents is straightforward because the elements in the periodic table are arranged in order of increasing atomic number.

Practice Exercise Use the format *A*X to write the symbols of the nuclides having (a) 26 protons and 30 neutrons, (b) 7 protons and 8 neutrons, (c) 17 protons and 20 neutrons, and (d) 19 protons and 20 neutrons.

(Answers to Practice Exercises are in the back of the book.)

SAMPLE EXERCISE 2.2 Determining the Number of Neutrons in a Nuclide LO2

How many neutrons are in each of the following nuclides: (a) ^{14}N; (b) ^{32}P; (c) ^{157}Gd?

Collect, Organize, and Analyze We are given the symbols of three nuclides and asked to determine the number of neutrons in each of their nuclei. We know the value of Z from the element's symbol and we know the value of A from its superscripted number. Subtracting Z from A gives us the number of neutrons.

Solve

1. ^{14}N is a nuclide of nitrogen, whose atoms each have seven protons. The number of neutrons is $A - Z = 14 - 7 = 7$.
2. ^{32}P is a nuclide of phosphorus ($Z = 15$) with 32 nucleons per nucleus. The number of neutrons is $32 - 15 = 17$.
3. ^{157}Gd is a nuclide of gadolinium ($Z = 64$). The number of neutrons is $157 - 64 = 93$.

Think About It If we compare the ratios of neutrons to protons in these nuclei, we find that they increase as the atomic numbers of the nuclei increase. This is a reasonable trend that is reflected in the average atomic masses and atomic numbers of all the elements in the periodic table on the inside of the front cover.

Practice Exercise Determine the number of protons and neutrons in each of these radioactive nuclides: (a) ^{60}Co, used in cancer therapy; (b) ^{131}I, used in thyroid therapy; (c) ^{192}Ir, used to treat coronary disease.

(Answers to Practice Exercises are in the back of the book.)

Glossary

isotopes
: atoms of the same element that contain different numbers of neutrons.

atomic number (Z)

the number of protons in the nucleus of an atom.

nucleon

either a proton or a neutron in a nucleus.

mass number (A)

the number of nucleons in an atom.

periodic table of the elements

a chart of the elements arranged in order of their atomic numbers and in a pattern based on their physical and chemical properties.

nuclide

an atom with particular numbers of neutrons and protons in its nucleus.

Learning Objectives

- Use the symbol of a nuclide to describe the composition of its nucleus: the number of protons, the number of neutrons, and the total number of nucleons **Return to Sample Exercises 2.1, 2.2**

- Use the symbol of a nuclide to describe the composition of its nucleus: the number of protons, the number of neutrons, and the total number of nucleons **Return to Sample Exercises 2.1, 2.2**

2.4 Average Atomic Mass

Each element in the periodic table is represented by its symbol. The number above this symbol is the element's atomic number (Z), and the number below the symbol is the element's average atomic mass. More precisely, the number below the symbol is the *weighted average* of the masses of all the isotopes of the element.

To understand the meaning of a weighted average, consider the masses and natural abundances of the three isotopes of neon in the table shown here. Natural abundances are usually expressed in percentages. Thus, 90.4838% of all neon atoms are neon-20, 9.2465% are neon-22, and only 0.2696% are neon-21. The abundance of neon-21 is so small that Aston could not detect it with his positive-ray analyzer. Modern mass spectrometers, which are the source of natural abundance data such as these, are vastly more sensitive and more precise than Aston's prototype.

Isotope	Mass (u)	Natural Abundance (%)
Neon-20	19.9924	90.4838
Neon-21	20.9940	0.2696
Neon-22	21.9914	9.2465

To determine the average atomic mass of any element, we multiply the mass of each isotope by its natural abundance (in the language of mathematics, we *weight* the isotope's mass by using natural abundance as the *weighting factor*) and then sum the three weighted masses. To simplify the calculation for neon, we convert the percent abundance values into their decimal equivalents:

After accounting for significant figures, the average atomic mass of neon is 20.1799 u. No atom of neon has the average atomic mass; every atom of neon in the universe must have a mass equal to that of one of the three neon isotopes. The value we have calculated is simply the weighted average of these three isotopic masses.

This method of calculating average atomic mass works for every element. The general formula for these calculations is

where m_X is the average atomic mass of element X, which has isotopes with masses m_1, m_2, m_3, . . . , the natural abundances of which, expressed in decimal form, are a_1, a_2, a_3, ...

The term *natural abundance* may seem to mean that the abundances of the isotopes of an element are the same no matter where the element occurs in nature. This is not always the case. The isotopic abundances of some elements can vary slightly depending on the origins of samples and the presence of certain other elements in them.

One element with variable isotopic abundances is strontium. Sample Exercise 2.3 is based on experimentally determined isotopic abundances of strontium in a quantity of strontium carbonate, $SrCO_3$, that was carefully purified, blended, and analyzed by the U.S. National Institute of Standards and Technology (NIST). Portions of it are sold by NIST to scientists who wish to check the accuracy of isotopic analyses determined in their laboratories using mass spectrometry.

CONNECTIONThe use of reference materials with known composition to check the accuracy of chemical analyses is described in Section 1.9.

SAMPLE EXERCISE 2.3 Calculating Average Atomic Mass LO3

The following table contains the atomic masses and experimentally determined relative abundances of the isotopes of strontium in NIST Standard Reference Material Number 987:

Symbol	Mass (u)	Abundance (%)
^{84}Sr	83.9134	0.557
^{86}Sr	85.9093	9.857
^{87}Sr	86.9089	7.002
^{88}Sr	87.9056	82.584

What is the average atomic mass of strontium in the sample? Compare the calculated average to the atomic mass of Sr in the periodic table in the front of this book (87.62 u).

Collect, Organize, and Analyze We know the masses and the relative abundances of the four stable isotopes of strontium in a sample and are asked to calculate the average atomic mass of Sr in the sample. Using Equation 2.1, we multiply the mass of each isotope by its abundance (expressed as a decimal) and then add the products together.

Solve The weighted average atomic mass of Sr in the sample is:

We carried one more digit (highlighted in red) than allowed by the significant-figure rules in Chapter 1 to avoid rounding errors. Rounding the sum to the allowed number of significant figures gives us 87.617 u.

Think About It In this calculation the abundance values of the isotopes contain fewer significant digits (3, 4, 4, and 5 for ^{84}Sr, ^{86}Sr, ^{87}Sr, and ^{88}Sr, respectively) than do their masses (6 in every value). Therefore, isotopic abundance is the *weak link* in calculating this average atomic mass. The four abundance values should add up to 1.000, and they do. Sometimes this is not the case (check the neon abundances in the previous calculation). Finally, rounding the calculated value to the nearest 0.01 u yields the same average atomic mass of Sr (87.62 u) as in the periodic table inside the front cover of the book.

Practice Exercise Silver (Ag) has two stable isotopes: silver-107 (106.905 u) and silver-109 (108.905 u). If the average atomic mass of silver is 107.868 u, what is the natural abundance of each isotope? (*Hint*: Let x be the natural abundance of one of the isotopes. Then $1 - x$ is the natural abundance of the other.)

(Answers to Practice Exercises are in the back of the book.)

Glossary

average atomic mass

a weighted average of the masses of all the isotopes of an element, calculated by multiplying the natural abundance of each isotope by its mass in atomic mass units and then summing these products.

natural abundance

the proportion of an isotope, usually expressed in percent, relative to all the isotopes of that element in a natural sample.

Learning Objectives

- Relate the natural abundance values of the stable isotopes of an element to the element’s average atomic masses **Return to Sample Exercise 2.3**

2.5 The Periodic Table of the Elements

Long before chemists knew about electrons, protons, and neutrons, they knew that groups of elements, such as Li, Na, and K, or F, Cl, and Br, had similar chemical (and sometimes physical) properties. When the elements were arranged by increasing atomic mass, repeating patterns of similar properties appeared among the elements. This *periodicity* in the chemical properties of the elements inspired several 19th-century scientists to create tables of the elements in which the elements were arranged in patterns based on similarities in their chemical properties.

The most successful of these scientists was the Russian chemist Dmitri Mendeleev (1834–1907). In 1872 he published a table (**Figure 2.11**) that was the forerunner of the modern periodic table (**Figure 2.12**). In addition to organizing all the elements that were known at the time, Mendeleev realized that there might be elements in nature that were yet to be discovered, so he left empty cells in his table for those unknown elements. Doing so allowed him to align the known elements so that those in each column had similar chemical properties. Based on the locations of the empty cells, Mendeleev predicted the chemical properties of the missing elements that ultimately were discovered. Mendeleev arranged the elements in his periodic table in order of increasing atomic mass, whereas the elements appear in order of increasing atomic number in modern periodic tables.

CONCEPT TEST

Why did Mendeleev skip cells in his periodic table?

(Answers to Concept Tests are in the back of the book.)

Navigating the Modern Periodic Table

The modern periodic table (Figure 2.12) contains seven horizontal rows (also called periods) and 18 columns (known as groups or *families*) of elements. The periods are numbered at the far left of each row, and the group numbers appear at the top of each column. The periodic table inside the front cover shows a second set of column headings containing numbers followed by the letter A or B. These secondary headings were widely used in earlier versions of the table, and many scientists (and students) still find them useful.

The elements in the periodic table can be broadly categorized as metals, nonmetals, and metalloids (or semimetals). The elements highlighted in tan in Figure 2.12 are the metals. They tend to conduct heat and electricity well, they tend to be malleable (capable of being shaped by hammering) or ductile (capable of being drawn out in a wire), and they are shiny solids at room temperature, except for mercury (Hg), which is a liquid at room temperature (**Figure 2.13a**). The elements highlighted in blue are the nonmetals. They are poor conductors of heat and electricity, and the solids among them, including sulfur (**Figure 2.13b**), tend to be brittle. Several are gases; bromine is a volatile (easily vaporized) liquid, and iodine is a volatile solid. Lastly, the elements highlighted in green are the metalloids or semimetals, so named because they tend to have the physical properties of metals but the chemical properties of nonmetals (**Figure 2.13c**).

In the modern periodic table, groups 1, 2, and 13–18 are referred to collectively as main group elements, or representative elements (**Figure 2.14a**). These groups include the most abundant elements in the solar system and many of the most abundant elements on Earth. These are the “A” elements in the older group labeling system shown on the table inside the front cover. The elements in groups 3 through 12 are called transition metals; these are the “B” elements. Nearly all the elements in groups 3 through 12 exhibit the characteristic properties of metals—namely, they are hard, shiny, ductile, malleable, and excellent conductors of heat and electricity.

The first row contains only two elements—hydrogen and helium—and the second and third rows each contain only eight. Starting with the fourth row, all 18 columns are full. The sixth and seventh rows contain additional elements, which appear in the two separate rows at the bottom of the main table. Elements in the row with atomic numbers from 58 to 71 are called the lanthanides (after element 57, lanthanum), and those with atomic numbers between 90 and 103 are called actinides (after element 89, actinium). All isotopes of the actinide elements are radioactive, and none of those with atomic numbers above 94 occur in nature. Therefore, they have no *natural* abundance, and their atomic mass values in the periodic table, which appear in brackets or parentheses, are based on the mass numbers of their isotopes that last the longest before undergoing radioactive decay.

Several of the groups have a name in addition to a number. The names are typically based on properties common to all the elements in that group (**Figure 2.14b**). For example, the elements in group 17 are called halogens. The word *halogen* is derived from the Greek for “salt former.” Chlorine (Cl), for example, reacts with sodium (a metal in group 1) to form table salt. Other elements in group 1 (which are called alkali metals) and in group 2 (which are called alkaline earth metals) also react with members of the halogen family to form different salts. These reactivity patterns, and others, were the basis for Mendeleev’s arrangement of the elements in his periodic table, and they illustrate what we mean by “similar chemical properties.”

Compare Figures 2.11 and 2.12. First note the similarity in the arrangements of the lighter (smaller atomic number) elements through calcium ($Z = 20$). All the elements in groups 1, 2, and 13 through 17 of the modern table appear in the same order in Mendeleev’s table, but group 18 (the noble gases) is missing from Mendeleev’s table. There is a good reason for this. Helium was the first noble gas to be discovered, and that was not until 1895, many years after Mendeleev published his table. Noble gases have very limited chemical reactivity (indeed, helium and neon don’t react at all) and so were elusive substances for early chemists to isolate and identify. Because Mendeleev arranged his table largely based on reactivity, he had no reason to predict the existence of the noble gases.

SAMPLE EXERCISE 2.4 Navigating the Periodic Table LO4

Use the periodic table on the inside front cover to determine the symbol and name of each of the following elements:

1. The third-row element in group 14
2. The fourth-row alkaline earth metal
3. The halogen with fewer than 16 protons in its nucleus

Collect and Organize We need to identify each element based on its: (a) row number and column number, (b) row number and the common name of its group, and (c) group name and atomic number.

Analyze (a) The target element is located at the intersection of row 3 and column 14, as shown in red in **Figure 2.15**. (b) The alkaline earth metals are in group 2, so the target element is located at the intersection of row 4 and column 2, as shown in blue in Figure 2.15. (c) The halogens are in group 17. As shown in green in Figure 2.15, only one of them has an atomic number (which is the number of protons per nucleus) that is less than 16.

Solve (a) Si, silicon; (b) Ca, calcium; (c) F, fluorine.

Think About It Each element has a unique location in the periodic table determined by its atomic number, which defines the row it is in, and by its patterns of reactivity with other elements, which defines the group it is in.

Practice Exercise Write the symbol and name of each element:

1. The metalloid in group 15 closest in mass to the noble gas krypton
2. The element in the fourth row that is an alkali metal
3. The transition metal in the fifth period with chemical properties most like those of zinc ($Z = 30$)
4. The nonmetal in the fourth period with chemical properties most like those of sulfur

(Answers to Practice Exercises are in the back of the book.)

Glossary

period
: a horizontal row in the periodic table.

group
: all the elements in the same column of the periodic table; also called *family*.

metals
: the elements on the left side of the periodic table that are typically shiny solids that conduct heat and electricity well and are malleable and ductile.

nonmetals
: the elements with properties opposite those of metals, including poor conductivity of heat and electricity.

metalloids (also called semimetals)
: the elements along the border between the metals and nonmetals in the periodic table; they have some metallic and some nonmetallic properties.

main group elements (also called representative elements)
: the elements in groups 1, 2, and 13 through 18 of the periodic table.

main group elements (also called representative elements)
: the elements in groups 1, 2, and 13 through 18 of the periodic table.

transition metals
: the elements in groups 3 through 12 of the periodic table.

halogens
: the elements in group 17 of the periodic table.

alkali metals
: the elements in group 1 of the periodic table.

alkaline earth metals
: the elements in group 2 of the periodic table.

noble gases
: the elements in group 18 of the periodic table.

2.6 Trends in Compound Formation

Mendeleev used patterns of reactivity to place elements in different groups in his early periodic table. Both Dalton and Mendeleev knew that when elements combine to form compounds, they do so in characteristic ratios. These ratios are reflected in the chemical formulas of compounds. For example, the formula of carbon dioxide, CO_2, indicates that every molecule of CO_2 consists of one atom of carbon combined with two atoms of oxygen.

Dalton's atomic view of compounds also explains why some elements (e.g., S and O) can form more than one compound (as in SO_2 and SO_3). Dalton determined that the ratio of the different masses of oxygen that react with a given mass of sulfur to form two distinct compounds could be expressed as a ratio of two small whole numbers. This principle was observed experimentally and is known as Dalton's law of multiple proportions.

To see what this principle means, consider SO_2 and SO_3. We determine in an experiment that under one set of conditions, 10 g of sulfur reacts with 10 g of oxygen to form SO_2. Under different conditions, however, 10 g of sulfur reacts with 15 g of oxygen to form SO_3. The ratio of the two masses of oxygen is 10:15, or 2:3, which is a ratio of two small whole numbers. This example illustrates the law of multiple proportions.

Similarly, we can confirm experimentally that the mass of oxygen that reacts with a given mass of nitrogen to form NO_2 (22.8 g of O for every 10.0 g of N) is twice as much as the mass of oxygen that reacts with the same mass of nitrogen to form NO (11.4 g of O for every 10.0 g of N). The ratio of the two oxygen masses is 22.8:11.4, or 2:1, again a ratio of small whole numbers. The law of multiple proportions and the law of constant composition (Section 1.2) were key ideas that formed the basis for Dalton's atomic theory.

SAMPLE EXERCISE 2.5 Relating Chemical Formulas to the Law of Multiple Proportions LO5

Carbon can combine with oxygen to form either CO or CO_2 (**Figure 2.16**), depending on reaction conditions. If 26.6 g of O_2 reacts with 10.0 g of C to make CO_2, how many grams of O_2 react with 10.0 g of C to make CO?

Collect, Organize, and Analyze We know the mass ratio of oxygen to carbon in CO_2 and need to calculate the mass ratio of oxygen to carbon in CO. The ratio of O atoms to C atoms in CO_2 is 2:1. The ratio of the O atoms to C atoms in CO is 1:1. Therefore, half as much oxygen reacts with 10.0 g of carbon to make CO as reacts with 10.0 g of carbon to make CO_2.

Solve

$$(26.6 \text{ g } O_2) \times \frac{1}{2} = 13.3 \text{ g } O_2$$

Think About It The result makes sense because it should take half as much O_2 (13.3 g instead of 26.6 g) to produce a compound that has one atom of oxygen for every atom of carbon instead of two atoms of oxygen for every atom of carbon.

Practice Exercise Predict the mass of oxygen required to react with 14.0 g of nitrogen to make N_2O_5 if 16.0 g of oxygen reacts with 14.0 g of nitrogen to make N_2O_2 (**Figure 2.17**).

(Answers to Practice Exercises are in the back of the book.)

Molecular Compounds

We need to distinguish between compounds that are composed of ions and those that are composed of molecules. Compounds composed of pairs of metallic and nonmetallic elements tend to be ionic, whereas compounds composed of two nonmetals or metalloids tend to be molecular. The compounds we have examined so far in this section have been molecular compounds, each of which consisted of molecules composed of two different nonmetals. The molecular structures of several of these compounds are shown in **Figure 2.18**. Other molecular compounds are composed of molecules that contain the atoms of three, four, or more elements, which may be nonmetals or metalloids, and that are bound together by shared pairs of electrons called covalent bonds.

All the compounds in Figure 2.18 are present in the air we breathe. Each chemical formula specifies the number of atoms of each element in one molecule of the compound. Therefore, these chemical formulas are molecular formulas. The fact that the same two elements can form compounds with different molecular formulas (consistent with Dalton’s law of multiple proportions) means that there are different ways to form covalent bonds between atoms of the same two elements.

Ionic Compounds

Binary (two-element) ionic compounds contain atoms of metals (shown in tan in the periodic table inside the front cover) that have each lost one or more electrons, forming positively charged cations, and atoms of nonmetals (shown in blue) that have each gained one or more electrons, forming negatively charged anions. For example, table salt (**Figure 2.19**) is composed of crystals of sodium chloride, NaCl, that each contain equal numbers of Na^+ ions (Na atoms that have each lost one electron),

$$Na \rightarrow Na^+ + e^-$$

and Cl^- ions (Cl atoms that have each gained one electron),

$$Cl + e^- \rightarrow Cl^-$$

CONNECTION In Chapter 1 we saw that ions are particles with either a positive charge (cations) or a negative charge (anions).

Within NaCl crystals, each sodium ion is surrounded by six chloride ions, and each chloride ion is surrounded by six sodium ions. However, the smallest whole-number ratio of sodium ions to chloride ions is simply 1:1. Formulas based on the lowest whole-number ratio of the elements in a compound are called empirical formulas. The chemical formulas of ionic compounds, such as NaCl for sodium chloride, are empirical formulas. The empirical formula of an ionic compound describes a formula unit, the smallest electrically neutral unit within the crystal.

Ions such as Na^+ and Cl^- that are each composed of a single atom are called *monatomic* ions. The charges on the monatomic ions that different elements form strongly influence their chemical reactivity and, therefore, their placement among the different groups of the periodic table. **Figure 2.20** shows how the elements within a given group tend to form cations or anions with the same charge. It also shows that there is a pattern in how these charges vary among groups. For example, atoms of group 1 elements each form $1+$ ions; atoms of group 2 elements each form $2+$ ions (Figure 2.20). The charges on these monatomic cations match their group numbers. This correlation between group number and cation charge breaks down among the transition metals and the metallic elements on the right side of the periodic table, but there are still similarities in cation charge within groups. Figure 2.20 also shows that there is a pattern in the charges of the monatomic anions formed by the nonmetallic elements, namely, $3-$ in group 15, $2-$ in group 16, and $1-$ in group 17. We explore how these trends are related to the structure of the atoms of these elements, particularly the number of electrons surrounding their nuclei, in Chapter 7.

It is important to remember that ionic compounds, like molecular compounds, are electrically neutral. This means that the total positive charge on all the cations in an ionic compound must be equal in magnitude to the total negative charge on all the anions in the compound. This neutrality requirement is the reason that the formula of the compound that contains only Na^+ ions and Cl^- ions is NaCl: the $1+$ and $1-$ charges on these ions balance out only if the ratio of the ions is 1:1. On the other hand, the formula of the compound that contains only Mg^{2+} and F^- ions is MgF_2 because it takes two F^- ions to offset the $2+$ charge on one Mg^{2+} ion.

CONCEPT TEST

Which of the following ionic formulas does *not* represent an electrically neutral compound? (*Hint*: Base your selection on the charges of the common ions in Figure 2.20.) (a) KBr; (b) CaF_2; (c) CsN; (d) TiO_2; (e) AgCl

(Answers to Concept Tests are in the back of the book.)

SAMPLE EXERCISE 2.6 Classifying Compounds as Molecular or Ionic LO5

Identify which of the following binary compounds are ionic and which are molecular: (a) sodium bromide (NaBr); (b) carbon dioxide (CO_2); (c) lithium iodide (LiI); (d) germanium tetrachloride ($GeCl_4$); (e) calcium chloride ($CaCl_2$).

Collect, Organize, and Analyze We must decide whether each of five binary compounds is ionic or covalent. A compound composed of a metallic and a nonmetallic element is usually ionic, whereas compounds composed of two nonmetals or metalloids tend to be molecular.

Solve NaBr, LiI, and $CaCl_2$ all contain a group 1 or group 2 metal and a group 17 nonmetal, so they are ionic compounds. CO_2 is composed of two nonmetals, and $GeCl_4$ is composed of a metalloid and a nonmetal, so both should be molecular compounds.

Think About It Labeling compounds as ionic or molecular is not as clear-cut as you might think based on this sample exercise. In later chapters we introduce binary molecular compounds that have some ionic "character," and we explore ways to predict how much ionic character they have.

Practice Exercise Identify the following compounds as molecular or ionic: (a) carbon disulfide (CS_2); (b) carbon monoxide (CO); (c) ammonia (NH_3); (d) water (H_2O); (e) sodium iodide (NaI).

(Answers to Practice Exercises are in the back of the book.)

Glossary

law of multiple proportions

the principle that, when two masses of one element react with a given mass of another element to form two different compounds, the two masses of the first element have a ratio of two small whole numbers.

molecular compound

a compound composed of molecules that contain the atoms of two or more elements covalently bonded together.

covalent bond

a bond between two atoms created by sharing one or more pairs of electrons.

molecular formula

a notation showing the number and type of atoms present in one molecule of a molecular compound.

ionic compound

a compound composed of positively and negatively charged ions held together by electrostatic attraction.

empirical formula

a formula showing the smallest whole-number ratio of the elements in a compound.

formula unit

the smallest electrically neutral unit of an ionic compound.

Learning Objectives

- Distinguish between ionic and molecular compounds and explain how the law of multiple proportions is connected to the formulas of common molecular compounds **Return to Sample Exercises 2.5 and 2.6**
- Distinguish between ionic and molecular compounds and explain how the law of multiple proportions is connected to the formulas of common molecular compounds **Return to Sample Exercises 2.5 and 2.6**

FIGURE 2.21 Aluminum cans resist corrosion because of a thin layer of aluminum oxide that forms on the surfaces of the can. This layer protects the aluminum beneath the surface from combining with oxygen or other elements.

2.7 Naming Inorganic Compounds and Writing Their Formulas

There are more than 140 million known chemical compounds, and new ones are being synthesized every day. Keeping track of all these compounds and assigning each a unique name that clearly conveys its chemical composition is an enormous undertaking. Today, the naming portion of this task is based on a widely used set of rules called chemical nomenclature from the Latin words *nomen* (name) and *calatus* (assigned).

Naming compounds is like naming life-forms in that it relies on dividing substances in categories, then subcategories, and so on. The two major categories in chemical nomenclature are *organic* and *inorganic* compounds. Inorganic compounds make up Earth's geosphere, including its crust (part of the lithosphere), the air we breathe (the atmosphere), and the water that covers most of Earth's surface (the hydrosphere). The biosphere, on the other hand, is rich in organic compounds, which are composed mostly of carbon and hydrogen, with lesser amounts of other elements such as nitrogen, oxygen, phosphorus, and sulfur.

For centuries, philosophers and scientists thought that organic compounds could be synthesized only by biological processes. In the 1820s, however, a German chemist named Friedrich WÖhler (1800–1882) showed that organic compounds could be synthesized in the laboratory from inorganic starting materials. Naming organic compounds and writing their molecular formulas is described in Section 2.8. The remainder of this section focuses on inorganic compounds, starting with those composed of only two elements.

Binary Molecular Compounds

Compounds formed by two nonmetals or by a metalloid and a nonmetal are usually composed of molecules, whereas most (though not all) compounds formed by a metal and a nonmetal are ionic. Let’s begin by translating the formulas of molecular inorganic compounds into two-word compound names using the following three steps:

TABLE 2.2 Prefixes for Naming Molecular Compounds

one *mono-*		
two *di-*		
three *tri-*		
four *tetra-*		
five *penta-*		
six *hexa-*		
seven *hepta-*		
eight *octa-*		
nine *nona-*		
ten *deca-*		

1. The first word is the name of the first element in the formula.
2. For the second word, change the ending of the name of the second element to -*ide*.
3. Use prefixes (**Table 2.2**) to indicate the number of atoms of each element in the molecule. (Exception: Do not use the prefix *mono*- with the first element in a name.)

For example, the name of CO is carbon monoxide, SO_2 is sulfur dioxide, and PCl_3 is phosphorus trichloride. When prefixes ending in *o*- or *a*- (like *mono*- and *tetra*-) precede a name that begins with a vowel (such as *oxide*), the *o* or *a* at the end of the prefix is deleted to make the combination of prefix and name easier to pronounce. Thus, CO is carbon monoxide, not carbon *mono*oxide.

The order in which the symbols of the elements appear in the formulas of compounds depends on the relative positions of the elements in the periodic table: the one with the smaller group number nearly always appears first in the formulas of inorganic compounds. If a compound contains two elements from the same group—for example, sulfur and oxygen—the symbol of the element with the larger atomic number appears first.

Some common binary molecular compounds have widely used names that do not follow the naming guidelines just described. For example, H_2O is called water, not dihydrogen monoxide. Similarly, the common name for the compound with the formula NH_3 is ammonia, not nitrogen trihydride. There are other important molecular compounds with common names that predate current rules of chemical nomenclature. Many of them are organic compounds, and their names and formulas are discussed in Section 2.8.

SAMPLE EXERCISE 2.7 Relating the Formulas and Names of Molecular Compounds LO6

What are the names of the compounds with these molecular formulas: (a) N_2O; (b) N_2O_4; (c) N_2O_5? What are the molecular formulas of (d) sulfur trioxide, (e) sulfur monoxide, and (f) diphosphorus pentoxide?

Collect and Organize We are asked to translate the formulas of three molecular compounds into names and the names of three compounds into molecular formulas. The prefixes in Table 2.2 are used in the names of compounds to indicate the number of atoms of each element in a molecule: *mono*- means 1 atom, *di*- means 2 atoms, *tri*- means 3, *tetra*- means 4, and *penta*- means 5.

Analyze In the first question, the first element in all three compounds is nitrogen, so the first word in each name is *nitrogen* with the appropriate prefix. The second element in all three compounds is oxygen, so the second word in each name is *oxide* with the appropriate prefix. In the second question, all the molecules contain oxygen because their names end in *oxide*.

Solve (a) dinitrogen monoxide; (b) dinitrogen tetroxide (not dinitrogen *tetra*oxide); (c) dinitrogen pentoxide (not dinitrogen *penta*oxide); (d) SO_3; (e) SO; (f) P_2O_5

Think About It The prefixes *mono*-, *tetra*-, and *penta*- dropped their final letter when they combined with *oxide* to make the names of the compounds easier to pronounce.

Practice Exercise Name (a) P_4O_{10}, (b) NO, and (c) NCl_3. Write the formulas for (d) sulfur hexafluoride, (e) iodine monochloride, and (f) dibromine monoxide.

(Answers to Practice Exercises are in the back of the book.)

Binary Ionic Compounds

Binary ionic compounds contain the monatomic cation of a metallic element and the monatomic anion of a nonmetal. Translating their formulas into names is a lot like the system we used for molecular compounds, but with fewer steps:

1. The first word is the name of the cation, which is simply the name of its parent element.
2. The second word is the name of the anion, which, for monatomic anions, is the name of its parent element, except that its ending is changed to -*ide*.

Prefixes are not needed in naming binary ionic compounds that each contain a metal and nonmetal whose ions nearly always have the same positive and negative charges (these elements are highlighted in Figure 2.20). Prefixes aren't needed because all ionic compounds are electrically neutral, which means the sums of the negative and positive charges of their ions must balance, and that dictates the number of each of the ions in each of their formulas. For example, a name like *magnesium fluoride* is unambiguous: it can mean only MgF_2 because all magnesium ions have $2+$ charges and all fluoride ions have $1-$ charges.

SAMPLE EXERCISE 2.8 Relating the Formulas and Names of Ionic Compounds LO6

Write the formulas of (a) potassium bromide, (b) calcium oxide, (c) sodium sulfide, (d) magnesium chloride, and (e) aluminum oxide

(**Figure 2.21**).

Collect, Organize, and Analyze We need to write the formulas of five binary ionic compounds. Checking the names of the compounds against the positions of the elements in the periodic table and the charges on the monatomic ions they form (Figure 2.20), we see that all five are made up of main group elements that form these ions: (a) K^+ and Br^-, (b) Ca^{2+} and O^{2-}, (c) Na^+ and S^{2-}, (d) Mg^{2+} and Cl^-, and (e) Al^{3+} and O^{2-}.

Solve We must balance the positive and negative charges on the ions in each compound:

1. The $1+$ and $1-$ charges of a K^+ ion and a Br^- ion add up to zero, so the formula is simply KBr.
2. The $2+$ and $2-$ charges of a Ca^{2+} and a O^{2-} ion add up to zero, so the formula is CaO.
3. It takes two Na^+ ions to offset the $2-$ charge of one S^{2-} ion, so the formula of sodium sulfide is Na_2S.
4. It takes two Cl^- ions to offset the $2+$ charge of one Mg^{2+} ion, so the formula of magnesium chloride is $MgCl_2$.
5. The simplest way to balance the $3+$ and $2-$ charges on Al^{3+} and O^{2-} ions is with a ratio of 2 Al^{3+} ions for every 3 O^{2-} ions because $2 \times (3+) + 3 \times (2–) = 0$. Therefore, the formula of aluminum oxide is Al_2O_3.

Think About It The formulas of ionic compounds are based on the principle that the positive and negative charges on all the cations and anions in them must be in balance, that is, the sum of their charges must equal zero.

Practice Exercise Write the chemical formulas of (a) strontium chloride, (b) magnesium oxide, (c) sodium fluoride, and (d) calcium bromide.

(Answers to Practice Exercises are in the back of the book.)

Compounds of Metals That Form More than One Cation

Many of the transition metals and metallic elements in groups 13 through 16 form monatomic cations with more than one charge. For example, most of the copper found in nature is present as Cu^{2+}, but some copper compounds contain Cu^{+} ions. Therefore, the name *copper chloride* does not distinguish between $CuCl_2$ and CuCl. To name these compounds, chemists historically used different names for Cu^{+} and Cu^{2+} ions: they were called *cuprous* and *cupric* ions, respectively. Similarly, Fe^{2+} and Fe^{3+} ions were called *ferrous* and *ferric* ions, respectively. In both pairs of ions, the name with the lower charge ends in -*ous*, whereas the name with the higher charge ends in -*ic*.

In modern chemical nomenclature Roman numerals are used to indicate the charge on these metal ions. Thus, the modern name of $CuCl_2$ is copper(II) chloride (pronounced "copper-two chloride"), whereas CuCl is copper(I) chloride. Roman numerals are used to indicate the charge of metal cations unless the metal commonly forms only one. These metals include those in groups 1 through 3, which form ions with charges of $1+$, $2+$, and $3+$, respectively, as well as Ag^{+}, Cd^{2+}, Zn^{2+}, and Al^{3+}.

SAMPLE EXERCISE 2.9 Relating the Formulas and Names of Compounds of Metals That Form More than One Monatomic Cation LO6

What are the chemical formulas of (a) iron(II) sulfide and (b) chromium(III) oxide (**Figure 2.22**)? What are the names of (c) V_2O_5 and (d) $NiCl_2$?

Collect, Organize, and Analyze We are asked to write the formulas of two transition metal compounds from their names and to write the names of two others from their formulas. In the names of all four compounds, Roman numerals indicate the charges on the transition metal cations. The charges of the most common monatomic anions are shown in Figure 2.20. They include S^{2-},

O^{2-}, and Cl^{-}. Both vanadium and lead can form more than one monatomic cation, so the names of compounds (c) and (d) must include Roman numerals. As with all ionic compounds, the sum of the positive and negative charges of their ions must be zero.

Solve

1. The Roman numeral II in the compound's name means that the iron ions are Fe^{2+}. All sulfide ions are 2−. A 1:1 ratio of Fe^{2+} and S^{2-} ions balances their charges, making the formula of iron(II) sulfide FeS.
2. The Roman numeral III means that the chromium ions in the compound are Cr^{3+}. All oxide ions are 2−. To balance their positive and negative charges, we need two Cr^{3+} ions for every three O^{2-} ions, because $2 \times (3+) + 3 \times (2-) = 0$. Therefore, the formula of chromium(III) oxide is Cr_2O_3.
3. The compound with the formula V_2O_5 has five O^{2-} ions for every two vanadium ions. The negative charge from five O^{2-} ions is 10−, so the positive charge from two vanadium ions must be 10+. This means that each vanadium ion is 5+. Expressing this 5+ charge with the Roman numeral V gives us the compound name vanadium(V) oxide.
4. There are two Cl^{-} ions for every nickel ion in $NiCl_2$. The negative charge from two Cl^{-} ions is 2−, so the positive charge from the one nickel ion must be 2+. Expressing this 2+ charge with the Roman numeral II gives us the compound name nickel(II) chloride.

Think About It To check our work, we could try translating the formulas developed in parts (a) and (b) back into names and the names developed in parts (c) and (d) back into formulas to see if we could reproduce the starting names and formulas.

Practice Exercise Write the formulas of manganese(II) chloride and manganese(IV) oxide.

(Answers to Practice Exercises are in the back of the book.)

Polyatomic Ions

TABLE 2.3 Names, Formulas, and Charges of Some Common Polyatomic Ions

Name	Chemical Formula
Acetate	CH_3COO^-
Carbonate	CO_3^{2-}
Hydrogen carbonate or bicarbonate	HCO_3^-
Cyanide	CN^-
Hypochlorite	ClO^-
Chlorite	ClO_2^-
Chlorate	ClO_3^-
Perchlorate	ClO_4^-
Dichromate	$Cr_2O_7^{2-}$
Chromate	CrO_4^{2-}
Permanganate	MnO_4^-
Azide	N_3^-
Ammonium	NH_4^+
Nitrite	NO_2^-
Nitrate	NO_3^-
Hydroxide	OH^-
Peroxide	O_2^{2-}
Phosphate	PO_4^{3-}
Hydrogen phosphate	HPO_4^{2-}
Dihydrogen phosphate	$H_2PO_4^-$
Disulfide	S_2^{2-}
Sulfate	SO_4^{2-}
Hydrogen sulfate or bisulfate	HSO_4^-
Sulfite	SO_3^{2-}
Hydrogen sulfite or bisulfite	HSO_3^-
Thiocyanate	SCN^-

Ions that consist of two or more atoms joined by covalent bonds are called polyatomic ions. The names and formulas of some common polyatomic ions appear in **Table 2.3**. Only one of them, ammonium ion ($NH_4{}^+$), is a cation. When writing the formula of a compound with two or more of the same polyatomic ion per formula unit, we put parentheses around the formula of the polyatomic ion to make it clear that the subscript that follows applies to the entire ion. For example, the formula $Al_2(SO_4)_3$ means there are two Al^{3+} ions for every three $SO_4{}^{2-}$ ions in each formula unit.

Polyatomic ions containing oxygen and one or more other elements are called oxoanions. Most oxoanions have a name based on the name of the element that appears first in the formula, with its ending changed to either -*ite* or -*ate*. The -*ate* oxoanion of an element has a greater number of oxygen atoms than its -*ite* counterpart; for example, $SO_4{}^{2-}$ is the sulf*ate* ion, whereas $SO_3{}^{2-}$ is the sulf*ite* ion, and $NO_3{}^{-}$ is the nitr*ate* ion, whereas $NO_2{}^{-}$ is the nitr*ite* ion.

If an element forms more than two oxoanions, as chlorine, bromine, and iodine do, prefixes are used to distinguish among them (see Table 2.3). The oxoanion with the greatest number of oxygen atoms may have the prefix *per*-, whereas the one with the fewest number of oxygen atoms may have the prefix *hypo*- in its name. Because these rules may not enable you to predict the chemical formula of an oxoanion from its name or its name from its formula, you need to memorize the formulas, charges, and names of the polyatomic ions in Table 2.3 that your instructor thinks are most important.

SAMPLE EXERCISE 2.10 Relating the Formulas and Names of Compounds Containing Oxoanions LO6

What are the formulas of (a) sodium sulfite and (b) magnesium phosphate? What are the names of (c) $CaCO_3$ and (d) $KClO_4$?

Collect, Organize, and Analyze We are asked to write the formulas of two compounds whose names tell us they contain oxoanions (because of their -ite and -ate endings), and to write the names of two other compounds from formulas that contain oxoanions. Table 2.3 contains these pairs of names and formulas: sulfite is $SO_3{}^{2-}$, phosphate is $PO_4{}^{3-}$, carbonate is $CO_3{}^{2-}$, and perchlorate is $ClO_4{}^{-}$. The charges of the cations in all four compounds are shown in Figure 2.20: they are Na^+, Mg^{2+}, Ca^{2+}, and K^+. As with all ionic compounds, the sum of the positive and negative charges of the ions in these compounds must be zero.

Solve

1. To balance charges, we need twice as many Na^+ ions as $SO_3{}^{2-}$ ions. Therefore, the formula of sodium sulfite is Na_2SO_3.
2. To balance charges, we need three Mg^{2+} ions for every two $PO_4{}^{3-}$ ions. Therefore, the formula of magnesium phosphate is $Mg_3(PO_4)_2$. The phosphate ion is placed in parentheses because there is more than one of it and it is polyatomic. The magnesium ion is not placed in parentheses, even though there is more than one magnesium ion, because it is monatomic.
3. Combining the names of the Ca^{2+} ions and $CO_3{}^{2-}$ ions, we have calcium carbonate.
4. Combining the names of the K^+ ions and $ClO_4{}^-$ ions, we have potassium perchlorate.

Think About It To complete this exercise, we had to know the formulas and charges of several monatomic ions and oxoanions. The charges on the most common monatomic ions can be inferred from the positions of their parent elements in the periodic table, but knowing the names and formulas of common polyatomic ions requires at least some memorization. There are patterns, however, that can reduce how much you must memorize. For example, if you learn the formulas and charges of the nitrate and sulfate ions, then you can remember that removing one oxygen atom from each yields the formulas and charges of the nitrite and sulfite ions.

Practice Exercise What are the formulas of (a) strontium nitrate and (b) potassium sulfate, and the names of (c) $NaClO$ and (d) $KMnO_4$?

(Answers to Practice Exercises are in the back of the book.)

Acids

Some compounds have special names that highlight their chemical properties. Among them are acids. We discuss acids in greater detail in later chapters, but for now it is sufficient to say that acids are compounds that release hydrogen ions (H^+) when they dissolve in water. The simplest acids are called binary acids because their molecules contain atoms of only two elements: hydrogen and a nonmetal such as one of the group 17 elements (**Table 2.4**). These compounds are all gases at room temperature, but when they dissolve in water, their molecules separate into hydrogen ions and halide ions. To name these binary acids:

1. Affix the prefix *hydro-* to the name of the second element in the formula.
2. Replace the last syllable in the second element's name with the suffix *-ic* and add *acid.*

A second important class of acids forms hydrogen ions and oxoanions when these acids dissolve in water. **Table 2.5** contains the formulas and names of several of these *oxoacids*. Compare their names to the names of the oxoanions (see Table 2.3) that they form when they dissolve in water. Note that the oxoacids with names ending in *-ic* form oxoanions with names ending in *-ate*. For example, an aqueous solution of perchlor*ic* acid ($HClO_4$) contains hydrogen ions and perchlor*ate* ($ClO_4{}^-$) ions. On the other hand, all the oxoacids whose names end in *-ous* form oxoanions with names ending in *-ite*. Solutions of chlor*ous* acid ($HClO_2$), for example, contain hydrogen ions and chlor*ite* ($ClO_2{}^-$) ions.

TABLE 2.4 Formulas and Names of Common Binary Acids

Molecular Formula	**Name of Gas**		**Name of Acid**
$HF(g)$	hydrogen fluoride	$HF(aq)$	hydrofluoric acid
$HCl(g)$	hydrogen chloride	$HCl(aq)$	hydrochloric acid
$HBr(g)$	hydrogen bromide	$HBr(aq)$	hydrobromic acid
$HI(g)$	hydrogen iodide	$HI(aq)$	hydroiodic acid

TABLE 2.5 Formulas and Names of Some Common Oxoacids

Chemical Formula	Name
H_2CO_3	Carbonic acid
HNO_3	Nitric acid
HNO_2	Nitrous acid
H_3PO_4	Phosphoric acid

H_2SO_4 Sulfuric acid	
H_2SO_3 Sulfurous acid	
$HClO$ Hypochlorous acid	
$HClO_2$ Chlorous acid	
$HClO_3$ Chloric acid	
$HClO_4$ Perchloric acid	

SAMPLE EXERCISE 2.11 Relating the Formulas and Names of Oxoacids and Oxoanions LO6

What are the names and formulas of the oxoacids that release the following oxoanions when they ionize in aqueous solutions: (a) NO_2^-; (b) CrO_4^{2-}; (c) MnO_4^-?

Collect, Organize, and Analyze We are given the formulas of three oxoanions and asked to name the formulas of the oxoacids that form them when the acids ionize in water. According to Table 2.3, the names of the oxoanions are (a) nitrite, (b) chromate, and (c) permanganate. When the oxoanion name ends in -*ite*, the corresponding oxoacid name ends in -*ous*. When the anion name ends in -*ate*, the oxoacid name ends in -*ic*.

Solve Making the appropriate changes to the endings of the oxoanion names and adding the word *acid*, we get (a) nitrous acid (HNO_2), (b) chromic acid (H_2CrO_4), and (c) permanganic acid ($HMnO_4$).

Think About It You cannot tell the names of the oxoanions just by looking at them. You must remember the names associated with each family of polyatomic ions.

Practice Exercise Name the following acids, and name and write the formulas of the oxoanions their molecules form when each of them releases a H^+ ion in an aqueous solution: (a) $HBrO$; (b) HIO_2; (c) H_2SeO_3.

(Answers to Practice Exercises are in the back of the book.)

Glossary

chemical nomenclature

the rules that are followed in naming substances.

organic compound

a compound composed of molecules containing carbon combined with hydrogen and other elements, such as nitrogen, oxygen, phosphorus, and sulfur.

polyatomic ion

a charged group of two or more atoms joined by covalent bonds.

oxoanion

a polyatomic ion that contains oxygen in combination with one or more other elements.

Learning Objectives

2.8 Organic Compounds: A First Look

All the compounds we have discussed so far in this chapter—those composed of molecules and those made of ions—have been *inorganic* compounds. These compounds make up most of the world *around* us, but, except for water, these compounds constitute very little of the matter *inside* us.

We are living organisms, which means our bodies are mostly water and *organic* compounds composed of molecules that always contain carbon atoms, almost always contain hydrogen atoms, and frequently contain heteroatoms—typically oxygen, nitrogen, sulfur, phosphorus, and the halogens. The study of these compounds is called organic chemistry. Although *organic* has connotations in everyday conversation that often refer to farming and foods grown without the use of pesticides or synthetic fertilizers, the word *organic* as used by chemists refers to a compound's chemical composition and molecular structure. Still, chemists tend to distinguish between organic compounds derived from *natural products*, which are produced by living organisms, and *synthetic* organic compounds produced in the laboratory.

Hydrocarbons

Organic compounds that contain no heteroatoms are called hydrocarbons because their molecules contain only hydrogen and carbon atoms. One class of hydrocarbons, called alkanes, is composed of molecules in which each carbon atom is bonded to four other atoms by sharing a pair of electrons with each of them, that is, by forming four covalent bonds. These bonds are also called single bonds because they each involve the sharing of a single pair of electrons.

The names and structural formulas of the two simplest alkanes are

The name of each of these alkanes ends in *-ane*, as do the names of all alkanes. Methane and ethane are important components of natural gas. Alkanes made of larger molecules make up other important fuels, including gasoline, diesel fuel, jet fuel, and heating oil. Because of their importance as fuels, we explore their molecular structures and chemical properties in detail in Chapter 6, which focuses on combustion and the energetics of chemical reactions.

Another class of hydrocarbons contains carbon atoms bonded to fewer than four other atoms because they contain pairs of carbon atoms that bond together by sharing *two* pairs or double bonds. These compounds are called alkenes. Two of the most common have these molecular structures:

Like all alkenes, the names of these compounds end in *-ene*. The names in parentheses, ethene and propene, follow the naming rules established by the International Union of Pure and Applied Chemistry (IUPAC). (We followed IUPAC rules in naming the inorganic compounds in Section 2.7.) The beginning letters of ethene and propene correspond to the names of the alkanes with the same number of carbon atoms (ethane and propane). This pattern is repeated for all alkenes. However, many organic compounds are better known by their common names, such as ethylene and propylene, which predate the current IUPAC naming rules. We use these common names throughout this book, providing the IUPAC names in parentheses.

A third class of hydrocarbons, called alkynes, contain pairs of carbon atoms that share three pairs of electrons, forming C≡

As with alkenes, the names of alkynes are linked to the names of the alkanes with the same number of carbon atoms. All their IUPAC names end in -*yne*.

Heteroatoms and Functional Groups

Incorporating heteroatoms into the molecular structure of hydrocarbons produces organic compounds with physical and chemical properties that are very different from those of their parent hydrocarbons. For example, replacing a hydrogen atom with an OH group in the molecular structures of methane and ethane produces molecules with these simplified structural formulas (the O–H bonds are not shown):

The names of these compounds use the parent alkane root (i.e., *methan*- and *ethan*-, respectively), but they each end in -*ol*. The presence of the OH groups, highlighted in red, means that these compounds are alcohols. Unlike their parent alkanes, which are gases at room temperature and pressure, methanol and ethanol are colorless liquids. Alkanes don't dissolve in water (at least, not much), but these two alcohols dissolve freely in water (and water dissolves freely in them).

The OH group in alcohols is an example of a functional group, that is, a group of atoms in the molecular structure of a compound that has a significant impact on the physical and chemical properties of the compound. The common functional groups, whose chemical reactivity we explore in the chapters ahead, are listed in **Table 2.6**. All the functional groups contain an atom of oxygen or nitrogen or both. The symbols R and R9 are used to represent portions of the molecule that contain only carbon and hydrogen atoms.

There are many other rules that apply to naming compounds such as those in Table 2.6. See Appendix 7 for a comprehensive summary. Rather than dwelling on all of them right now, try instead to relate the names and structures of the sample compounds by using the names of methane and ethane and the class of compounds to which each belongs. For example, the name of the sample aldehyde in Table 2.6, *ethanal*, is derived from *ethane*, the alkane that also has two carbon atoms per molecule, and the functional group *al*dehyde.

TABLE 2.6 Classes of Organic Compounds and Their Functional Groups

Class of Compound	Formula of Functional Group	Example	Name of Example Compound	Sample Uses
Alcohol	—OH	CH_3CH_2OH	Ethanol	Alcoholic beverages
Ether	$R—O—R'$	CH_3OCH_3	Dimethyl ether (methoxymethane)	[illegible]
Aldehyde	 $R—C(=O)—H$	 $H_3C—C(=O)—H$	Ethanal (acetaldehyde)	Making plastics
Ketone	 $R—C(=O)—R'$	 $H_3C—C(=O)—CH_3$	Acetone (propanone)	Nail polish remover
Carboxylic acid	 $R—C(=O)—OH$	 $H_3C—C(=O)—OH$	Acetic acid (ethanoic acid)	Vinegar
Ester	 $R—C(=O)—O—R'$	 $H_3C—C(=O)—O—CH_3$	Methyl acetate (methyl ethanoate)	Nail polish remover, glue
Amine	$R—NH_2$	CH_3NH_2	Methylamine (aminomethane)	Synthesis of pharmaceuticals and industrial chemicals
Amide	 $R—C(=O)—NH_2$	 $H_3C—C(=O)—NH_2$	Acetamide (ethanamide)	Solvent, plastics additive

CONCEPT TEST

What functional group is present in each of the three organic compounds shown in **Figure 2.23**? These molecular models use different colors to represent atoms (see Section 1.2), namely, black is carbon, white is hydrogen, red is oxygen, and blue is nitrogen.

(Answers to Concept Tests are in the back of the book.)

Glossary

heteroatom
: an atom of an element other than carbon and hydrogen within a molecule of an organic compound.

organic chemistry
: the study of organic compounds.

hydrocarbon

an organic compound whose molecules are composed only of carbon and hydrogen atoms.

alkane

a hydrocarbon in which all the bonds are single bonds.

alkyne

a hydrocarbon containing one or more carbon–carbon triple bonds.

alcohol

an organic compound containing the OH functional group.

functional group

a group of atoms in the molecular structure of an organic compound that imparts characteristic chemical and physical properties.

alkene

hydrocarbon containing one or more carbon-carbon double bonds.

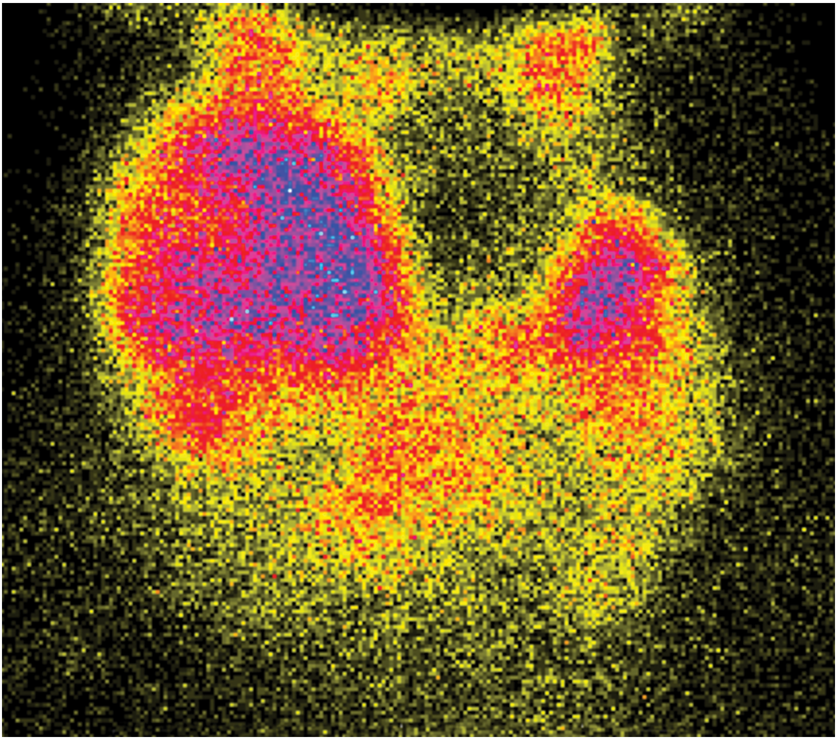

FIGURE 2.27 Technetium is used to study the function of organs such as the thyroid gland. Typically, an image is taken soon after injection of a radioactive Tc compound. After a time, the thyroid is re-imaged to see how much Tc remains. The distribution of Tc should be symmetrical. Here the lobes are not the same, indicating abnormal thyroid function.

2.9 Nucleosynthesis: The Origin of the Elements

We began this chapter by discussing remarkable advances in the early 20th century that provided insights into the structure of atoms and helped to explain why elements react the way they do. Later in the century, scientists increased our understanding of how the elements may have originally formed by determining the composition of the very early universe—the particles that appeared in the moments immediately following the Big Bang.

Scientists believe that much of the energy released at the instant of the Big Bang transformed into matter within a few microseconds (**Figure 2.24**). This matter consisted of electrons and quarks. Less than a millisecond later, the universe had expanded and “cooled” to a mere 10^{12} K, and quarks combined with one another to form neutrons and protons. Thus, in less than a second, the matter in the universe consisted of the three types of subatomic particles that would eventually make up all atoms.

Primordial Nucleosynthesis

By about four minutes after the Big Bang, the universe had expanded and cooled to 10^9 K. In this hot, dense subatomic “soup,” neutrons and protons that collided with one another began to fuse in a process called primordial nucleosynthesis. (We discuss nuclear fusion in more detail in Chapter 19.) In one step, protons (p) and neutrons (n) fused to form *deuterons* (d), which are nuclei of the deuterium {${}^{2}_{1}\mathrm{H}$) isotope of hydrogen:

In writing this equation, we follow the rules presented in Section 2.3 for writing nuclide symbols: the superscript is a mass number and the subscript is an atomic number. We use a similar convention for writing the symbols of subatomic particles, except that subscripts represent the charges on particles. For example, the symbol of the neutron is ${}^{1}_{0}\mathrm{n}$ because a neutron has a mass number of 1 and a charge of 0.

Equation 2.2 is an example of a *nuclear equation*. It is related to the chemical equations we begin working with in Chapter 3 in that it is *balanced*. This means that the sum of the masses (superscripts) of the particles to the left of the arrow is equal to the sum of the masses of the particles to the right of the arrow. Similarly, the sum of the charges (subscripts) of the particles on the left side is equal to the sum of the charges of the particles on the right side.

Deuteron formation proceeded rapidly, consuming most of the neutrons in the universe in a matter of seconds. No sooner did deuterons form than they, too, were rapidly consumed by additional collisions and fusion reactions. These processes rapidly produced a universe that consisted nearly entirely of the nuclei of hydrogen (mostly ${}^{1}_{1}\text{H}$) and helium (mostly ${}^{4}_{2}\text{He}$). However, production of the other elements through continued fusion reactions did not happen. For example, collisions between ${}^{1}_{1}\text{H}$ and ${}^{4}_{2}\text{He}$ nuclei did not produce ${}^{5}_{3}\text{Li}$, and collisions between pairs of ${}^{4}_{2}\text{He}$ nuclei did not produce ${}^{8}_{4}\text{Be}$. Why? Because these isotopes of lithium and beryllium are unstable. In fact, there are no nuclides with five or eight nucleons.

Within minutes of the Big Bang, therefore, primordial nucleosynthesis shut down, leaving an expanding and cooling universe that consisted nearly entirely of hydrogen and helium. The fact that the universe today is still 99% hydrogen and helium and that these elements occur in the same proportion predicted by physicists’ models of primordial nucleosynthesis (about 3 parts hydrogen to 1 part helium, by mass) is strong evidence in support of the theory of the Big Bang.

Stellar Nucleosynthesis

How, then, did the other elements in the periodic table form, including those that make up most of our planet? Scientists theorize that the synthesis of elements more massive than helium had to wait until nuclear fusion resumed in the first generation of stars. Inside the coalescing masses of hydrogen and helium that would turn into the first stars, the gases underwent enormous compressional heating. The nuclear furnaces that are the source of the energy in all stars were ignited as hydrogen nuclei began to fuse, making more helium nuclei.

Once nuclear fusion begins in stars, it may continue in stages. When the hydrogen at the star’s core has all fused into helium, gravity causes the core to contract, creating even higher temperatures and pressures. In the cores of large stars, helium nuclei are so densely packed that they collide three at a time. When they do, they fuse to form a nucleus that contains 6 protons and 6 neutrons, which is the most common isotope of carbon:

With the formation of ^{12}C, the barrier that had halted primordial nucleosynthesis is overcome, and the stage is set for additional fusion reactions with progressively more massive nuclei.

For billions of years, chains of fusion reactions have simultaneously fueled the nuclear furnaces of stars and produced elements as heavy as iron (**Figure 2.25**). Once the core of a star turns into iron, however, the star is in trouble because fusion reactions involving iron nuclei do *not* release energy. Instead, they *consume* it, because ^{56}Fe is the most stable nuclide in the universe. Thus, a star with an iron core has essentially run out of fuel. Its nuclear furnace goes out, and the star begins to cool and collapse into itself.

As the star collapses, compression reheats its core to temperatures above 10^9 K. At such high temperatures, nuclei begin to disintegrate into individual protons and neutrons. These individual neutrons may collide and fuse with atomic nuclei in a process called neutron capture. If a stable nucleus captures enough neutrons, it becomes unstable—that is, radioactive. For example, if a nucleus of ^{56}Fe captures three neutrons, it forms the radioactive nuclide ^{59}Fe:

The neutron *richness* of ^{59}Fe means that this radioactive nuclide spontaneously undergoes a kind of radioactive decay that reduces the ratio of neutrons to protons in its nucleus. This is called beta (β) decay because it involves the ejection of a high-energy electron, or β particle. The decay process is summarized in the following nuclear equation:

The nuclide formed in the reaction has an atomic number of 27, or one more than the radioactive isotope that produced it. This increase is the result of the decomposition of a neutron into a proton, which remains in the nucleus, and an electron (β particle) that is ejected from it. The additional proton results in an increase in atomic number. The combination of repeated neutron capture and β decay events in the cores of collapsing stars produces the most massive stable nuclides in the periodic table.

Eventually, the enormous heating that occurs when a massive star collapses produces a gigantic explosion. Cosmologists call such an event a *supernova*. In addition to finishing the job of synthesizing the elemental building blocks found in the universe—up to and including the isotopes of uranium—a supernova serves as its own element-distribution system, blasting its inventory of elements throughout its galaxy (**Figure 2.26**). The legacies of supernovas are found in the elemental composition of later-generation stars like our Sun and in the planets that orbit these stars. Indeed, all the matter in our solar system—and in us—is essentially demolition debris from ancient exploding stars.

SAMPLE EXERCISE 2.12 Integrating Concepts: Radioactive Isotopes in Medicine

Dmitri Mendeleev predicted the existence of technetium ($Z = 43$), one of the elements that was unknown in his time. Technetium has more than 30 isotopes, with mass numbers ranging from 85 to 118. Every isotope of technetium is radioactive. There are medical procedures that take advantage of this radioactivity, using ^{99}Tc to image many parts of the human body, including the brain, heart, thyroid, lungs, and kidneys (**Figure 2.27**). More than 20 million medical procedures using ^{99}Tc are performed each year. One challenge, though, is how to make ^{99}Tc available to doctors precisely where and when it is needed because it rapidly undergoes radioactive decay. The solution to this problem is to transport a more stable substance, in this case, molybdenum-99 ($Z = 42$), from which technetium-99 can be isolated. Most of the molybdenum-99 on Earth is produced from ^{235}U in nuclear reactors.

1. What are the nuclide symbols for the lightest and the heaviest isotopes of technetium?
2. How many protons, neutrons, and electrons are in a neutral atom of ^{99}Tc ?
3. When doctors need to administer ^{99}Tc to a patient, they obtain a sample of radioactive molybdenum-99 that then undergoes beta decay, forming ^{99}Tc. Write a balanced nuclear equation to show the beta decay of molybdenum-99 to form technetium-99.

Collect and Organize We are given the mass numbers of two technetium isotopes and are asked to write their complete nuclide symbols, and we need to translate the nuclide symbol ^{99}Tc into the numbers of protons, neutrons, and electrons per atom. We are also given the molybdenum isotope that decays to ^{99}Tc and are asked to write a balanced chemical equation describing the reaction.

Analyze The atomic number (*Z*) of an element is the same as the number of protons and the number of electrons in each of its atoms. The mass number (*A*) of a nuclide is the sum of the numbers of protons and neutrons in each of its nuclei. In the symbol of a nuclide, *Z* is the subscript and *A* is the superscript that precede the element symbol. Beta decay involves the ejection of high-energy electrons, ${}_{-1}^{0}\beta$, and produces nuclides with an atomic number one greater than the radionuclides undergoing decay.

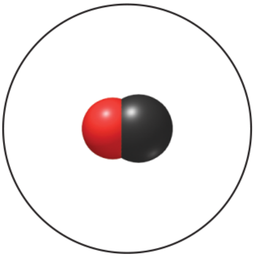
Solve

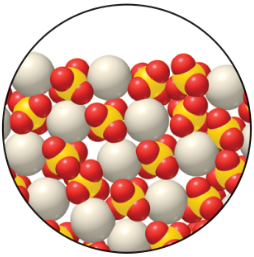
1. For the lightest isotope of Tc, $Z = 43$ and $A = 85$; for the heaviest isotope, $Z = 43$ and $A = 118$. Therefore, the two symbols are ${}_{43}^{85}\mathrm{Tc}$ and ${}_{43}^{118}\mathrm{Tc}$, respectively.
2. For ^{99}Tc: 43 protons, 56 neutrons, 43 electrons
3. ${}_{42}^{99}\mathrm{Mo} \rightarrow {}_{43}^{99}\mathrm{Tc} + {}_{-1}^{0}\beta$

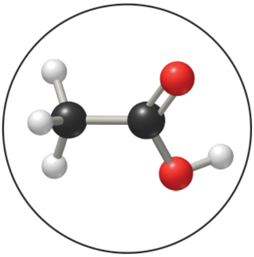
Think About It Because one of its isotopes emits radiation that can be easily detected, technetium incorporated into soluble molecules can be used to observe the flow of fluids in organisms. The thyroid is a symmetrical, butterfly-shaped gland that surrounds the trachea. It appears in Figure 2.27 as the two lobes imaged after the administration of a technetium-containing agent. The gland should be symmetrical, but one lobe is smaller than the other. The irregular uptake of the agent indicates a malfunctioning thyroid.

Glossary

quarks	elementary particles that combine to form neutrons and protons.
neutron capture	the absorption of a neutron by a nucleus.
beta (β) decay	a spontaneous process by which a neutron in a radioactive nuclide is transformed into a proton and emits a high-energy electron (β particle).
nucleosynthesis	the natural formation of nuclei because of fusion and other nuclear processes.



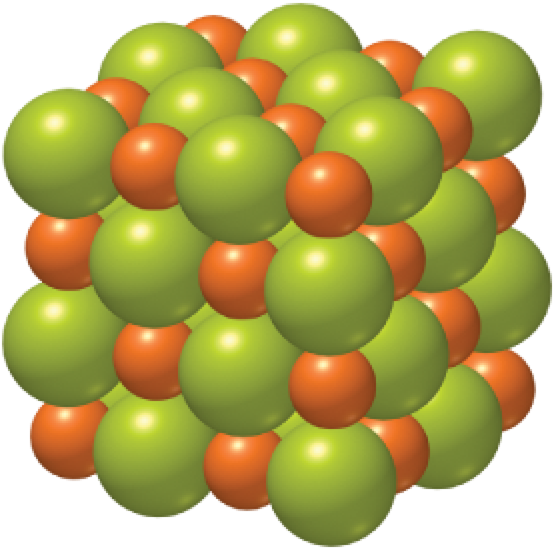




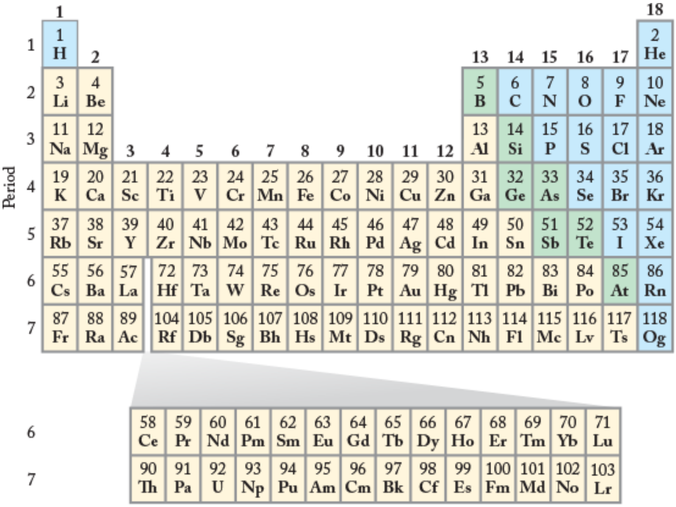
SUMMARY

LO1 Thomson’s experiments with cathode rays, Millikan’s oil-drop experiments, Rutherford’s gold-foil experiments, and studies of radioactivity by Henri Becquerel and Marie and Pierre Curie led to our understanding of atomic structure. (Sections 2.1 and 2.2)

- LO2 Atoms consist of nuclei that each contain one or more nucleons, that is, protons and neutrons. The nucleus accounts for nearly all the mass of an atom; it is surrounded by much less massive electrons, whose negative charges balance the positive charges of the protons. Unique symbols for each isotope of every element indicate the identity of an atom by showing its atomic number (the number of protons in its nucleus) and its mass number (the number of nucleons in the nucleus). (Sections 2.2 and 2.3)
- LO3 The average atomic mass of an element is the weighted average of all the isotopes of that element. It is calculated by multiplying the mass of each stable isotope by the isotope’s natural abundance and then summing these products. (Section 2.4)



- LO4 Russian chemist Dmitri Mendeleev developed a forerunner of the modern periodic table of the elements in which the elements were arranged in patterns based on their physical and chemical properties. Elements in the same vertical column are said to be in the same group. The main group (or representative) elements are in groups 1, 2, and 13–18, and the transition metals are in groups 3–12. Within the periodic table, three regions contain metals, metalloids, and nonmetals. (Sections 2.3 and 2.5)



Period	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18

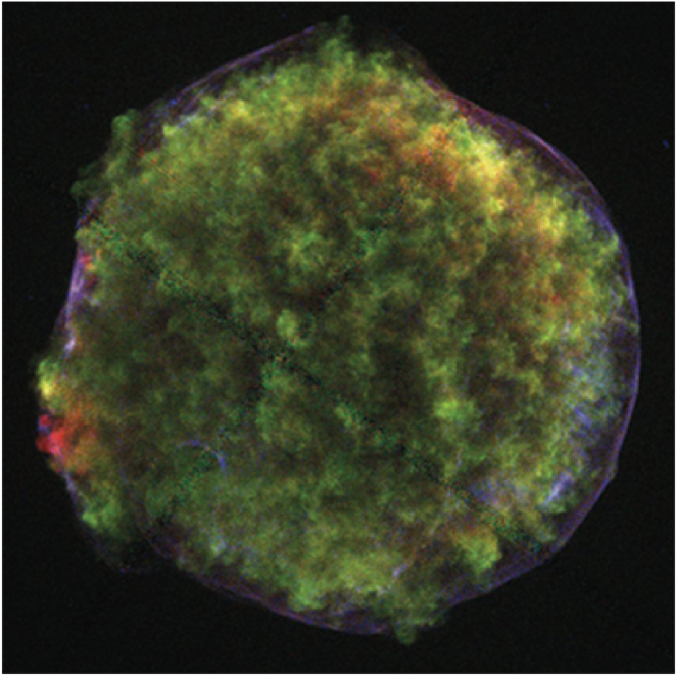
- LO5 The law of multiple proportions describes the ratio of the masses of elements in simple compounds in terms of small whole numbers. Compounds composed of pairs of metallic and nonmetallic elements tend to be ionic compounds, whereas those composed of two non- metals or metalloids tend to be molecular compounds. The empirical formula of a molecular or ionic compound gives the smallest whole-number ratio of the atoms (or ions) in it. (Section 2.6)
- LO6 Standardized naming conventions allow us to translate the names of molecular and ionic compounds into their chemical formulas, and vice versa. (Section 2.7)
- LO7 Organic compounds always contain carbon atoms and almost always contain hydrogen atoms. Different classes of organic compounds are composed of molecules with characteristic functional groups. (Section 2.8)



- LO8 During primordial nucleosynthesis, protons and neutrons fused, producing nuclei of helium. Nuclei of atoms as massive as ^{56}Fe formed when the nuclei of lighter elements fused in the cores of giant stars in a process called stellar nucleosynthesis, which continues today. Even more massive nuclei are formed by a combination of other nuclear reactions, leading to supernovas (explosions of giant stars). (Section 2.9)

PARTICULATE PREVIEW WRAP-UP

The middle compound is ionic because it contains two types of particles (one is a polyatomic ion) arranged in an extended, ordered array. The other two are molecular compounds. The images show single molecules containing atoms of two (on the left) and three (on the right) elements bonded together.

PROBLEM-SOLVING SUMMARY

Type of Problem	Concepts and Equations	Sample Exercises
Writing symbols of isotopes	Next to the element symbol, place a superscript for the mass number (A) and (if needed) a subscript for the atomic number (Z).	2.1, 2.2
Calculating the average atomic mass of an element	Multiply the mass (m) of each isotope of the element times the natural abundance (a) of that isotope converted to a decimal; then sum these products: $m_X = a_1m_1 + a_2m_2 + a_3m_3 + \ldots$ (2.1)	2.3
Locating elements in the periodic table	Use the group numbering, the period designation, and chemical properties to locate elements.	2.4
Predicting the composition of different compounds formed by the same two elements	Use the chemical formulas of the two compounds and the law of multiple proportions.	2.5
Classifying compounds as ionic and molecular	Ionic compounds contain metallic and nonmetallic elements, whereas molecular compounds contain nonmetals or metalloids.	2.6
Naming binary compounds and writing their formulas	Apply the naming rules in Section 2.7.	2.7, 2.8
Naming transition metal compounds and writing their formulas	Use Roman numerals to indicate the charge on the transition metal cation.	2.9
Naming oxoacids and compounds containing oxoanions and writing their formulas	Apply the naming rules in Section 2.7.	2.10, 2.11

VISUAL PROBLEMS

(Answers to boldface end-of-chapter questions and problems are in the back of the book.)

Alpha and beta particles emitted by a sample of pitchblende escape through a narrow channel in the shielding surrounding the sample and into an electrical field as shown in Figure P2.1. Which path in the figure corresponds to each form of radiation?

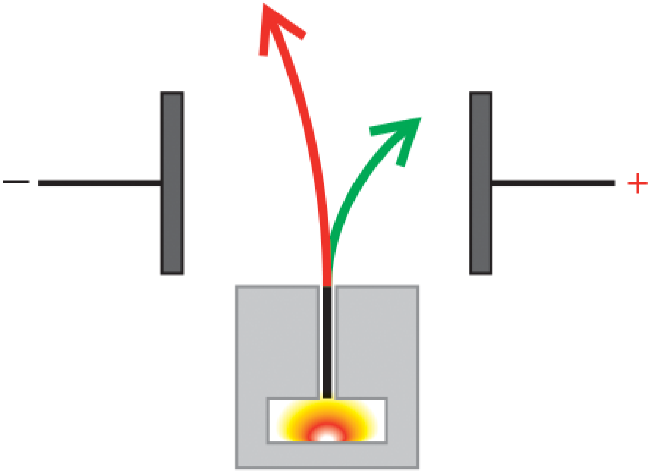


FIGURE P2.1

Does the particle that follows the red path in Figure P2.1 penetrate solid objects better than the radiation following the green path? Explain your answer.

The images in Figure P2.3 represent the nuclei of three nuclides. Assuming all the nucleons are visible, what are the symbols of these nuclides (include both mass number and atomic number).

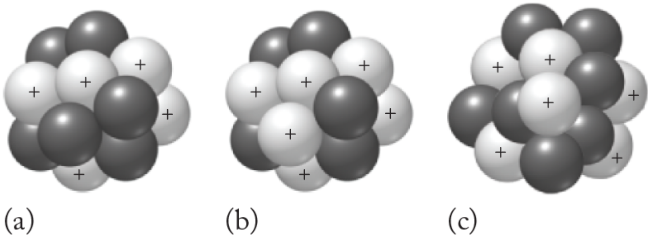

FIGURE P2.3

The images in Figure P2.4 represent the nuclei of three nuclides. Assuming all the nucleons are visible, what are the symbols of these nuclides (include both mass number and atomic number).

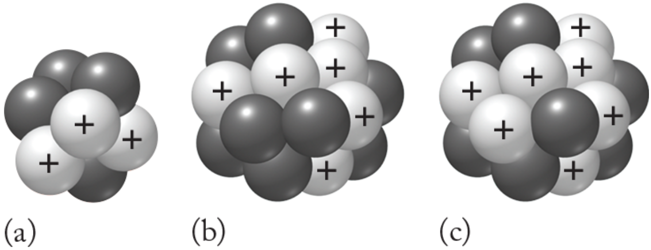

FIGURE P2.4

In Figure P2.5 the blue spheres represent nitrogen atoms and the red spheres represent oxygen atoms. The figure represents which of the following gases? (a) N_2O_3; (b) N_7O_{11}; (c) a mixture of NO_2 and NO; (d) a mixture of N_2 and O_3

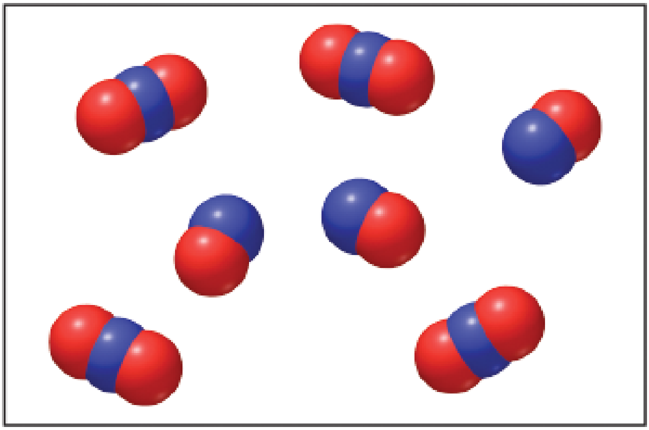

FIGURE P2.5

In Figure P2.6 the black spheres represent carbon atoms and the red spheres represent oxygen atoms. Which of the following statements about the two equal-volume compartments is or are true?

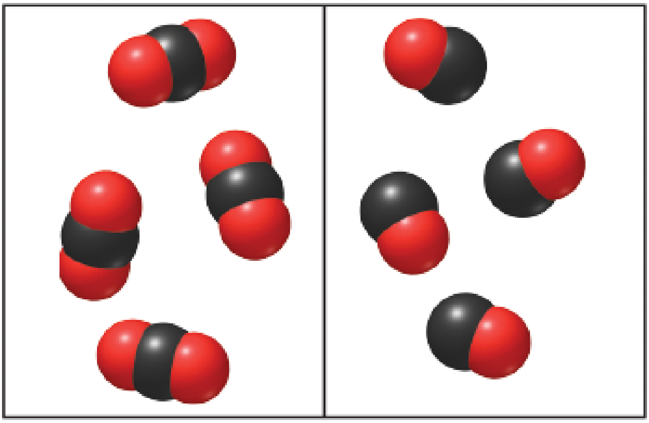

FIGURE P2.6

---

1. The compartment on the left contains CO_2; the one on the right contains CO.
2. The compartments contain the same mass of carbon.
3. The ratio of oxygen to carbon in the gas in the left compartment is twice that of the gas in the right compartment.
4. The pressures inside the two compartments are equal. (Assume that the pressures are proportional to the number of molecules in each compartment.)

Which of the highlighted elements in Figure P2.7 is (a) a reactive nonmetal, (b) a chemically inert gas, (c) a reactive metal?

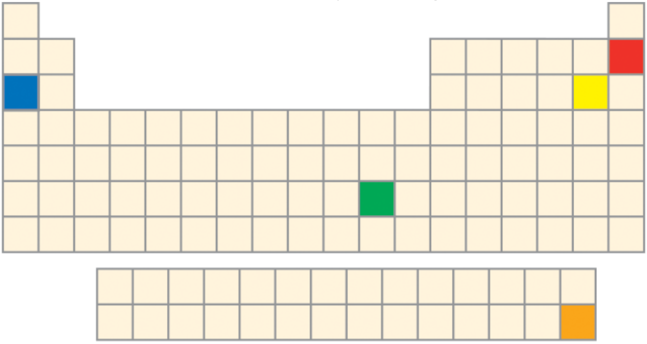

FIGURE P2.7

Which of the highlighted elements in Figure P2.8 forms monatomic ions with a charge of (a) $1+$, (b) $2+$, (c) $3+$, (d) $1-$, (e) $2-$?

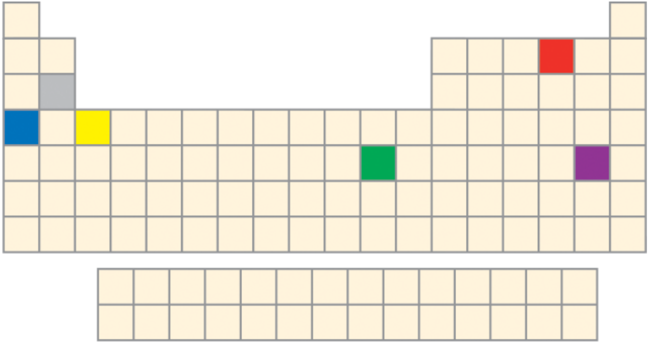

FIGURE P2.8

Which of the highlighted elements in Figure P2.9 forms an oxide with the following formula: (a) XO; (b) X_2O; (c) XO_2; (d) X_2O_3?

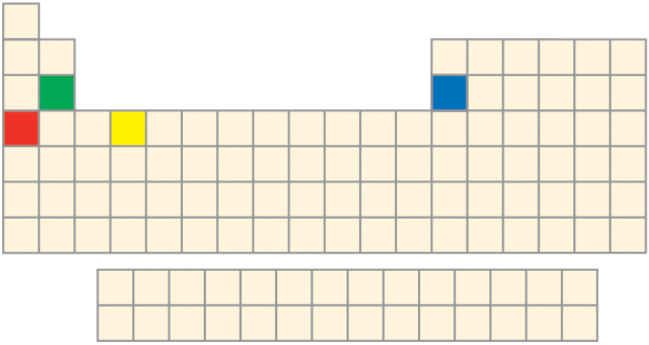

FIGURE P2.9

Which of the highlighted elements in Figure P2.10 forms an oxoanion with the following generic formula: (a) XO_4^-; (b) XO_4^{2-}; (c) XO_4^{3-}; (d) XO_3^-?

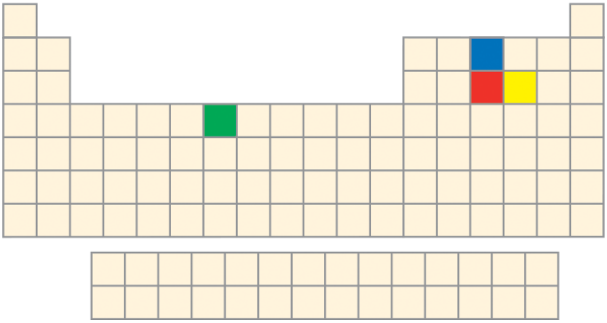

FIGURE P2.10

Which of the highlighted elements in Figure P2.11 is *not* formed by the fusion of lighter elements in the cores of giant stars?

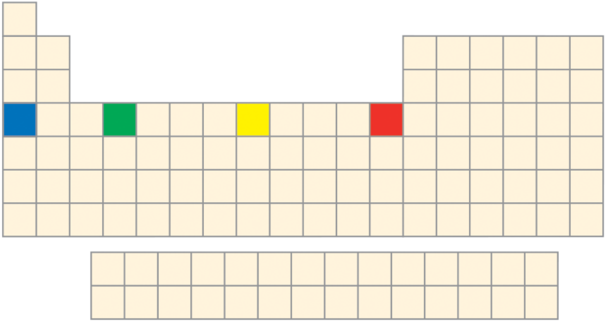

FIGURE P2.11

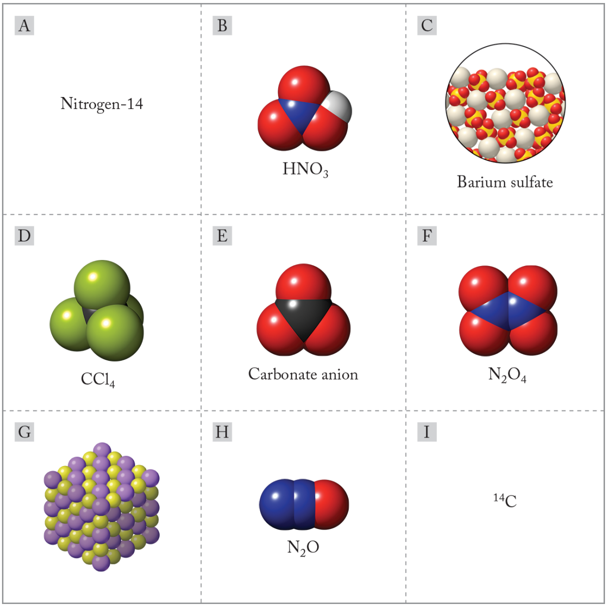
Use representations [A] through [I] in Figure P2.12 to answer questions (a)–(f).

Which 1. are molecular compounds?
Which 2. are ionic compounds?
Which 3. incorporates both covalent and ionic bonding?
Which 4. two representations demonstrate the law of multiple proportions?
Which 5. of the representations, if any, have the same empirical formula?
What 6. are the names of the substances in [D], [F], and [H]?



A
Nitrogen-14
B
HNO_3
C
Barium sulfate
D
CCl_4
E
Carbonate anion
F
N_2O_4
G
H
N_2O
I
^{14}C

FIGURE P2.12

QUESTIONS AND PROBLEMS

The Rutherford Model

Concept Review

Explain how the results of the gold-foil experiment led Rutherford to dismiss the plum-pudding model of the atom and create his own model based on a nucleus surrounded by electrons.

Had the plum-pudding model been valid, how would the results of the gold-foil experiment have differed from what Geiger and Marsden observed?

What properties of cathode rays led Thomson to conclude that they were not pure energy, but rather particles with an electric charge?

What would be observed if the charges on the plates of Millikan's apparatus (Figure 2.4) were reversed?

Isotopes and Average Atomic Mass

Concept Review

What is meant by a *weighted average*?

Explain how natural abundance percentages are related to average atomic masses.

Explain the inherent redundancy in the nuclide symbol $^{A}_{Z}X$.

How are the mass number and atomic number of a nuclide related to the number of neutrons and protons in each of its nuclei?

Use the data in the periodic table on the inside of the front cover of this book to decide which of the isotopes in each of the following pairs is more abundant. (a) ^{10}B or ^{11}B; (b) ^{6}Li or ^{7}Li; (c) ^{14}N or ^{15}N; (d) ^{20}Ne or ^{22}Ne

If the nucleus of an atom contains an equal number of neutrons and protons, is the ratio of its mass number to its atomic number greater than, less than, or equal to 1?

Problems

How many protons, neutrons, and electrons are there in the following atoms? (a) ^{14}C; (b) ^{59}Fe; (c) ^{90}Sr; (d) ^{210}Pb

How many protons, neutrons, and electrons are there in the following atoms? (a) ^{11}B; (b) ^{19}Fe; (c) ^{131}I; (d) ^{222}Rn

Fill in the missing information about atoms of the four nuclides in the following table.

Symbol	^{16}O
Number of Protons	[illegible]
Number of Neutrons	[illegible]
Number of Electrons	[illegible]
Mass Number	[illegible]

Fill in the missing information about atoms of the four nuclides in the following table.

Symbol	^{27}Al
Number of Protons	[illegible]
Number of Neutrons	[illegible]
Number of Electrons	[illegible]
Mass Number	[illegible]

The natural abundances of the two stable isotopes of boron can vary. If a sample collected from a volcanic crater lake in southeastern Australia contained 81.07% ^{11}B (mass = 11.0093 u) and 18.93% ^{10}B (mass = 10.0129 u), what is the average atomic mass of the boron in the sample? Compare your calculated result to the average atomic mass of boron listed on the inside of the front cover of this book.

The natural abundances of the two stable isotopes of lithium can vary a little. If a sample of Li is 7.714% ^{6}Li (mass = 6.015123 u) and 92.286% ^{7}Li (mass = 7.016003 u), what is the average atomic mass of the lithium in the sample? Compare your calculated result to the average atomic mass of lithium listed on the inside of the front cover of this book.

Chemistry of Mars NASA's 1997 mission to Mars included a small robot, the *Sojourner*, that analyzed the composition of Martian rocks. Magnesium oxide from a boulder dubbed "Barnacle Bill" was analyzed and found to have the following isotopic composition:

Mass (u)	Natural Abundance (%)
[illegible]	[illegible]
[illegible]	[illegible]

41.9846	11.27

If essentially all the oxygen in the Martian MgO sample is oxygen-16 (which has a mass of 15.9948 u), is the average atomic mass of magnesium on Mars the same as on Earth (24.31 u)?

Platinum has six isotopes: ^{190}Pt, ^{192}Pt, ^{194}Pt, ^{195}Pt, ^{196}Pt, and ^{198}Pt.

1. How many neutrons are there in each isotope?
2. The natural abundances of the six isotopes are 0.014% ^{190}Pt (189.96 u); 0.782% ^{192}Pt (191.96 u); 32.967% ^{194}Pt (193.96 u); 33.832% ^{195}Pt (194.97 u); 25.242% ^{196}Pt (195.97 u); and 7.163% ^{198}Pt (197.97 u). Calculate the average atomic mass of platinum and compare it with the value in the periodic table on the inside front cover.

Use the following table of abundances and masses of five naturally occurring titanium isotopes to calculate the mass of ^{48}Ti.

Symbol	Mass (u)	Natural Abundance (%)
^{46}Ti	45.95263	8.25
^{47}Ti	46.9518	7.44
^{48}Ti		73.72
^{49}Ti	48.94787	5.41
^{50}Ti	49.9448	5.18
Average	47.87	

Use the following table of abundances and masses of the three naturally occurring argon isotopes to calculate the mass of ^{40}Ar.

Symbol	Mass (u)	Natural Abundance (%)
^{36}Ar	35.96755	0.337
^{38}Ar	37.96272	0.063
^{40}Ar		99.60
Average	39.948	

The Periodic Table of the Elements

Concept Review

Mendeleev ordered the elements in his version of the periodic table according to their atomic masses instead of their atomic numbers. Why?

Why didn't Mendeleev include the noble gases in his version of the periodic table?

Mendeleev arranged the elements on the left side of his periodic table according to the formulas of the binary compounds they form with oxygen, and he used those formulas as column labels. For example, group 1 of the modern periodic table was labeled "R_2O" in Mendeleev's table, where "R" represented one of the elements in the group. What labels did Mendeleev use for groups 2, 3, and 4 of the modern periodic table?

Mendeleev arranged the elements on the right side of his periodic table according to the formulas of the binary compounds they form with hydrogen, and he used those formulas as column labels. Which groups of the modern periodic table were labeled "HR," "H_2R," and "H_3R" in Mendeleev's table, where "R" represented one of the elements in the group?

Problems

Which element is most likely to form a cation with a 3+ charge? (a) S; (b) P; (c) Be; (d) Al

Which element is most likely to form a monatomic ion with a 3− charge? (a) S; (b) P; (c) Be; (d) Al

Which ions have the same number of electrons as an atom of argon? (a) S^{2-}; (b) P^{3-}; (c) Be^{2+}; (d) Ca^{2+}

Which ions have the same number of electrons as an atom of krypton? (a) Se^{2-}; (b) As^{3-}; (c) Ca^{2+}; (d) K^{+}

Classify each of the following fifth-row elements as a metal, a metalloid, or a nonmetal: (a) Y; (b) Ag; (c) Sn; (d) Te; (e) I.

Classify each of the following fourth-row elements as a metal, a metalloid, or a nonmetal: (a) Ca; (b) Cr; (c) Cu; (d) As; (e) Br.

Classify each of the following fourth-row elements as an alkali metal, an alkaline earth metal, a transition metal, a halogen, or a noble gas: (a) Br; (b) Ca; (c) K; (d) Kr; (e) V.

Which element in the second row of the periodic table is (a) a halogen; (b) an alkali metal; (c) an alkaline earth metal; (d) a noble gas?

Elements in TNT Molecules of the explosive called TNT contain atoms of hydrogen and of the second-row elements in groups 14, 15, and 16. Which three elements are these?

Chemical Weapons Phosgene, a colorless, poisonous gas, was used as a chemical weapon during World War I. Despite its name, molecules of phosgene contain no atoms of phosphorus. Instead, they contain atoms of carbon, of the group 16 element in the second row of the periodic table, and of the group 17 element in the third row. What are the names and the atomic numbers of these last two elements?

Catalytic Converters The catalytic converters used to remove pollutants from automobile exhaust contain the compounds of several expensive elements, including those described below. Which elements are they?

1. The group 10 transition metal in the fifth row of the periodic table.
2. The transition metal whose atoms contain one less proton than the atoms of your answer to part (a).
3. The name of the transition metal with an average atomic

mass of 195.08 u.

Swimming Pool Chemistry Compounds containing chlorine have long been used to disinfect the water in swimming pools, but in recent years a compound of a less corrosive halogen has become a popular alternative disinfectant. What is the name of this fourth-row element?

Trends in Compound Formation

Concept Review

How does Dalton's atomic theory of matter explain the fact that when water is decomposed into hydrogen and oxygen gas, the ratio of the volumes of the two gases is 2:1?

Pollutants in Automobile Exhaust In the internal combustion engines that power most automobiles, nitrogen and oxygen may combine to form NO. When NO in automobile exhaust is released into the atmosphere, it reacts with more oxygen, forming NO_2, a key ingredient in smog. How do these reactions illustrate Dalton's law of multiple proportions?

Describe the types of elements that combine to form molecular compounds and the types that combine to form ionic compounds.

How do the properties of ionic compounds differ from those of molecular compounds?

Problems

Cobalt forms two sulfides: CoS and Co_2S_3. Predict the ratio of the two masses of sulfur that combine with a fixed mass of cobalt to form CoS and Co_2S_3.

Lead forms two oxides: PbO and PbO_2. Predict the ratio of the two masses of oxygen that combine with a fixed mass of lead to form PbO and PbO_2.

When 5.0 g of sulfur is combined with 5.0 g of oxygen, 10.0 g of sulfur dioxide (SO_2) is formed. What mass of oxygen would be required to convert 5.0 g of sulfur into sulfur trioxide (SO_3)?

Nitrogen monoxide (NO) is 46.7% nitrogen by mass. Use the law of multiple proportions to calculate the mass percentage of nitrogen in nitrogen dioxide (NO_2).

Fill in the missing information in the following table of monatomic ions.

Symbol	$^{34}S^{2-}$ [illegible]
Number of Protons	[illegible]
Number of Neutrons	[illegible]
Number of Electrons	[illegible]
Mass Number	[illegible]

Fill in the missing information in the following table of monatomic ions.

Symbol	$^{40}Ca^{2+}$ [illegible]
Number of Protons	[illegible]
Number of Neutrons	[illegible]
Number of Electrons	[illegible]
Mass Number	[illegible]

Which of these compounds consist of molecules, and which consist of ions? (a) P_4O_{10}; (b) $SrCl_2$; (c) MgF_2; (d) SO_3

Which of these compounds consist of molecules, and which consist of ions? (a) Mg_3N_2; (b) BaS; (c) AgCl; (d) NCl_3

Would compounds formed from each pair of elements contain covalent bonds or ionic bonds? (a) cesium and fluorine; (b) nitrogen and chlorine; (c) carbon and oxygen; (d) magnesium and oxygen

Would compounds formed from each pair of elements contain covalent bonds or ionic bonds? (a) silver and oxygen; (b) sulfur and oxygen; (c) carbon and hydrogen; (d) barium and nitrogen

Give the total number of atoms in a formula unit of these compounds: (a) $Mg(NO_3)_2$; (b) Al_2O_3; (c) $(NH_4)_2CO_3$; (d) $Ca_3(PO_4)_2$.

Give the total number of atoms in a formula unit of these compounds: (a) K_2SO_4; (b) $Sr_3(AsO_4)_2$; (C) $Fe(NO_3)_3$; (d) $In_2(SO_4)_3$.

Naming Compounds and Writing Formulas

Concept Review

Consider a mythical element X, which forms only two oxoanions: XO_2^{2-} and XO_3^{2-}. Which of the two has a name that ends in *-ite*?

Concerning the oxoanions in Problem 2.65, would the name of either of them require a prefix such as *hypo-* or *per-*? Explain why or why not.

What is the role of Roman numerals in the names of the compounds formed by transition metals?

Why do the names of the ionic compounds formed by the alkali metals and by the alkaline earth metals not include Roman numerals?

Problems

What are the names of these compounds of phosphorus and oxygen? (a) PO; (b) P_2O_3; (c) P_2O_4; (d) P_2O_5

What are the names of these compounds of chlorine and oxygen?

(a) ClO_3; (b) ClO; (c) ClO_2; (d) Cl_2O_7

What are the formulas and names of the ionic compounds containing the following pairs of elements? (a) sodium and sulfur; (b) strontium and chlorine; (c) aluminum and oxygen; (d) lithium and hydrogen

What are the formulas and names of the ionic compounds containing the following pairs of elements? (a) potassium and bromine; (b) barium and oxygen; (c) lithium and nitrogen; (d) aluminum and chlorine

Milk of Magnesia Milk of magnesia is a slurry of $Mg(OH)_2$ in water. What is the chemical name of this compound?

Smelling Salts Smelling salts are an antidote for fainting, made of $(NH_4)_2CO_3$, which smells of ammonia. What is the chemical name of $(NH_4)_2CO_3$?

What are the names of these sodium compounds? (a) Na_2O; (b) Na_2S; (c) Na_2SO_4; (d) $NaNO_3$; (e) $NaNO_2$

What are the names of these potassium compounds? (a) K_3PO_4; (b) K_2O; (c) K_2SO_3; (d) KNO_3; (e) KNO_2

What are the formulas of these compounds? (a) potassium sulfide; (b) potassium selenide; (c) rubidium sulfate; (d) rubidium nitrite; (e) magnesium sulfate

What are the formulas of these compounds? (a) rubidium nitride; (b) potassium selenite; (c) rubidium sulfite; (d) rubidium nitrate; (e) magnesium sulfite

What are the formulas of these compounds? (a) sodium hypobromite; (b) potassium sulfate; (c) lithium iodate; (d) magnesium nitrite

What are the formulas of these compounds? (a) potassium tellurite;

(b) sodium arsenate; (c) calcium selenite; (d) potassium chlorate

Which compound is magnesium nitrite? (a) Mg_3N_2; (b) $Mg(NO_2)_2$; (c) $Mg(NO_3)_2$; (d) $Mg(NO)_2$

Which compound is aluminum phosphate? (a) Al_3P_3; (b) $AlPO_3$; (c) $AlPO_4$; (d) $Al_2(PO_4)_3$

Which of these chemical names is followed by a chemical formula that does not fit the name? (a) calcium oxide, CaO; (b) lithium sulfate, $LiSO_4$; (c) barium sulfide, BaS; (d) potassium oxide, K_2O

Which of these chemical names is followed by a chemical formula that does not fit the name? (a) aluminum nitride, AlN; (b) aluminum sulfate, $Al_2(SO_4)_3$; (c) potassium chloride, KCl_2; (d) cesium sulfate, Cs_2SO_4

Ions in Blood The most abundant cations in blood plasma are Na^+, K^+, Mg^{2+}, and Ca^{2+}. Two of the principal anions are Cl^- and $H_2PO_4^-$. Write the formulas of the eight ionic compounds these cations and anions form.

Evaporation of seawater gives a mixture of sodium compounds that also contain chloride, sulfate, carbonate, and fluoride ions. Write the chemical formulas of all these compounds.

What are the names of these compounds? (a) Cr_2Te_3; (b) $V_2(SO_4)_3$; (c) $Fe_2(CrO_4)_3$; (d) MnO

What are the names of these compounds? (a) $FePO_4$; (b) $CuSO_4$; (c) Ag_2CO_3; (d) $Zn(NO_2)_2$

What are the formulas for these transition metal compounds? (a) zinc dichromate; (b) iron(III) acetate; (c) mercury(I) peroxide; (d) scandium thiocyanate

What are the formulas for these transition metal compounds? (a) mercury(II) hydroxide; (b) silver perchlorate; (c) manganese(IV) nitrate; (d) vanadium(IV) oxide

What are the formulas of the following acids? (a) hydroiodic acid; (b) hypobromous acid; (c) iodic acid; (d) hydrobromic acid

What are the formulas of the following acids? (a) selenous acid; (b) hydrocyanic acid; (c) phosphoric acid; (d) nitrous acid

What are the names of the acids with the following formulas? (a) HF; (b) $HBrO_3$; (c) HBr; (d) HIO_4

What are the names of the acids with the following formulas? (a) HF; (b) HClO; (c) $HBrO_2$; (d) $HClO_2$

Organic Compounds: A First Look

Concept Review

What classes of organic compounds contain no heteroatoms?

What classes of organic compounds contain oxygen atoms?

What classes of organic compounds contain nitrogen atoms? Does any class of organic compounds contain both oxygen and nitrogen atoms?

Are most organic compounds molecular or ionic?

Problems

To which class of organic compounds does each of the following compounds belong?

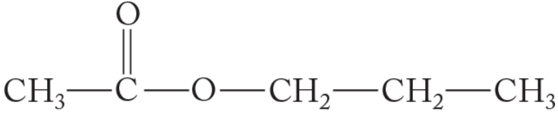
$CH_3CH_2CH_2CH_2CH_2CH_2CH_2CH_3$ (octane—a principal component of gasoline)

$HC\equiv CH$ (ethyne, also known as acetylene—used in welding torches)

To which class of organic compounds does each of the following compounds belong?

1. CH_3CH_2—O—CH_2CH_3 (once used as anesthesia for surgery)
2. $CH_3CH_2CH_2CH_2OH$ (a component of brake fluids and perfumes)

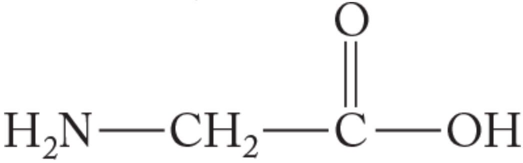
Scent of Pears What is the functional group present in propyl acetate (the substance responsible for the smell of pears; Figure P2.101)?



$CH_3-\overset{\overset{\displaystyle O}{\|}}{C}-O-CH_2-CH_2-CH_3$

FIGURE P2.101

What two functional groups are present in glycine (the simplest amino acid; Figure P2.102)?



$H_2N-CH_2-\overset{\overset{\displaystyle O}{\|}}{C}-OH$

FIGURE P2.102

Nucleosynthesis: The Origin of the Elements

Concept Review

In the history of the universe, which of these particles formed first, and which formed last? (a) deuteron; (b) neutron; (c) proton; (d) electron

Why did early nucleosynthesis last such a short time?

In the current cosmological model, the volume of the universe is increasing with time. How might this expansion affect the density of the universe?

Components of Solar Wind Most of the ions in the solar wind emitted by the Sun are hydrogen ions. The ions of which element should be next most abundant?

Additional Problems

The molecular compounds HClO, $HClO_2$, and $HClO_4$ are three of the four common oxoacids of chlorine. Give the formula and chemical name of the fourth oxoacid of chlorine.

Fusion in Stars One reaction in the process of carbon fusion in massive stars involves the combination of two carbon-12 nuclei to form the nucleus of a new element and an alpha particle. Write an equation that describes this process.

A process called neon fusion takes place in massive stars. In one of the reactions in this process, an alpha particle combines with a neon-21 nucleus to produce another element and a neutron. Write an equation that describes this process.

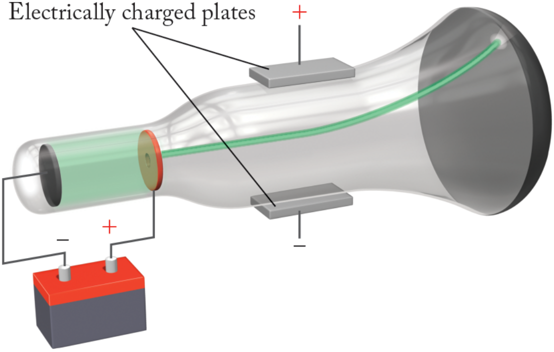


FIGURE P2.110

In April 1897, J. J. Thomson presented the results of his experiment with cathode-ray tubes (Figure P2.110) in which he proposed that the rays were beams of negatively charged particles, which he called “corpuscles.”

1. What is the name we use for these particles today?
2. Why did the beam deflect when passed between electrically charged plates, as shown in Figure P2.110?
3. If the polarity of the plates was switched, how would the position of the light spot on the phosphorescent screen change?
4. If the voltage on the plates was reduced by half, how would the position of the light spot change?

Suppose the electrically charged disks at the end of the cathode-ray tube were replaced with a radioactive source, as shown in Figure P2.111. Also suppose the radioactive material inside the source emits α and β particles. The only way for either kind of particle to escape the source is through a narrow channel drilled through a block of lead.

1. How many light spots do you expect to see on the phosphorescent screen?
2. What are their positions relative to the electrical plates, and which particle produces which spot?

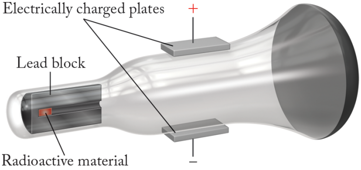

FIGURE P2.111

Suppose the radioactive material inside the source in the apparatus shown in Figure P2.111 emits protons and α particles and suppose both kinds of particles have the same velocities.

1. How many light spots do you expect to see on the phosphorescent screen?
2. What are their positions on the screen (above, at, or below the center)? Which particle produces which spot?

Early Universe Cosmologists estimate that the matter in the early universe was 75% hydrogen-1 and 25% helium-4, by mass, when atoms first formed.

1. Assuming these proportions are correct, what was the ratio of hydrogen to helium *atoms* in the early universe?
2. The ratio of hydrogen to helium atoms in our solar system is slightly less than 10:1. Compare this value with the value you calculated in part (a).
3. Propose a hypothesis that accounts for the difference in composition between the solar system and the early universe.
4. Describe an experiment that would test your hypothesis.

Emergency Air Supply Potassium forms three compounds with oxygen: K_2O (potassium oxide), K_2O_2 (potassium peroxide), and KO_2 (potassium superoxide). Elemental potassium is rarely encountered; it reacts violently with water and is very corrosive to human tissue. Potassium superoxide is used in self-contained breathing apparatuses as a source of oxygen for use in mines, submarines, and spacecraft. Potassium peroxide binds carbon dioxide and is used to scrub (remove) toxic CO_2 from the air in submarines. Predict the ratio of the masses of oxygen that combine with a fixed mass of potassium in K_2O, K_2O_2, and KO_2.

Bronze Age Historians and archaeologists often apply the term “Bronze Age” to the period in Mediterranean and Middle Eastern history when bronze was the preferred material for making weapons, tools, and other metal objects. Ancient bronze was prepared by blending molten copper (88% by mass) and tin (12% by mass) into a mixture called an alloy. What is the ratio of copper to tin atoms in a piece of bronze with this composition?

In his version of the periodic table, Mendeleev arranged elements according to the formulas of the compounds they formed with hydrogen and oxygen. The elements in one of his eight groups formed compounds with the generic formulas MH_3 and M_2O_5, where M was the symbol of an element in the group. Which Roman numeral did Mendeleev assign to this group?

In the Mendeleev table in Figure 2.11, there are no symbols for elements with predicted atomic masses of 44, 68, and 72.

1. Which elements are these?
2. Mendeleev anticipated the later discovery of these three elements and gave them the tentative names ekaaluminum, ekaboron, and ekasilicon, reflecting the probability that their properties would resemble those of aluminum, boron, and silicon, respectively. What are the modern names of ekaaluminum, ekaboron, and ekasilicon?
3. When were these elements finally discovered? (*Hint*: Consult a reference such as webelements.com.)

In chemical nomenclature, the prefix *thio-* is used to indicate that a sulfur atom has replaced an oxygen atom in the structure of a molecule or a polyatomic ion.

1. With this rule in mind, write the formula for the thiosulfate ion.
2. What is the formula of sodium thiosulfate?

There are two stable isotopes of gallium. Their masses are 68.92558 u and 70.9247050 u. If the average atomic mass of gallium is 69.7231 u, what is the natural abundance of the lighter isotope?

There are two stable isotopes of bromine. Their masses are 78.9183 u and 80.9163 u. If the average atomic mass of bromine is 79.9091 u, what is the natural abundance of the heavier isotope?

Using the information in the previous question:

1. Predict the possible masses of individual molecules of Br_2.
2. Calculate the natural abundance of molecules with each of the masses predicted in part (a) in a sample of Br_2.

There are three stable isotopes of magnesium. Their masses are 23.9850 u, 24.9858 u, and 25.9826 u. If the average atomic mass of magnesium is 24.3050 u and the natural abundance of the lightest isotope is 78.99%, what are the natural abundances of the other two isotopes?

Write the names and formulas of the following compounds from this list of elements: Li, Fe, Al, O, C, and N.

1. A molecular substance AB_2, where A is a group 14 element and B is a group 16 element
2. An ionic compound C_3D, where C is a group 1 element and D is a group 15 element

Write the chemical symbol of each of the following species: (a) a cation with a mass number of 24, an atomic number of 12, and a charge of 2+; (b) a member of group 15 that has a charge of 3+, 48 electrons, and 70 neutrons; (c) a noble gas atom with 48 neutrons.

Predict some physical and chemical properties of radium (Ra). Predict the melting points of $RaCl_2$ and RaO. (*Hint*: Research the melting points of the other alkaline earth element chlorides and oxides.)

From their positions in the periodic table, predict which of the following elements would be good electrical conductors: Ti, Ne, N, Ag, Tb, Br, and Mo.

Argon has a larger average atomic mass than potassium, yet it is placed before potassium in the modern periodic table. Explain.

It takes nearly twice the energy to remove an electron from a helium atom as it does to remove an electron from a hydrogen atom. Propose an explanation for this.

Glossary

radioactivity
: the spontaneous emission of high-energy radiation and particles by materials.

nucleon
: either a proton or a neutron in a nucleus.

proton
: a positively charged subatomic particle present in the nucleus of an atom.

neutron
: an electrically neutral (uncharged) subatomic particle found in the nucleus of an atom.

electron
: a subatomic particle that has a negative charge and little mass.

isotopes
: atoms of the same element that contain different numbers of neutrons.

average atomic mass
: a weighted average of the masses of all the isotopes of an element, calculated by multiplying the natural abundance of each isotope by its mass in atomic mass units and then summing these products.

natural abundance
: the proportion of an isotope, usually expressed in percent, relative to all the isotopes of that element in a natural sample.

periodic table of the elements
: a chart of the elements arranged in order of their atomic numbers and in a pattern based on their physical and chemical properties.

group
: all the elements in the same column of the periodic table; also called *family*.

element

a pure substance that cannot be separated into simpler substances.

transition metals

the elements in groups 3 through 12 of the periodic table.

metals

the elements on the left side of the periodic table that are typically shiny solids that conduct heat and electricity well and are malleable and ductile.

metalloids (also called semimetals)

the elements along the border between the metals and nonmetals in the periodic table; they have some metallic and some nonmetallic properties.

nonmetals

the elements with properties opposite those of metals, including poor conductivity of heat and electricity.

law of multiple proportions

the principle that, when two masses of one element react with a given mass of another element to form two different compounds, the two masses of the first element have a ratio of two small whole numbers.

ionic compound

a compound composed of positively and negatively charged ions held together by electrostatic attraction.

molecular compound

a compound composed of molecules that contain the atoms of two or more elements covalently bonded together.

empirical formula

a formula showing the smallest whole-number ratio of the elements in a compound.

organic compound

a compound composed of molecules containing carbon combined with hydrogen and other elements, such as nitrogen, oxygen, phosphorus, and sulfur.

functional group

a group of atoms in the molecular structure of an organic compound that imparts characteristic chemical and physical properties.

nucleus

the positively charged center of an atom that contains nearly all the atom’s mass.

atomic number (Z)

the number of protons in the nucleus of an atom.

mass number (A)

the number of nucleons in an atom.

main group elements (also called representative elements)

the elements in groups 1, 2, and 13 through 18 of the periodic table.

main group elements (also called representative elements)

the elements in groups 1, 2, and 13 through 18 of the periodic table.

nucleosynthesis

the natural formation of nuclei because of fusion and other nuclear processes.

WILDFIRE: THE RESULT OF UNCONTROLLED COMBUSTION The principal products of combustion of wood and fossil fuels are carbon dioxide and water.

Mass, Formulas, and Reactions

PARTICULATE REVIEW

Molecules and Names

In Chapter 3 we examine the composition of pure substances and explore how the quantities of reactants and products in chemical reactions are related. Unlike today's atmosphere, which is mostly elemental nitrogen and oxygen, Earth's early atmosphere consisted predominantly of the compounds shown here.

- Name these compounds.

  (Review Section 2.7 if you need help.)

(Answers to Particulate Review questions are in the back of the book.)

PARTICULATE PREVIEW

How Many Particles?

Combustion can be uncontrolled, as in the fire above, or a controlled reaction used for heating and cooking. Methane, the principal component of natural gas, undergoes a combustion reaction with oxygen. As you read Chapter 3, look for ideas that will help you answer these questions:

- How many oxygen molecules are necessary to completely react with these methane molecules?
- Identify the products of this reaction.
- Draw all the molecules of product formed in this reaction.

Learning Outcomes

- LO1 Use molar mass and the Avogadro constant to make conversions among mass, number of particles, and number of moles

  Sample Exercises 3.1, 3.2, 3.3, 3.4, 3.5, 3.6, 3.7

- LO2 Write balanced chemical equations to describe chemical reactions

  Sample Exercises 3.8, 3.9, 3.10, 3.11

- LO3 Use balanced chemical equations and molar masses to relate the quantities of reactants consumed and the quantities of products formed

  Sample Exercises 3.12, 3.13

- LO4 Identify the limiting reactant in a chemical reaction

  Sample Exercises 3.14

- LO5 Calculate the theoretical and percent yields in a chemical reaction

  Sample Exercises 3.15, 3.16, 3.17

- LO6 Convert between the chemical formula and percent composition of a compound

  Sample Exercises 3.18, 3.19, 3.20

- LO7 Determine the molecular formula of a compound from its empirical formula and molar mass

  Sample Exercise 3.21

- LO8 Use data from combustion analysis to determine the empirical formula of a substance

  Sample Exercises 3.22, 3.23

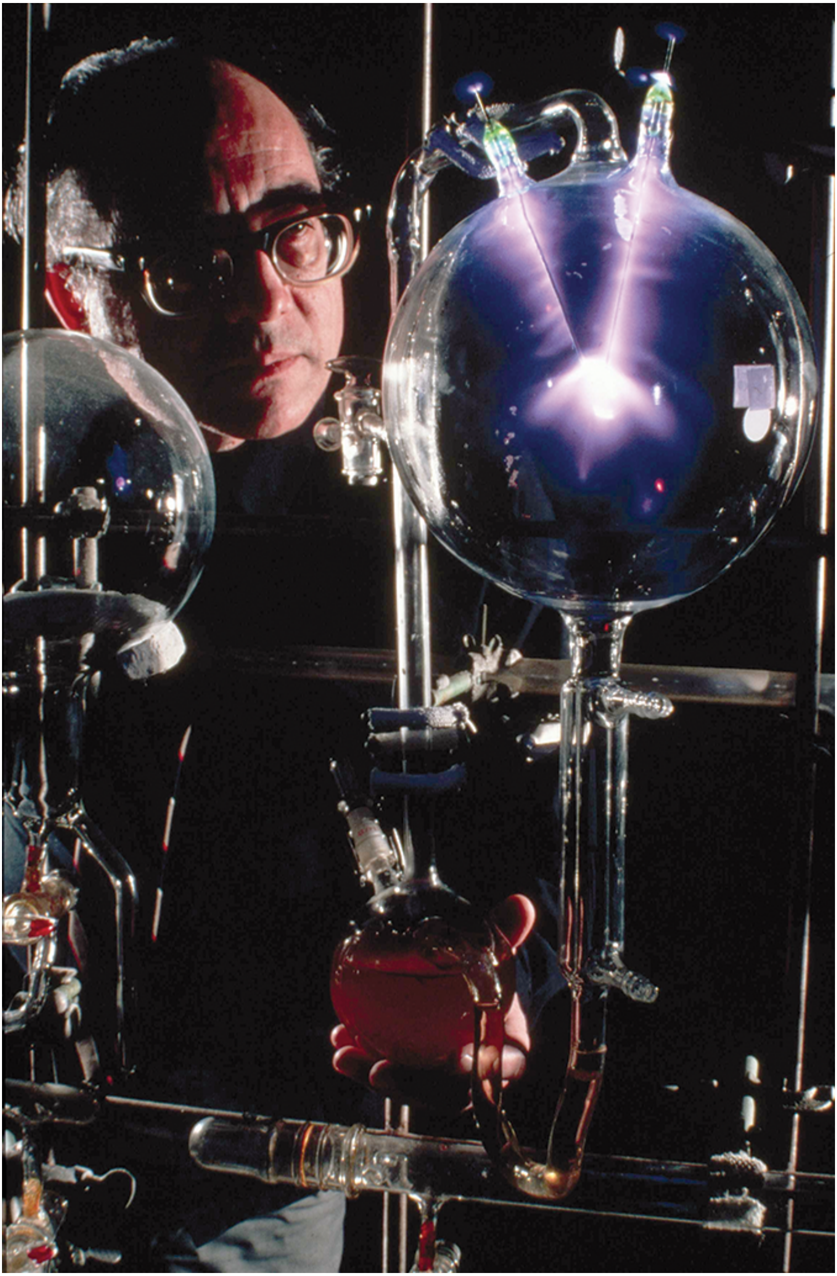

FIGURE 3.1 The apparatus used by Miller (shown) and Urey to simulate the synthesis of amino acids in the atmosphere of early (prebiotic) Earth. Discharges between the tungsten electrodes were

meant to provide the sort of energy that might have come from lightning.

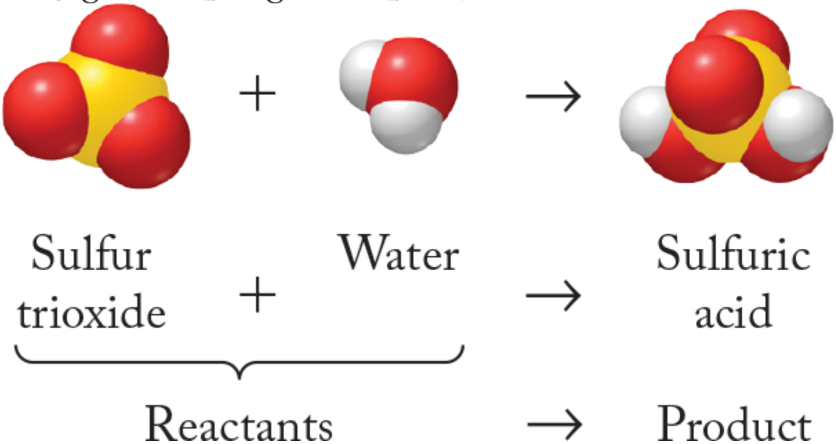

FIGURE 3.5 In this combination reaction, a molecule of SO_3 and a molecule of H_2O form a molecule of H_2SO_4.

$$Fe_2O_3(s) + 3\ H_2SO_4(aq) \rightarrow 3\ H_2O(\ell) + Fe_2(SO_4)_3(aq) \qquad (3.2)$$

3.1 Air, Life, and Molecules

In Chapter 2 we described how elements are synthesized in the cores of giant stars and dispersed throughout galaxies when the stars explode as supernovas. The dispersed elements become the building blocks of other stars and planets. As our solar system formed, the inner planets—Mercury, Venus, Earth, and Mars—were rich in nonvolatile elements such as iron, silicon, magnesium, and aluminum. Earth was also rich in oxygen—in the form of stable compounds with these and other elements. These compounds formed the rocks and minerals of Earth’s crust and an early atmosphere. As Earth cooled, atmospheric water vapor condensed into torrential rains that filled up depressions in the crust, forming the first oceans.

How could the substances in lifeless rocks and air or dissolved in primordial seas have combined to become the organic building blocks of life—compounds like simple sugars, amino acids, and the molecules that form DNA? No one knows for sure, but in the early

1950s Nobel Prize winner Harold Urey (1893–1981) and his student Stanley Miller (1930–2007) tested this hypothesis by assembling a mixture of gases believed to have been present in Earth's early (prebiotic) atmosphere. Urey and Miller subjected that mixture of gases to an electric current, simulating the lightning that would have been prevalent on early Earth (**Figure 3.1**). The resulting chemical reactions produced several amino acids, the building blocks of proteins. Samples from additional experiments by Miller in an apparatus simulating the composition of gases from a volcanic eruption were reanalyzed in 2007, and more than 20 amino acids were detected.

Amino acids have also been found in meteorites, which have bombarded Earth since it formed. Extensive analyses of the Murchison meteorite, which landed in Australia in 1969, showed that it contains many of the same amino acids synthesized in the Miller–Urey experiments. Regardless of whether important precursors to biological compounds were synthesized throughout the early atmosphere, formed in the localized environment around volcanic eruptions, or arrived on Earth in meteors, current thinking favors an early Earth with a primitive atmosphere and an ocean of water that provided an environment conducive to the synthesis of the molecules of life.

These scientific theories about the origin of life from simple inorganic molecules and the evidence that supports them are the product of research carried out in the 20th and 21st centuries. In the early 19th century, when molecular science was in its infancy, scientists believed that organic compounds could only be made by living organisms. In addition, the prevailing understanding held that chemical compounds were different only because they had different elemental compositions. A serendipitous experiment by Friedrich Wöhler (1800–1882) in 1828 led to the demise of both ideas and to their replacement with a view of matter that is a cornerstone of modern molecular science.

Wöhler attempted to synthesize the compound ammonium cyanate (NH_4NCO; **Figure 3.2a, b**) by using silver cyanate (AgNCO) and ammonium chloride (NH_4Cl). The product of his reaction demonstrated none of the chemical or physical properties of cyanates. After several other attempts at synthesis, he established that the white crystals produced by the reaction were urea (H_2NCONH_2; **Figure 3.2c**). At that time, urea was known only as a material isolated from urine—that is, the product of a living being. Wöhler famously reported to his scientific mentor Jöns Jacob Berzelius (1779–1848) that he had succeeded in making urea "without the intervention of a kidney." This result and others like it ultimately led to the modern definition of organic compounds (Chapter 2)—namely, compounds of carbon and hydrogen, often including other elements—and to the understanding that organic compounds identical to those found in living systems can be made in the laboratory.

Wöhler's result had another very important consequence. The formulas for ammonium cyanate and urea, when written to simply illustrate their composition, are both CH_4N_2O. Thus, two different substances can have the same atomic composition. Scientists ultimately reasoned that the *arrangement* of atoms within the molecules of each compound must be different. As a result, chemical substances must be defined not only by the number and kind of atoms in their molecules but also by the arrangement of those atoms. Composition and arrangement both matter. Berzelius called urea and ammonium cyanate isomers (literally, "same units"), which is the term still used to describe two or more different compounds with the same molecular formula.

Here in Chapter 3 we begin with a molecular view of the physical processes and chemical reactions that may have occurred on early Earth. We explore how the quantities of substances produced and consumed in chemical reactions are related. Then we examine the analytical methods that reveal the composition of pure substances. Finally, we consider a class of chemical reactions that consume oxygen and a fuel, liberating energy—including the energy necessary for life. We concentrate on the quantitative aspects of identifying chemical substances and their reactions but keep Wöhler's result in mind: how the atoms within molecules are arranged matters, too. We address the important issue of how atoms connect to each other and the resulting shapes of molecules in detail in Chapters 8 and 9.

Chemical Reactions and Earth's Early Atmosphere

The Earth that formed 4.6 billion years ago was a hot, molten sphere that gradually separated into distinct regions based on differences in density and melting point. The densest elements, notably iron and nickel, sank to the center of the planet. A less dense mantle, rich in compounds containing aluminum, magnesium, silicon, and oxygen, formed around the core. As time passed and Earth cooled, the mantle fractionated further, allowing a solid crust to form from the components of the mantle that were the least dense and had the highest melting points. The core also separated into a solid inner core and a molten outer core. **Figure 3.3** shows the elemental compositions of these layers.

Earth's early crust was torn by the impact of asteroids and widespread volcanic activity. The gases released by these impacts and eruptions generated a primitive atmosphere with a chemical composition different from that of the air we breathe now. Current research suggests that the early atmosphere of Earth was nearly devoid of molecular oxygen (O_2) yet was rich in oxygen-containing compounds, including carbon dioxide (CO_2), carbon monoxide (CO), and water vapor (H_2O). Minor components of the atmosphere included hydrogen (H_2), methane (CH_4), and hydrogen sulfide (H_2S). Oxides of nitrogen and additional CO may have arisen when the atmosphere was heated during bombardment by large meteorites, whereas traces of other volatile oxides, including sulfur dioxide (SO_2) and sulfur trioxide (SO_3), may have resulted from volcanic activity. Today, the most abundant gases released by volcanoes like Mount Shiveluch in Russia are water vapor, CO_2, and SO_2 (**Figure 3.4**).

Sometimes these compounds in Earth's prebiotic atmosphere combined to make substances with more elaborate molecular structures. For example, sulfur trioxide gas and water vapor are the reactants that combine to form liquid sulfuric acid, H_2SO_4, as a product (**Figure 3.5**). The reaction between SO_3 and H_2O is an example of a combination reaction, a reaction in which two (or more) substances combine to form one product. We use the formulas of the reactants and products in a chemical equation to describe the reaction:

An important feature of any chemical equation is that it is *balanced*: every atom that is present in the reactants is also present in the products. This conservation of atoms means that there is also a conservation of mass: the sum of the masses of the reactants always equals the sum of the masses of the products. Keep in mind that chemical equations do not explain *how* or *why* reactions occur. They just tell us how the quantities of reactants and products are related.

CONNECTION In Section 1.2 we defined a *chemical reaction* as the transformation of one or more substances into different substances, and we used *chemical formulas* in a *chemical equation* to describe this transformation.

The sulfuric acid that formed in Earth's early atmosphere eventually fell to the planet's surface as highly acidic rain. This rain landed on a crust made up mostly of metal oxides and metalloid oxides, including the mineral hematite, Fe_2O_3. When that sulfuric acid mixed with hematite, another chemical reaction took place—one that produced slightly water-soluble iron(III) sulfate, $Fe_2(SO_4)_3$, and liquid water. This reaction is described by the following chemical equation:

CONNECTION In Section 2.9 we wrote balanced *nuclear equations* in terms of both mass and charge.

The "3"s in front of both H_2SO_4 and H_2O are coefficients that balance the number of atoms of each element on both sides of the reaction arrow—something we explore in Section 3.3. The absence of a coefficient in front of Fe_2O_3 and $Fe_2(SO_4)_3$ is the same as having a coefficient of "1" in front of them. The chemical formula itself indicates the composition of one molecule (or one formula unit) of the substance. As we explain

in Section 3.2, the chemical formula also indicates the number of *moles* of each element in one *mole* of a compound.

Glossary

isomers	compounds with the same molecular formula but different arrangements of the atoms in their molecules.
reactant	a substance consumed during a chemical reaction.
product	a substance formed during a chemical reaction.
combination reaction	a reaction in which two (or more) substances combine to form one product.

3.2 The Mole

Equation 3.1 describes a chemical reaction between one molecule of sulfur trioxide and one molecule of water. In our macroscopic world, chemists rarely work with individual atoms or single molecules because they are too small to manipulate easily. Instead, we usually deal with quantities of reactants and products large enough to see and work with comfortably. Such measurable quantities contain enormous numbers of particles—atoms, molecules, or ions—so we need a unit that can relate measurable quantities of substances to the quantities of particles they contain. That unit is the mole (mol), the SI base unit for expressing quantities of substances (see Table 1.2).

One mole of any pure substance is defined as the amount of it that contains exactly $6.02214076 \times 10^{23}$ characteristic particles of the substance, for example, atoms of an element, molecules of a molecular substance, formula units of an ionic compound. When used in calculations this very large value is called the Avogadro constant (N_A) after the Italian scientist Amedeo Avogadro (1776–1856), whose research enabled other scientists to accurately determine the atomic masses of the elements. We round off the Avogadro constant to four significant figures, 6.022×10^{23} particles/mol throughout this book. One mole of water contains 6.022×10^{23} particles—in this case, molecules of water. To put this quantity in perspective, 1 mole of basketballs would fill an empty sphere the size of Earth, but 1 mole of water molecules occupies a volume of roughly 15 mL (i.e., one tablespoon).

Multiplying a number of moles of a substance by the Avogadro constant produces the number of particles in that many moles. For example, a 1 L bottle of seltzer water contains 55 moles of H_2O. The number of molecules of water in that 1 L bottle is

The use of this conversion factor is illustrated in **Figure 3.6**, and one-mole quantities of some common elements are shown in **Figure 3.7**.

SAMPLE EXERCISE 3.1 Converting Number of Moles into Number of Particles LO1

It’s not unusual for the polluted air above a large metropolitan area to contain as much as 5×10^{-10} moles of SO_2 per liter of air. How many molecules of SO_2 are there per liter of air?

Collect and Organize The problem gives the number of moles of SO_2 per liter of air. We want to find the number of molecules of SO_2 in 1 L. There are 6.022×10^{23} particles in 1 mole.

Analyze We convert the number of moles/liter into the number of molecules/liter by multiplying by 6.022×10^{23} molecules/mole:

We can estimate the answer using an approximate value of the Avogadro constant (about 6×10^{23}) and the number of moles of SO_2 (5×10^{-10}). The product of the two is 3×10^{14}.

Solve The number of SO_2 molecules per liter of air is

Think About It The result tells us that a tiny fraction of 1 mole of a molecular substance (10^{-10}) is equivalent to a very large number of molecules (10^{14}), which makes sense given the immensity of the Avogadro constant (between 10^{23} and 10^{24}).

Practice Exercise If 1.0 mL of seawater contains about 2.5×10^{-14} moles of dissolved gold, how many atoms of gold are in that volume of seawater?

(Answers to Practice Exercises are in the back of the book.)

SAMPLE EXERCISE 3.2 Relating Formulas, Moles, and Particles LO1

Dental fillings contain compounds with the formulas Ag_2Hg_3, Ag_3Sn, and Sn_8Hg (**Figure 3.8**). Which compound contains the most atoms per mole? How many atoms of silver are there in 1 mole of Ag_3Sn?

Collect, Organize, and Analyze We are given the formulas of three compounds: Ag_2Hg_3, Ag_3Sn, and Sn_8Hg. A chemical formula indicates the number of moles of each element in 1 mole of that compound. The number of atoms in a mole of *any* element is defined by the Avogadro constant: $N_A = 6.022 \times 10^{23}$ atoms/mol.

Solve From the formulas of the three compounds we have:

- 1 mole of Ag_2Hg_3 contains 2 moles of silver and 3 moles of mercury, or $2 + 3 = 5$ total moles of atoms.
- 1 mole of Ag_3Sn contains 3 moles of silver and 1 mole of tin, or $3 + 1 = 4$ total moles of atoms.
- 1 mole of Sn_8Hg contains 8 moles of tin and 1 mole of mercury, or $8 + 1 = 9$ total moles of atoms.

Thus, 1 mole of Sn_8Hg contains the greatest number of atoms:

The number of atoms of Ag per mole of Ag_3Sn is:

Think About It Chemical formulas reveal the number of moles of each element per mole of that compound. When we compare two compounds, their chemical formulas allow us to quickly determine the relative numbers of each type of atom.

Practice Exercise How many electrons are in a 1-ounce gold coin (**Figure 3.9**) that contains 0.143 mol of pure gold?

(Answers to Practice Exercises are in the back of the book.)

The mole enables us to calculate the number of particles in any sample of a given substance from the known (or measured) mass of the sample. We can do this because the mole represents a fixed number of particles (the Avogadro constant). One useful analogy is to compare quantities of different fruits. A dozen grapes and a dozen apples have very different masses, but each contains 12 pieces of fruit (**Figure 3.10**). Indeed, the mole is sometimes referred to as “the chemist’s dozen.”

CONCEPT TEST

How does a unit of measure such as a gross (144 units) relate to the concept of the mole?

(Answers to Concept Tests are in the back of the book.)

Molar Mass

The mole provides an important link between the values of atomic mass in the periodic table and the masses of macroscopic quantities of elements and compounds. Recall from Section 2.4 that the mass value listed for each element in the periodic table is the average atomic mass of the atoms of the element, expressed in unified atomic mass units (u) or daltons (Da). That same value is also the mass of 1 mole of atoms of that element expressed in grams. Thus, the average mass of one atom of helium is 4.003 u, and the mass of 1 mole of helium is 4.003 g. The mass in grams of 1 mole of any pure substance is called its molar mass ($\mathscr{M}$). Thus, the molar mass of helium is 4.003 g/mol (**Figure 3.11**). This numerical equality is not a coincidence: the value of N_A was defined to create an equality between the average atomic mass (u) of any element in the periodic table and its molar mass in g/mol.

Because the mass of electrons is insignificant compared with that of protons and neutrons (Table 2.1), the mass of an ion (e.g., Na^+ or Cl^-) is essentially the same as the mass of the corresponding atom, even though cations have fewer electrons than neutral atoms and anions have more.

Molar mass is an extremely useful conversion factor that allows us to convert between the mass of a sample of any substance and the number of moles in that sample or to convert a quantity in moles to an equivalent mass in grams. Although chemical reactions take place between particles (i.e., atoms, molecules, and ions), in the laboratory we almost always measure the *masses* of products and reactants.

SAMPLE EXERCISE 3.3 Converting Mass into Number of Moles LO1

The active ingredient in many antacid tablets is calcium carbonate. Some of these tablets contain 0.400 g of calcium (as Ca^{2+} ions). How many moles of calcium are in each tablet?

Collect, Organize, and Analyze We are given the mass of Ca^{2+} ions in each tablet, and asked to convert this mass into an equivalent number of moles of calcium. We can convert a mass of Ca^{2+} in grams into an equivalent quantity in moles by dividing by the molar mass of Ca, which is 40.08 g/mol to four significant figures.[1]

As noted in the text, the tiny mass of an electron means that the mass of a monatomic ion is not significantly different from the mass of its parent atom. The ratio of the mass of Ca^{2+} ions in the sample (0.400 g) to the molar mass of Ca (about 40.1 g/mol) is about 0.01, so our answer should be about 0.01 mol.

Solve

Think About It We predicted that the antacid tablet contained about 0.01 mol of calcium, and that prediction was very close to the calculated value.

Practice Exercise The mass of the diamond in **Figure**

3.12 is 3.25 carats (1 carat = 0.200 g). Diamonds are nearly pure carbon. How many moles of carbon are in the diamond?

(Answers to Practice Exercises are in the back of the book.)

SAMPLE EXERCISE 3.4 Converting Number of Moles into Mass LO1

A helium balloon sold at an amusement park contains 0.462 mol He. How many grams of He are in the balloon?

Collect, Organize, and Analyze We are asked to convert 0.462 mol He into g He. We will need to use the molar mass of helium, 4.003 g/mol, to convert from moles to grams:

Because the balloon contains nearly $\frac{1}{2}$ mole of helium, the answer should be a little less than half of 4, or about 2 g.

Solve

Think About It We predicted that the balloon contained a little less than 2 g He, and that prediction turned out to be correct.

Practice Exercise How many grams of gold are there in 0.250 mol of gold?

(Answers to Practice Exercises are in the back of the book.)

CONCEPT TEST

Which contains more atoms: 1 gram of gold (Au) or 1 gram of silver (Ag)?

(Answers to Concept Tests are in the back of the book.)

Molecular Masses and Formula Masses

The molecular mass of a molecular compound is the sum of the atomic masses of the atoms in that molecule. Because atomic masses are given in unified atomic mass units, molecular masses are also reported in u. Thus, the molecular mass of sulfur trioxide, SO_3, is the sum of the masses of 1 sulfur atom and 3 oxygen atoms (**Figure 3.13**):

$$32.06 \text{ u} + (3 \times 16.00 \text{ u}) = 80.06 \text{ u}$$

Just as the molar mass of an element in grams per mole is numerically the same as the atomic mass of one atom of the element in unified atomic mass units (Figure 3.11), the molar mass of a molecular compound in grams per mole is numerically the same as its molecular mass in unified atomic mass units. Thus, the molar mass of SO_3 is 80.06 g/mol (Figure 3.13).

As with atomic masses, we can use the concept of moles to scale from molecular masses to molar masses, which are quantities that are large enough to measure and manipulate in the laboratory. For example, the molar mass of SO_3 in grams per mole is the sum of the masses of 1 mole of sulfur atoms and 3 moles of oxygen atoms:

$$\mathscr{M}_{SO3} = 32.06 \text{ g/mol} + 3(16.00 \text{ g/mol}) = 80.06 \text{ g/mol}$$

The concept of molar mass applies not only to molecular compounds but also to ionic compounds. For example, 1 mole of BaS contains 1 mole (137.33 g) of Ba^{2+} ions and 1 mole (32.06 g) of S^{2-} ions. Therefore, the molar mass of BaS is

$$\mathscr{M}_{BaS} = 137.33 \text{ g/mol} + 32.06 \text{ g/mol} = 169.39 \text{ g/mol}$$

There are no discrete molecules of BaS. It is an ionic compound, so its crystals consist of ordered arrays of cations and anions (**Figure 3.14**). The formula unit defines the smallest integer ratio of positive and negative ions (1:1, in this case) that describes the composition of an ionic compound. The mass of one formula unit of an ionic compound is called its formula mass, which is analogous to the molecular mass of a molecular compound. **Figure 3.15** summarizes how to use the Avogadro constant and molar mass to interconvert quantities of elements or compounds expressed in grams, moles, or numbers of particles.

CONNECTION In Section 2.6 we defined the composition of an ionic compound in terms of the formula unit.

SAMPLE EXERCISE 3.5 Calculating the Molar Mass of a Compound LO1

Calculate the molar masses of (a) H_2O and (b) H_2SO_4.

Collect and Organize We are given the formulas of two compounds and want to find their molar masses. The molar mass of a molecular compound is the sum of the molar masses of the elements in the molecular formula of the compound, each multiplied by the number of atoms of that element in the molecular formula. The molar mass of an element in grams per mole can be found in the periodic table.

Analyze

1. One mole of H_2O contains 2 moles of H atoms and 1 mole of O atoms. Therefore,

   $$\mathscr{M}_{\text{H2O}} = (2 \times \mathscr{M}_{\text{H}}) + \mathscr{M}_{\text{O}}$$

2. One mole of H_2SO_4 contains 2 moles of H atoms, 1 mole of S atoms, and 4 moles of O atoms. Therefore,

   $$\mathscr{M}_{\text{H2SO4}} = (2 \times \mathscr{M}_{\text{H}}) + \mathscr{M}_{\text{S}} + (4 \times \mathscr{M}_{\text{O}})$$

Solve

1. The molar mass of H_2O is

$$2(1.008\ \text{g/mol}) + 16.00\ \text{g/mol} = 18.02\ \text{g/mol}\ H_2O$$

2. The molar mass of H_2SO_4 is

$$2(1.008\ \text{g/mol}) + 32.06\ \text{g/mol} + 4(16.00\ \text{g/mol}) = 98.08\ \text{g/mol}\ H_2SO_4$$

Think About It The molar mass of a compound is the sum of the masses of the elements in that compound. Because H_2SO_4 contains more atoms and heavier atoms than H_2O does, we expect the molar mass of sulfuric acid to be larger than that of water.

Practice Exercise When green plants take in water (H_2O) and carbon dioxide (CO_2), they produce glucose ($C_6H_{12}O_6$) and oxygen (O_2). Calculate the molar masses of carbon dioxide, oxygen, and glucose.

(Answers to Practice Exercises are in the back of the book.)

SAMPLE EXERCISE 3.6 Converting Between Grams, Moles, and Formula Units LO1

Lithium carbonate is used in the treatment of bipolar disorder (**Figure 3.16**). How many moles and how many formula units of lithium carbonate are in a capsule containing 0.300 g Li_2CO_3?

Collect and Organize We are given the mass of Li_2CO_3 in a capsule and asked to express that mass in moles and in formula units of Li_2CO_3. The number of formula units of an ionic compound is analogous to the number of molecules of a molecular compound. The formula unit of lithium carbonate is Li_2CO_3. The Avogadro constant relates the number of formula units of an ionic compound to the number of moles of an ionic compound.

Analyze Figure 3.15 illustrates how to convert the mass of a substance in grams into an equivalent number of moles by dividing by the substance’s molar mass and then into an equivalent number of particles (formula units in this case) by multiplying the number of moles by the Avogadro constant:

The capsule contains 0.300 g of Li_2CO_3, which probably has a molar mass of ~100 g/mol, so the number of moles of Li_2CO_3 should be about 0.003, and the number of formula units should be about 2×10^{21}.

Solve First we need to calculate the molar mass of Li_2CO_3 by adding twice the molar mass of Li to the molar mass of C, and three times the molar mass of O:

$2(6.941\ \text{g/mol}) + 12.01\ \text{g/mol} + 3(16.00\ \text{g/mol}) = 73.89\ \text{g/mol}\ Li_2CO_3$

Using this molar mass to convert g Li_2CO_3 into mol Li_2CO_3:

This value should be expressed with three significant figures, 4.060×10^{-3} mol, because the mass of Li_2CO_3 has only three significant figures.

Converting the calculated moles of Li_2CO_3 into formula units of Li_2CO_3:

Think About It The calculated number of moles of Li_2CO_3 is about the predicted value, as is the number of formula units, so both values are reasonable. We could never count out such an enormous number of formula units, but calculations such as this one allow us to know how many there are in a sample.

Practice Exercise How many moles of $CaCO_3$ are in an antacid tablet containing 0.500 g of $CaCO_3$? How many formula units of $CaCO_3$ are in this tablet?

(Answers to Practice Exercises are in the back of the book.)

SAMPLE EXERCISE 3.7 Calculating the Masses of Elements in Their Compounds LO1

The discovery that iron metal could be extracted from iron-containing minerals such as hematite (Fe_2O_3) and magnetite (Fe_3O_4) ushered in the Iron Age around 1200 bce (**Figure 3.17**). If a metalworker were able to extract all the iron in 250.0-g samples of Fe_2O_3 and Fe_3O_4, what masses of iron would each sample produce?

Collect and Organize We are given the masses of two iron oxide samples and asked to calculate the mass of iron in each of them. The chemical formulas of the oxides tell us the number of moles of Fe per mole of each oxide. The molar mass of a compound or element can be used to convert its mass into the equivalent number of moles as shown in Figure 3.15.

Analyze To begin, we need to calculate the molar masses of Fe_2O_3 and Fe_3O_4, and then use these values to convert the masses of Fe_2O_3 and Fe_3O_4 into moles of Fe_2O_3 and Fe_3O_4 as shown in Figure 3.15. Next, we convert these mole values into moles of Fe: there are 2 mol Fe/1 mol Fe_2O_3 and 3 mol Fe/1 mol Fe_3O_4. Then, we convert the two mol Fe values into mass (g) Fe values by multiplying by the molar mass of Fe, 55.84 g/mol. Summarizing the conversion steps for Fe_2O_3:

Solve Calculating the molar masses of Fe_2O_3 and Fe_3O_4:

Fe_2O_3: $2(55.84 \text{ g/mol}) + 3(16.00 \text{ g/mol}) = 159.68 \text{ g/mol } Fe_2O_3$

Fe_3O_4: $3(55.84 \text{ g/mol}) + 4(16.00 \text{ g/mol}) = 231.52 \text{ g/mol } Fe_3O_4$

Converting grams of Fe_2O_3 into grams of Fe:

Repeating the calculation for Fe_3O_4:

Think About It The mass of extractable iron in 250.0 g Fe_3O_4 is greater than that in the same mass of Fe_2O_3. This makes sense because the mole ratio of Fe:O in Fe_3O_4 is 3:4, which is greater than the Fe:O mole ratio in Fe_2O_3 (2:3). Its greater Fe:O ratio means that more of the mass of Fe_3O_4 is iron and less of it is oxygen.

Practice Exercise How many grams of chromium are there in 225 g sodium chromate (Na_2CrO_4) and in 225 g sodium dichromate ($Na_2Cr_2O_7$)?

(Answers to Practice Exercises are in the back of the book.)

Moles and Chemical Equations

The concepts of mole and molar mass offer three new interpretations of Equation 3.1:

$SO_3(g) + H_2O\,(g) \rightarrow H_2SO_4(\ell)$

1. Based on the coefficients in the chemical equation, 1 *mole* of SO_3 reacts with 1 *mole* of H_2O, producing 1 *mole* of H_2SO_4.
2. Based on the molar masses of the reactants and products, 80.06 *grams* of SO_3 react with 18.02 *grams* of H_2O, producing 98.08 *grams* of H_2SO_4.
3. Based on the Avogadro constant, 6.022×10^{23} *molecules* of SO_3 react with 6.022×10^{23} *molecules* of H_2O, forming 6.022×10^{23} *molecules* of H_2SO_4. In terms of lowest whole-number ratios, 1 *molecule* of SO_3 reacts with 1 *molecule* of H_2O, forming 1 *molecule* of H_2SO_4.

These interpretations of this equation, however, do not limit the amount of SO_3 that can react to 80.06 g. Reacting twice that amount, or 160.12 g of SO_3, is possible if twice the molar mass of water, 36.04 g of H_2O, is available. That is, 2 moles of SO_3 can react with 2 moles of H_2O to produce 2 moles of H_2SO_4. In fact, the equation means that *any* number of moles (x mol) of SO_3 react with an equal number of moles (x mol) of H_2O to produce the same quantity (x mol) of H_2SO_4 as shown in the table that follows.

[illegible]
Particle Ratios [illegible]
Mole Ratios [illegible]
Mass Ratios [illegible]
General Case (moles) [illegible]
General Case (masses) [illegible]

The mole ratio differs when different substances combine and is therefore specific for a given reaction. For example, in the reaction in Equation 3.2 between sulfuric acid and Fe_2O_3,

$$Fe_2O_3(s) + 3\ H_2SO_4(aq) \rightarrow 3\ H_2O\ (\ell) + Fe_2(SO_4)_3(aq)$$

the mole ratio of Fe_2O_3 to H_2SO_4 is 1:3, and an abbreviated version of the table above with just these two reactants looks like this.

[illegible]
Particle Ratios [illegible]
Mole Ratios [illegible]
Mass Ratios [illegible]
General Case (moles) [illegible]
General Case (masses) [illegible]

This quantitative relationship between the reactants and products involved in a chemical reaction is called the stoichiometry of the reaction. In a reaction where all reactants are completely converted into products, the sum of the masses of the reactants equals the sum of the masses of the products. This fact illustrates a fundamental relation known as the law of conservation of mass, which applies to all chemical reactions. This law works in an equation representing any chemical reaction for two reasons: (1) the total number of atoms (and hence moles) of each element to the left of the reaction arrow must equal the total number of atoms (and moles) of that element to the right of the reaction arrow, and (2) the identity of atoms does not change in a chemical reaction.

SAMPLE EXERCISE 3.8 Visualizing Chemical Reactions LO2

Using blue spheres to represent nitrogen atoms and red spheres to represent oxygen atoms, sketch a picture describing the reaction between two molecules of N_2 and four molecules of O_2 to form NO_2.

Collect, Organize, and Analyze We are given the chemical formulas for two reactants and will use colored spheres to sketch their conversion to a product. We choose blue spheres to represent nitrogen atoms and red spheres to represent oxygen atoms. We use the atoms contained in two molecules of nitrogen and four molecules of oxygen to construct the appropriate number of NO_2 molecules.

Solve From a total of 4 nitrogen and 8 oxygen atoms, we can make four molecules of NO_2:

Think About It A chemical reaction involves rearrangements of atoms and molecules, resulting in new molecules. The number of each type of atom present before the reaction equals the number of each type of atom present after the reaction.

Practice Exercise Using colored spheres to represent nitrogen atoms (blue) and hydrogen atoms (white), sketch a picture describing the reaction between two molecules of N_2 and six molecules of H_2 to form ammonia, NH_3.

(Answers to Practice Exercises are in the back of the book.)

Glossary

mole (mol)

the SI base unit for expressing quantities of substances. One mole contains $6.02214076 \times 10^{23}$ particles: atoms, molecules, or formula units.

molar mass ($\mathscr{M}$)

the mass of 1 mole of a substance; the molar mass of an element in grams per mole is numerically equal to that element's average atomic mass in unified atomic mass units.

molecular mass

the mass of one molecule of a molecular compound.

formula mass

the mass of one formula unit of an ionic compound.

stoichiometry

the quantitative relationship between reactants and products in a chemical reaction.

law of conservation of mass

the principle that the sum of the masses of the reactants in a chemical reaction is equal to the sum of the masses of the products.

Avogadro constant (N_A)

the fundamental constant representing the number of characteristic particles in 1 mole of a substance: $6.02214076 \times 10^{23}$ particles/mol.

Endnotes

- In sample exercises involving molar masses, we usually round off the values given in the periodic table to four significant figures, except for elements with molar masses greater than 100. Return to reference 1

Learning Objectives

- Use molar mass and the Avogadro constant to make conversions among mass, number of particles, and number of moles **Return to Sample Exercises 3.1, 3.2, 3.3, 3.4, 3.5, 3.6, 3.7**
- Use molar mass and the Avogadro constant to make conversions among mass, number of particles, and number of moles **Return to Sample Exercises 3.1, 3.2, 3.3, 3.4, 3.5, 3.6, 3.7**

- Use molar mass and the Avogadro constant to make conversions among mass, number of particles, and number of moles **Return to Sample Exercises 3.1, 3.2, 3.3, 3.4, 3.5, 3.6, 3.7**

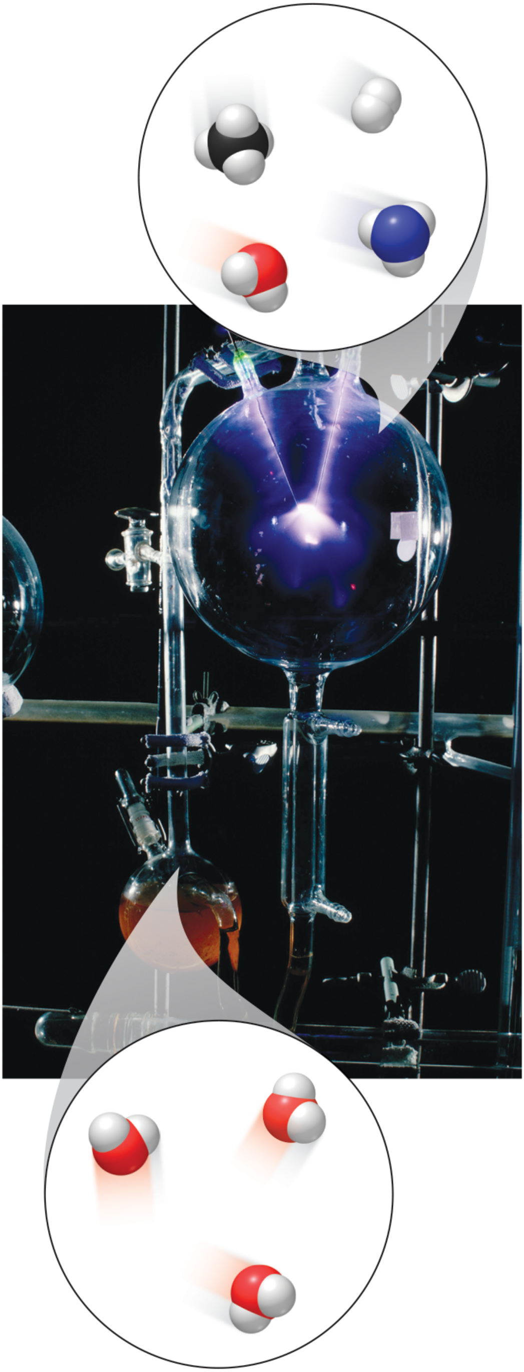

FIGURE 3.18 A molecular

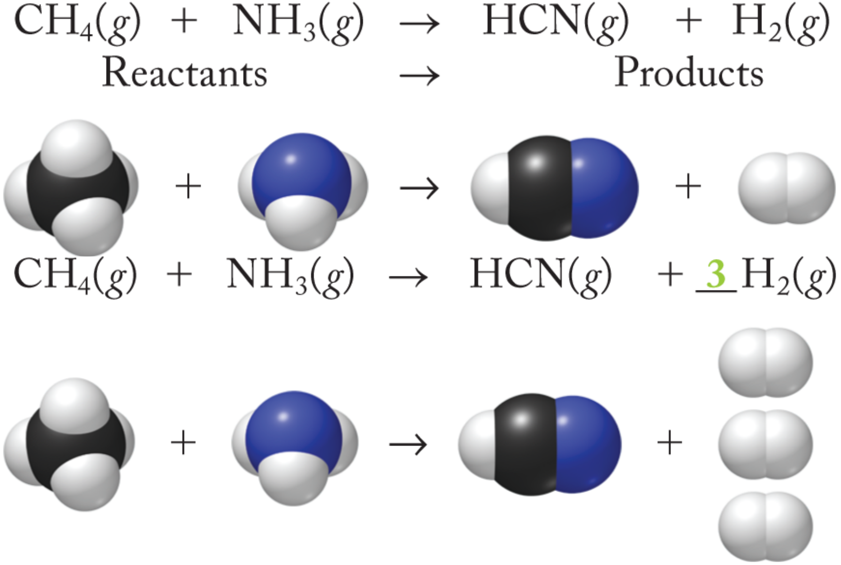
view of the reaction mixture in the Miller–Urey experiment. The large flask contained water, ammonia, hydrogen, and methane in ratios believed at that time to represent the composition of Earth's early atmosphere. The smaller flask was heated to add water vapor to the gas mixture in the large flask.



$$CH_4(g) + NH_3(g) \rightarrow HCN(g) + H_2(g)$$

$$CH_4(g) + NH_3(g) \rightarrow HCN(g) + \underline{3}\,H_2(g)$$

3.3 Writing Balanced Chemical Equations

A *balanced* chemical equation has the same number of atoms of each element on both sides of the equation. Here in Section 3.3, we practice writing balanced chemical equations describing chemical reactions that may account for the products observed by Miller and Urey in their experiments on the origins of life on Earth mentioned at the beginning of this chapter.

Figure 3.18 revisits the apparatus we saw in Figure 3.1. A key molecule in the synthesis of glycine, one of the amino acids produced in the Miller–Urey experiment, is hydrogen cyanide (HCN). Hydrogen cyanide can be formed from methane (CH_4) and ammonia (NH_3) in a reaction that also produces hydrogen (H_2).

Let’s write a balanced chemical equation describing this reaction. We know the formulas of the reactants and products, but we don’t know the stoichiometry of the reaction—that is, we need to determine the coefficients that precede their formulas in a balanced chemical equation. There are several approaches to writing chemical equations. Let’s apply the following four-step method, which works well if we have correctly identified all the reactants and products.

1. *Write a preliminary expression containing a single particle (atom, molecule, or formula unit) of each reactant and product with a reaction arrow separating reactants from products. Include phase symbols indicating physical states.*

The following expression represents the reaction of interest (particulate models of the molecules involved are included):

---

1. *Check whether the expression is balanced by counting the atoms of each element on each side of the reaction arrow.*

Adding up the atoms of each element in the reactants and products, we find that the numbers of C atoms and N atoms are balanced, but the number of H atoms is not: there are 7 on the reactant side but only 3 on the product side.

[illegible]				
C ✓				
N ✓				
H + 3 = 7				

1. *Choose an element that appears in only one reactant and one product and balance it first.*

In this example, the two elements that occur only once on each side of the reaction arrow are C and N, but they are already balanced, so we can skip this step.

1. *Choose coefficients for the other substances so that the number of atoms for each element is the same on both sides of the reaction arrow.*

We need 4 more H atoms on the product side to have a balanced equation. Changing the coefficient in front of either HCN or H_2 could increase the number of H atoms but changing the coefficient of HCN would also increase the numbers of C and N atoms, which are already balanced. Therefore, the simplest approach is to increase the coefficient of H_2 from 1 to 3, which increases the number of H atoms from 2 for one molecule of H_2 to 6 for three molecules of H_2.

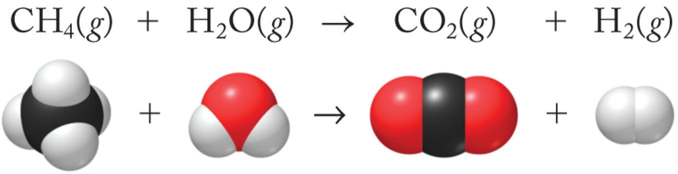
A final check of the number of atoms of each element on both sides of the reaction arrow confirms that the equation is balanced:

Element	Reactant Side	Product Side	Balanced
C	1	1	✓
N	1	1	✓
H	4 + 3 = 7	1 + (3 × 2) = 7	✓

Note that balance was achieved by changing a coefficient, *not* by changing any subscripts in the chemical formulas. Changing subscripts would change the identities of the substances, and that would change the reaction itself. Consequently, only coefficients may be changed when balancing chemical equations.

Let's get more practice writing balanced chemical equations by using another important reaction in the Miller–Urey experiment. Analysis of the vapor above the solution in the large flask revealed the presence of both carbon dioxide and carbon monoxide gas. The reaction between methane and water yields carbon dioxide and hydrogen.

1. *Write a preliminary expression containing a single particle of each reactant and product.* Methane has the formula CH_4, water is H_2O, carbon dioxide is CO_2, and hydrogen is H_2. Recall from Chapter 1 that all the gaseous nonmetallic elements—except for the noble gases—exist in nature as diatomic molecules: H_2, N_2, O_2, F_2, and Cl_2. Bromine, a liquid at room temperature, and I_2, a solid, are also diatomic (**Figure 3.19**). Whenever these substances are involved in chemical reactions, they must be written as diatomic molecules.



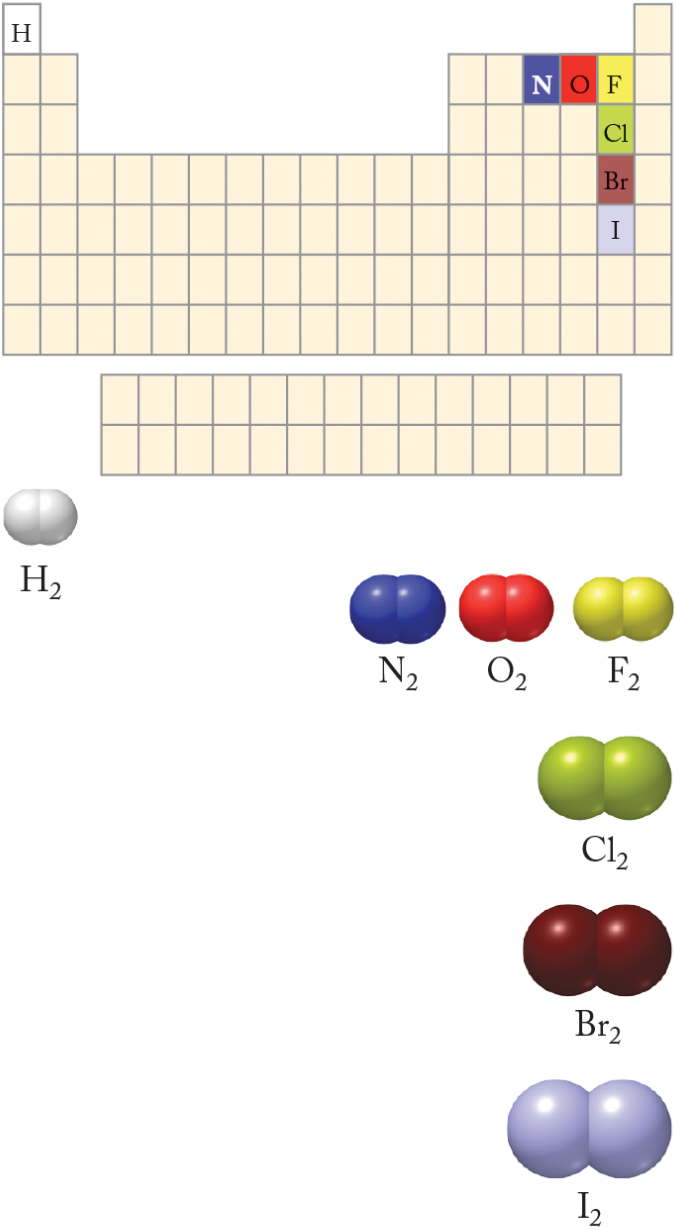
$CH_4(g) + H_2O(g) \rightarrow CO_2(g) + H_2(g)$

---

2. *Check whether the expression is balanced.*

[illegible]					
[illegible]					
[illegible]					
[illegible] + 2 = 6					

The expression is not yet balanced.



H
N
O
F
Cl
Br
I
H_2
N_2
O_2
F_2
Cl_2
Br_2
I_2

FIGURE 3.19 The diatomic elements are hydrogen, nitrogen, oxygen, and the group 17 halogens. The halogen astatine (At) near the bottom of group 17 is the rarest terrestrial element, and virtually none of its bulk physical properties are known.

3. *Choose an element that appears in only one reactant and one product to balance first.* In this case we could choose either carbon or oxygen. Carbon is already balanced, so we focus on oxygen. With 1 O atom on the reactant side and 2 O atoms on the product side, we can make the number of O atoms equal on both sides of the equation by placing a coefficient of 2 in front of H_2O.

$$CH_4(g) + \underline{2}\,H_2O(g) \rightarrow CO_2(g) + \underline{\quad}\,H_2(g)$$

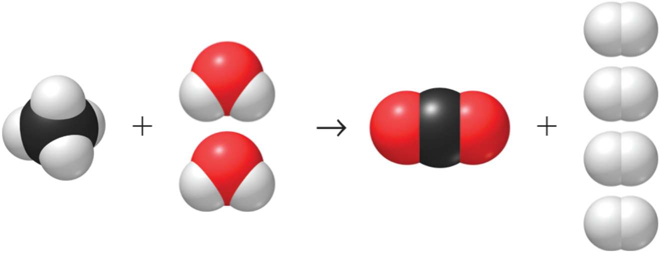
Assigning this coefficient balances the number of oxygen atoms but not the number of hydrogen atoms.

Element	Reactant Side	Product Side	
C	1	1	✓
O	2 × 1 = 2	2	✓
H	4 + (2 × 2) = 8	2	✗

4. *Choose coefficients for the other substances so that the numbers of atoms of each element are the same on both sides of the equation.*

We can balance the H atoms by placing a coefficient of 4 in front of H_2, which completes the balancing process:

$$CH_4(g) + \underline{2}\,H_2O(g) \rightarrow CO_2(g) + \underline{4}\,H_2(g)$$



Element	Reactant Side	Product Side	
C	1	1	✓
O	2 × 1 = 2	2	✓
H	4 + (2 × 2) = 8	4 × 2 = 8	✓

SAMPLE EXERCISE 3.9 Writing a Balanced Chemical Equation LO2

Write a balanced chemical equation for the gas-phase reaction between SO_2 and O_2 that forms SO_3. This reaction, one of the causes of acid rain, occurs when fuels containing sulfur are burned.

Collect, Organize, and Analyze We are given the chemical formulas and physical states of the reactants and products. We need to write a balanced chemical equation in which the same number of atoms of each element appear on both sides of the equation. To do so, we assign coefficients as needed to make the numbers of atoms of each element on the reactant (left) and product (right) sides of the reaction arrow equal.

Solve

1. Starting with a reaction expression that has single molecules of the reactants and product:

   $$SO_2(g) + O_2(g) \rightarrow SO_3(g)$$

2. Checking whether the expression is already balanced:

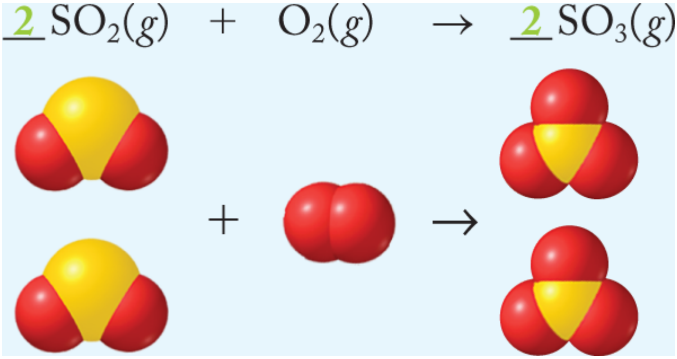
[illegible]
✓
2 + 2 = 4

   The sulfur atoms are balanced but the oxygen atoms are not.

3. Balancing the O atoms presents a challenge because increasing their number on the product side by increasing the SO_3 coefficient from 1 to 2 unbalances the sulfur atoms:

   $$SO_2(g) + O_2(g) \rightarrow \underline{2}\,SO_3(g)$$

   There are now two more O atoms and one more S atom on the product side than on the reactant side. Fortunately, both imbalances can be solved simultaneously by increasing the SO_2 coefficient from 1 to 2:



A check of the atom inventory on both sides confirms that the equation is now balanced:

Element	Reactant Side	Product Side	Balanced?
S	$2 \times 1 = 2$	$2 \times 1 = 2$	✓
O	$(2 \times 2) + 2 = 6$	$2 \times 3 = 6$	✓

Think About It Instead of increasing the number of O atoms on the product side to bring the equation into balance, we might have tried *decreasing* their number on the reactant side by reducing the coefficient in front of O_2 from 1 to $\frac{1}{2}$:

$$SO_2(g) + \frac{1}{2}\,O_2(g) \rightarrow SO_3(g)$$

This fix has the advantage of bringing the number of O atoms into balance without unbalancing the number of S atoms. It has the disadvantage of creating a fractional coefficient, but this problem can be solved by multiplying all the coefficients by 2, which gives us the same balanced equation we obtained in the Solve section:

$$2\,SO_2(g) + O_2(g) \rightarrow 2\,SO_3(g)$$

We use this strategy again in Sample Exercise 3.10 and in writing chemical equations for some of the combustion reactions in Section 3.4.

Practice Exercise Write balanced chemical equations for (a) the reaction between elemental phosphorus, $P_4(s)$, and oxygen to make $P_4O_{10}(s)$ and (b) the reaction of water with $P_4O_{10}(s)$ to produce phosphoric acid, $H_3PO_4(aq)$.

(Answers to Practice Exercises are in the back of the book.)

CONCEPT TEST

Why can't we write a balanced equation for the reaction between SO_2 and O_2 in Sample Exercise 3.9 this way?

$$SO_2(g) + O(g) \rightarrow SO_3(g)$$

(Answers to Concept Tests are in the back of the book.)

A chemical equation is analogous to a mathematical equation, because the equation in Sample Exercise 3.9 is still balanced if we multiply all the coefficients by the same number, such as 2:

$$4\ SO_2(g) + 2\ O_2(g) \rightarrow 4\ SO_3(g)$$

It is also still balanced if we multiply all the coefficients by a fraction, such as $\frac{1}{2}$. It is conventional, however, to write a balanced equation with the smallest whole-number coefficients.

SAMPLE EXERCISE 3.10 Writing Balanced Chemical Equations Using Fractional Coefficients LO2

Write a balanced chemical equation for the gas-phase reaction in which dinitrogen pentoxide is formed from nitrogen and oxygen.

Collect, Organize, and Analyze We are asked to write a balanced chemical equation given the names and physical states of the reactants and products. Nitrogen and oxygen gases exist in nature as diatomic molecules, so their molecular formulas are N_2 and O_2. The formula for dinitrogen pentoxide is N_2O_5. To write a balanced chemical equation, we must assign coefficients as needed to make the numbers of atoms of each element on the reactant (left) and product (right) sides of the reaction arrow equal.

Solve

1. Write a preliminary expression using correct formulas:

   $$N_2(g) + O_2(g) \rightarrow N_2O_5(g)$$

2. The expression is not balanced as written:

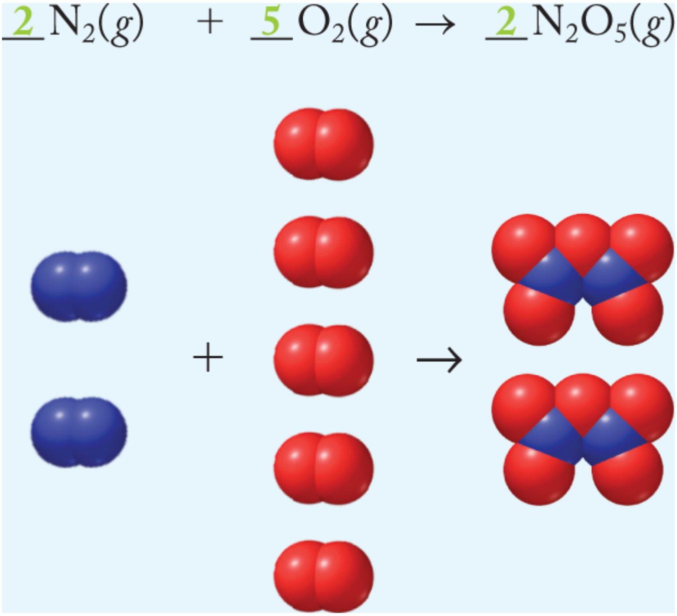
[illegible]
[illegible]
[illegible]

3. One way to balance the O atoms without unbalancing the N atoms is to place the fractional coefficient $\frac{5}{2}$ in front of O_2:

   $$N_2(g) + \frac{5}{2}O_2(g) \rightarrow N_2O_5(g)$$

   ---

   which gives us five O atoms on both sides. To obtain whole-number coefficients we multiply all three coefficients by 2:



$\underline{2}\ N_2(g) + \underline{5}\ O_2(g) \rightarrow \underline{2}\ N_2O_5(g)$
+
→

The equation is now balanced.

Think About It The use of a fractional coefficient in front of O_2 allowed us to balance the number of O atoms without unbalancing the number of N atoms (see the solution to Sample Exercise 3.9), thereby completing the exercise in fewer steps. In balancing a chemical equation, always check the equation after you are done to make sure that an element balanced in a previous step is still balanced at the end.

Practice Exercise Write a balanced chemical equation for the reaction between carbon monoxide, $CO(g)$, and oxygen to form carbon dioxide, $CO_2(g)$.

(Answers to Practice Exercises are in the back of the book.)

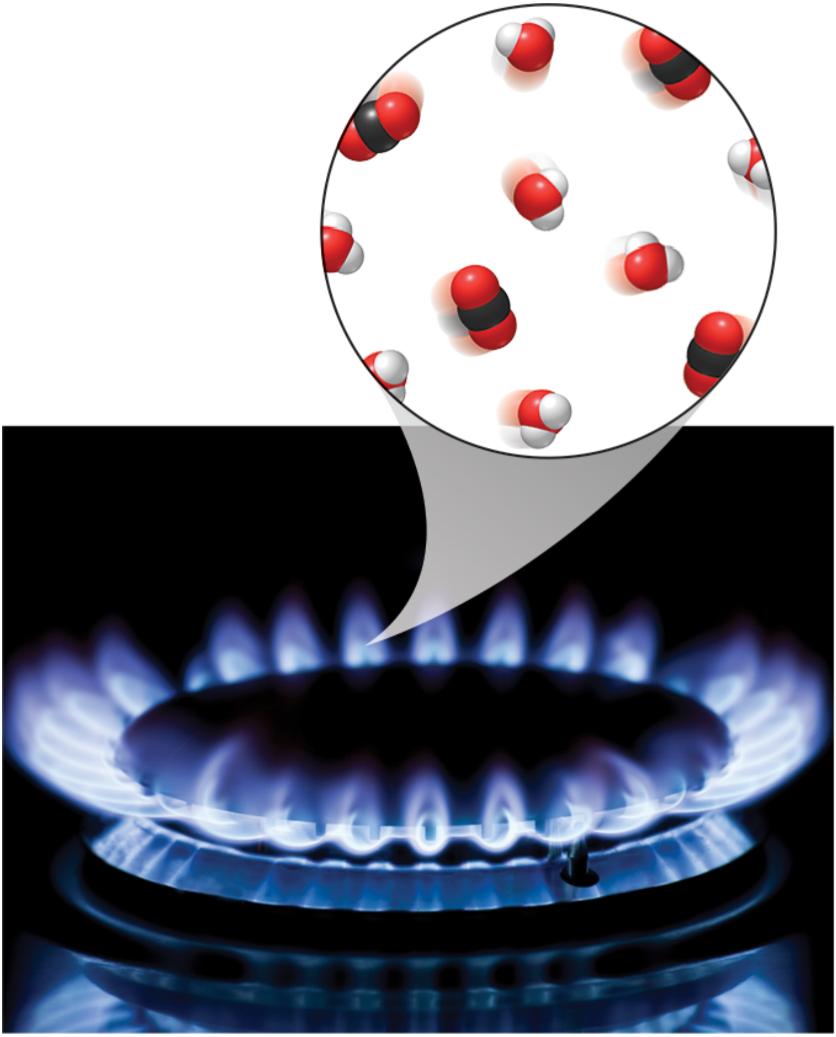

FIGURE 3.20 The combustion of methane in a gas stove produces carbon dioxide and water.

$$C_2H_6(g) + \underline{\quad} O_2(g) \rightarrow \underline{\ 2\ } CO_2(g) + \underline{\quad} H_2O(g)$$

$$C_2H_6(g) + \underline{\quad} O_2(g) \rightarrow \underline{\ 2\ } CO_2(g) + \underline{\ 3\ } H_2O(g)$$

$$C_2H_6(g) + \tfrac{7}{2} O_2(g) \rightarrow \underline{\ 2\ } CO_2(g) + \underline{\ 3\ } H_2O(g)$$

$$\underline{\ 2\ } C_2H_6(g) + \underline{\ 7\ } O_2(g) \rightarrow \underline{\ 4\ } CO_2(g) + \underline{\ 6\ } H_2O(g)$$

3.4 Combustion Reactions

Both methane and carbon monoxide are still present in our atmosphere, although at much lower concentrations than on early Earth. Atmospheric methane (natural gas) can be traced to several sources, including wetlands, cattle ranching, rice production, and oil drilling and fracking operations. Carbon dioxide in the atmosphere arises from burning carbon-containing compounds. Natural sources of CO_2 include volcanic activity and forest fires. In our industrialized world, the greatest use of methane and petroleum-based fuels is energy production.

CONNECTION Molecules like methane (CH_4) are members of a class of organic compounds known as hydrocarbons because they are composed of only hydrogen and carbon (see Chapter 2).

Natural gas and other hydrocarbon fuels are burned to heat buildings and to warm water. Burning CH_4 is an example of an important class of chemical reactions known as combustion reactions, or simply *combustion* (**Figure 3.20**). Combustion refers to the reaction of a fuel with oxygen, such as the burning of a substance in air, which contains 21% oxygen.

When the combustion of a hydrocarbon is complete, the only products are carbon dioxide and water. In the presence of O_2, the more stable form of carbon is CO_2, not CO, so carbon monoxide also reacts with oxygen to form carbon dioxide. In the combustion reaction between methane and oxygen, the carbon becomes carbon dioxide when a sufficient supply of oxygen is available. The hydrogen in the fuel combines with oxygen to form water vapor. Let's see how to write a balanced equation describing the combustion of methane.

1. Our first step is to write the formulas of the reactants on the left and products on the right.

   $$CH_4(g) + O_2(g) \rightarrow CO_2(g) + H_2O(g)$$

[illegible]			

C
H
O 2 + 1 = 3

The carbon atoms are balanced but the hydrogen and oxygen atoms are not.

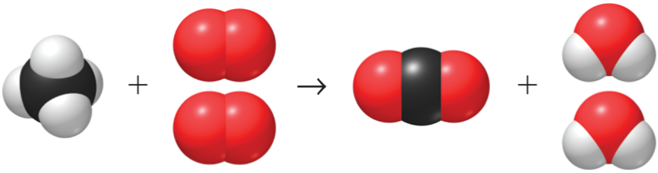
2. Like carbon, H appears in only one reactant and one product. Adding a coefficient of 2 in front of H_2O makes the number of H atoms equal on both sides of the equation but increases the number of O atoms on the product side:

$$CH_4(g) + \_\_\ O_2(g) \rightarrow CO_2(g) + \underline{2}\ H_2O(g)$$

Reactant Side / Product Side / Balanced
C
H 2 × 2 = 4
O 2 + (2 × 1) = 4

3. This leaves only the O atoms to balance. A coefficient of 2 in front of O_2 makes the atoms of O equal on both sides of the equation:

$$CH_4(g) + \underline{2}\ O_2(g) \rightarrow CO_2(g) + \underline{2}\ H_2O(g)$$



Reactant Side / Product Side / Balanced
C
H 2 × 2 = 4
O 2 × 2 = 4 / 2 + (2 × 1) = 4

Balancing first C, then H, then O is a useful strategy when writing the equations for many combustion reactions involving hydrocarbons.

SAMPLE EXERCISE 3.11 Writing a Balanced Chemical Equation for a Combustion Reaction LO2

Methane (CH_4) is the principal ingredient in natural gas, but significant amounts of the hydrocarbon gases ethane (C_2H_6) and propane (C_3H_8) are also present in most natural gas samples. Write a balanced chemical equation describing the complete combustion of C_2H_6.

Collect, Organize, and Analyze We need to write a balanced chemical equation for the combustion of C_2H_6. The products of complete combustion of hydrocarbons are carbon dioxide and water.

Solve The preliminary expression with single particles of all known reactants and products describing the combustion of ethane is

$$C_2H_6(g) + O_2(g) \rightarrow CO_2(g) + H_2O(g)$$

[illegible]			
[illegible]			
[illegible]			
[illegible] + 1 = 3			

None of the elements is currently balanced. Because this reaction is between oxygen and a hydrocarbon, we balance C first, then H, then O. Balance the carbon atoms first by giving CO_2 in the products a coefficient of 2:

[illegible]			
[illegible] × 1 = 2			
[illegible]			
[illegible] × 2) + 1 = 5			

Then balance the hydrogen atoms by giving H_2O (a product) a coefficient of 3:

[illegible]			
[illegible] × 1 = 2			
[illegible] × 2 = 6			
[illegible] × 2) + (**3** × 1) = 7			

At this stage, the oxygen atoms (and the entire equation) can be balanced by giving O_2 a coefficient of $\frac{7}{2}$:

[illegible]						
2 × 1 − 2						
3 × 2 − 6						
(2 × 2) + (3 × 1) = 7						

To remove the fraction, we multiply all of the coefficients by 2:

Think About It Balancing chemical equations for combustion reactions of hydrocarbons often requires several iterations of the coefficients, but, as in Sample Exercise 3.10, all the elements were balanced in fewer steps by giving O_2 a temporary fractional coefficient.

Practice Exercise Write a balanced chemical equation describing the complete combustion of propane (C_3H_8).

(Answers to Practice Exercises are in the back of the book.)

3.5 Stoichiometric Calculations and the Carbon Cycle

Earth's atmosphere underwent a major change beginning about 2.5 billion years ago with the evolution of bacteria capable of *photosynthesis.* Photosynthesis is driven by the energy in sunlight and involves several steps, but the overall reaction is

Although photosynthetic bacteria are believed to have been the initial source of oxygen in our atmosphere, today O_2 comes mostly from green plants. The reverse reaction, called *respiration,* is the major source of energy for all living things on Earth:

Photosynthesis and respiration are key reactions in the *carbon cycle* (**Figure 3.21**). The two processes are nearly, but not exactly, in balance in Earth's biosphere. If they were exactly in balance, no net change would have taken place in the concentrations of atmospheric carbon dioxide or oxygen in the past 2.5 billion years. However, about 0.01% of the decaying mass of plants and animals (called *detritus*) is incorporated into sediments and soil when organisms die. Shielded in this way from exposure to oxygen, the carbon in this mass is not converted back into CO_2. Although 0.01% may not seem like much, over hundreds of millions of years it has added up to the removal of about 10^{20} kg of carbon dioxide from the atmosphere. About 10^{15} kg of this buried carbon is in the form of fossil fuels: coal, petroleum, and natural gas.

Fossil fuels have served as the world's primary energy resoure for more than a century with a rapid increase in the rate of consumption of these fuels since 1950. In 2018, the combustion of fossil fuels and a variety of industrial processes resulted in the conversion of 10.1 trillion (10.1×10^{12}) kilograms of fossil carbon into carbon dioxide gas, which was released into the atmosphere. Assessing the environmental impacts of these additions of CO_2 to Earth's atmosphere has been the subject of intense research in recent years for reasons we discuss in Chapters 8 and 16. For now, let’s focus on how we can use balanced chemical equations to calculate how much fossil CO_2 is produced by combustion of a widely used fossil fuel: gasoline.

In many industrial countries, including the United States and Canada, the most heavily used fossil fuel is petroleum. In the United States nearly half of the petroleum is refined into gasoline: 1.43×10^{11} U.S. gallons of it in 2017. To evaluate the environmental impact of converting this much gasoline into atmospheric CO_2, let’s calculate how much is produced by the complete combustion of just one gallon (3.785 liters) of it. Gasolines are complex mixtures of hydrocarbons of variable composition, so we will make two simplifying assumptions: (1) a typical density of gasoline is 0.73 g/mL and (2) the average number of carbon atoms per molecule in gasoline is 7. Therefore, we will use heptane, C_7H_{16}, as a model gasoline hydrocarbon.

To begin, let’s write a chemical equation describing the combustion of heptane. We start with a reaction expression that contains single molecules (or moles) of the known reactants and products:

$$C_7H_{16}(\ell) + O_2(g) \rightarrow CO_2(g) + H_2O(g)$$

To balance the expression, we begin by balancing the number of atoms of carbon on both sides of the reaction arrow:

then balancing the number of atoms of hydrogen:

and finally, balancing the number of atoms of oxygen:

This yields a balanced chemical equation.

Next, we need to calculate the mass of heptane in a gallon and then convert that mass into an equivalent quantity in moles by dividing by the molar mass of heptane. The last step requires our first calculating the molar mass of a compound that has 7 atoms of carbon and 16 atoms of hydrogen per molecule:

$\mathcal{M}\ C_7H_{16} = 7(12.01\ \text{g/mmol}) + 16(1.008\ \text{g/mol}) = 100.20\ \text{g/mol}$

The starting quantity of gasoline is a volume of exactly one U.S. gallon or 3.785 liters. Multiplying volume by density with the appropriate unit conversions will yield a mass in grams, which can be converted to a quantity of moles using the calculated molar mass:

The mole ratio of CO_2 to C_7H_{16} in the balanced chemical equation is 7:1 and the molar mass of CO_2 is

$12.01\ \text{g/mol} + 2(16.00\ \text{g/mol}) = 44.01\ \text{g/mol}\ CO_2$

Using these two values as the final conversion factors:

The mass of CO_2 is expressed to two significant figures because that was the number in the density value used in its calculation. If 8.7 kg CO_2 (about 19 pounds) per gallon of gasoline seems like a lot, remember that one mole (12.01 g) of carbon produces one mole (44.01 g) of CO_2, which represents a mass gain of 44.01/12.01 or nearly 4 times. Then consider the mass of CO_2 produced by all the gasoline engines in the United States in 2017:

This procedure can be applied to determining the mass of any substance (reactant or product) involved in any chemical reaction if we know (1) the mass of another substance in the reaction and (2) the *stoichiometric relation* between the two substances, that is, their mole ratio in the balanced chemical equation.

SAMPLE EXERCISE 3.12 Calculating a Product Mass from a Reactant Mass LO3

In 2014 electric power plants in the United States consumed about 1.57×10^{11} kg of natural gas. Natural gas is mostly methane (CH_4), so we can approximate the combustion reaction generating the energy by the equation:

$CH_4(g) + 2\ O_2(g) \rightarrow CO_2(g) + 2\ H_2O(g)$

How many kilograms of CO_2 were released into the atmosphere from these power plants in 2014?

Collect, Organize, and Analyze We are asked to calculate the mass of CO_2 produced from the combustion of 1.57×10^{11} kg of CH_4. We can change the mass of CH_4 in kilograms to grams and then convert into moles of CH_4 by multiplying by the molar mass of CH_4. According to the balanced equation, 1 mole of carbon dioxide is produced for every 1 mole of methane consumed (i.e., the mole ratio of CO_2:CH_4 is 1:1), so moles of CH_4 = moles of CO_2. Finally, we convert moles of CO_2 into kilograms of CO_2. We can combine all these steps into a single calculation:

Solve The chemical equation is balanced as written (you should always check to be sure). To convert between grams and moles of CH_4 and CO_2, we need to calculate the molar masses of these compounds. The molar mass of CH_4 is

$$12.01 \text{ g/mol} + 4(1.008 \text{ g/mol}) = 16.04 \text{ g/mol } CH_4$$

and the molar mass of CO_2 is

$$12.01 \text{ g/mol} + 2(16.00 \text{ g/mol}) = 44.01 \text{ g/mol } CO_2$$

Convert the mass of CH_4 into moles:

Convert moles of CH_4 into moles of CO_2 by using the mole ratio from the balanced chemical equation:

Convert moles of CO_2 into mass of CO_2:

We can combine the three separate calculations into a single calculation, and in subsequent problems we may not show the individual steps:

Think About It Complete combustion of 1 mole (16.04 g) of CH_4 produces 1 mole (44.01 g) of CO_2. Therefore, there will be a reactant-to-product gain in mass of 44.01/16.04 = 2.744 times when the 4 moles of H atoms (4.03 g) in each mole of CH_4 are replaced by 2 moles of O atoms (32.00 g) in each mole of CO_2. Therefore, the calculated mass of CO_2 should be 1.57×10^{11} kg $\times$ 2.744 = 4.31×10^{11} kg of CO_2, and it is.

Practice Exercise Disposable lighters burn butane (C_4H_{10}) and produce CO_2 and H_2O. Write a balanced chemical equation for this combustion reaction and determine how many grams of CO_2 are produced by burning 1.00 g of C_4H_{10}.

(Answers to Practice Exercises are in the back of the book.)

SAMPLE EXERCISE 3.13 Calculating the Mass of a Reactant Needed to Produce a Mass of Product LO3

Copper was among the first metals to be refined from minerals collected by ancient metalworkers. The production of copper was already an industry by 3500 BCE. Cuprite is a copper mineral commonly found near Earth's surface, making it a likely resource for Bronze Age coppersmiths. Cuprite has the formula Cu_2O and can be converted to copper metal by reacting it with charcoal:

$$2\ Cu_2O(s) + C(s) \rightarrow 4\ Cu(s) + CO_2(g)$$

How much cuprite must be consumed in the above reaction to prepare 256 g of copper for a bracelet such as the one shown in **Figure 3.22**?

Collect and Organize We are given a balanced chemical equation and the mass of a product, Cu, and are asked to find the mass of one of the reactants, Cu_2O. The mole ratio is 4 mol Cu:2 mol Cu_2O, which simplifies to 2:1.

Analyze To use this mole ratio, we first need to convert g Cu to mol Cu, and then use the 2:1 ratio to calculate an equivalent mol Cu_2O

value. Finally, we use the molar mass of Cu_2O to calculate the mass of it required for the reaction.

Solve Carrying out the steps described in the analysis of the problem:

Think About It There are only three significant figures in our answer because there are three significant figures in 256 g of Cu. The 2:1 mole ratio in the stoichiometry of the reaction makes sense because there are 2 moles of Cu in 1 mole of Cu_2O. The presence of oxygen in Cu_2O explains the greater mass of it (288 g) that was needed to produce 256 g of copper.

Practice Exercise The copper mineral chalcocite (Cu_2S) can be converted to copper simply by heating in air: $Cu_2S(s) + O_2(g) \rightarrow 2\ Cu(s) + SO_2(g)$. How much Cu_2S is needed to make 256 g of Cu? How many grams of SO_2 are also produced?

(Answers to Practice Exercises are in the back of the book.)

$$= \boxed{\text{theoretical yield}}$$

$$\boxed{\%\text{ yield}} = \boxed{\frac{\text{actual yield}}{\text{theoretical yield}}} \times 100\%$$

$$6.00 \cancel{\text{kg } H_2} \times \frac{10^3 \cancel{\text{g } H_2}}{1 \cancel{\text{kg } H_2}} \times \frac{1 \cancel{\text{mol } H_2}}{2.016 \cancel{\text{g } H_2}} \times \frac{2 \cancel{\text{mol } NH_3}}{3 \cancel{\text{mol } H_2}} \times \frac{17.03 \cancel{\text{g } NH_3}}{1 \cancel{\text{mol } NH_3}} \times \frac{1 \text{ kg } NH_3}{10^3 \cancel{\text{g } NH_3}}$$

$$= 33.8 \text{ kg } NH_3$$

$$\frac{18.20 \cancel{\text{kg } NH_3}}{33.8 \cancel{\text{kg } NH_3}} \times 100\% = 53.8\%$$

$$90.9 \cancel{\text{mol CO}} \times \frac{1 \cancel{\text{mol } H_2}}{1 \cancel{\text{mol CO}}} \times \frac{2.016 \text{ g } H_2}{1 \cancel{\text{mol } H_2}} = 183 \text{ g } H_2$$

$$\frac{176\text{ g H}_2}{183\text{ g H}_2} \times 100\% = 96\%$$

3.6 Limiting Reactants and Percent Yield

Let’s return to photosynthesis, the process responsible for the O_2 in our present-day atmosphere and for the energy that sustains life on Earth’s surface. The stoichiometry of the reaction calls for equal moles, referred to as *equimolar amounts*, of CO_2 and H_2O:

In nature there is little likelihood of having the exact mole ratio of reactants at a reaction site, so let’s consider what happens when more than six molecules of water are available for every six molecules of CO_2 (this is not a theoretical consideration because having water in excess is a common occurrence in biological systems). The photosynthetic production of glucose will continue until all the CO_2 at the reaction site is consumed, leaving surplus water unreacted. In this example, carbon dioxide is the limiting reactant, meaning that the maximum amount of product is determined by the quantity of CO_2 available and not by the quantity of H_2O, which is in excess. **Figure 3.23** provides another example of a reaction mixture with a limiting reactant.

The concept of the limiting reactant applies to everyday tasks, too. Suppose you are assembling bicycles that consist of one bike frame, one bike seat, and two wheels:

frame + bike seat + 2 wheels → bicycle

You have 100 bike frames, 100 seats, and 100 wheels. If you used all the bike frames and all the seats, you could build 100 bicycles. But you only have enough wheels to build 50 bicycles, because each bicycle needs two wheels. The wheels, then, are the limiting reactant in this scenario.

Calculations Involving Limiting Reactants

Suppose you are asked to calculate the mass of a product formed from given masses of two or more reactants. How do you know whether one reactant is limiting? And how do you know which one is limiting? It is tempting to select the reactant present in the smaller amount by mass. Avoid this temptation and instead take a systematic approach based on the stoichiometry of the reaction. Several approaches are possible, two of which we present here—namely, one that uses stoichiometric calculations and one that uses mole ratios of reactants.

In our first method, we calculate how much product would be formed if reactant A were completely consumed. Then we repeat the calculation for reactant B (and so on for any additional reactants). Let's try this approach with the earlier reaction of Equation 3.1 between sulfur trioxide gas and water vapor to form sulfuric acid:

This reaction contributed to the acidity of Earth's early atmosphere (see Section 3.1). Suppose we carry out this reaction in the laboratory by using 20.00 g of $SO_3(g)$ and 10.00 g of $H_2O(g)$. Which is the limiting reactant, and how many grams of H_2SO_4 are produced from these masses of reactants?

Calculating the numbers of moles of SO_3 and H_2O from the two masses:

Then we calculate the mass of sulfuric acid produced if all the SO_3 were consumed:

Next, we carry out the same calculation to determine how much sulfuric acid is produced if the 10.00 g of H_2O were to react completely:

The sulfur trioxide is the limiting reactant because, when it is completely consumed, a smaller amount of product is formed. Thus, when 20.00 g of SO_3 and 10.00 g of H_2O react, the maximum amount of product that can form is 24.50 g of H_2SO_4. Making that amount of sulfuric acid consumes all the available SO_3 but not all the available H_2O.

The second method compares the mole ratio of the reactants to the mole ratio required by the balanced chemical equation. To use this approach, we take the following steps:

1. Convert masses of reactants A and B into moles.
2. Calculate the mole ratio of A to B.
3. Compare this mole ratio with the stoichiometric mole ratio from the balanced chemical equation. If

   $$\left(\frac{\text{mol A}}{\text{mol B}}\right)_{\text{calculated}} > \left(\frac{\text{mol A}}{\text{mol B}}\right)_{\text{stoichiometric}} \tag{3.3}$$

   then the reaction mixture has more A than is needed to consume all of B, and B is the limiting reactant. If

   $$\left(\frac{\text{mol A}}{\text{mol B}}\right)_{\text{calculated}} < \left(\frac{\text{mol A}}{\text{mol B}}\right)_{\text{stoichiometric}} \tag{3.4}$$

   then there is not enough A in the reaction mixture to consume all of B, and A is the limiting reactant. If the two ratios are equal, the masses are the stoichiometric amounts and both reactants are consumed completely.

For the same example using 20.00 g of SO_3 and 10.00 g of H_2O, we calculate the mole ratio of SO_3 to H_2O after calculating the moles of SO_3 and H_2O available:

According to Equation 3.1, the stoichiometric ratio of SO_3 to H_2O is $1/1 = 1$. The SO_3/H_2O mole ratio for our reaction conditions is $0.2498/0.5549 = 0.4502$. Expressing this outcome as a mathematical relationship, we get

This inequality matches Equation 3.4, which tells us that SO_3 (reactant A in Equation 3.4) must be the limiting reactant.

These two approaches to determining a limiting reactant lead to the same conclusion and are of similar complexity. In both cases, the masses of the reactants are given in grams, so we must convert those masses into moles. The advantage of the first method is that it not only determines the identity of the limiting reactant, but it also determines the theoretical yield, the maximum amount of product that would be produced by the given mixture if the limiting reactant were completely converted into product. The theoretical yield is sometimes called the *stoichiometric yield* or *100% yield*.

SAMPLE EXERCISE 3.14 Identifying Limiting Reactants LO4

During strenuous exercise, respiration (the reaction between glucose and oxygen that produces CO_2 and water; Section 3.5) is limited by the availability of oxygen to the muscles. We can model this situation by considering the reaction between 1.32 g $C_6H_{12}O_6$ (**Figure 3.24**) and 1.32 g O_2. Is one of these reactants a limiting reactant, or is the mixture stoichiometric? If one reactant is limiting, which one is it?

Collect and Organize We are given quantities of two reactants ($C_6H_{12}O_6$ and O_2) and we want to determine which, if either, is limiting. Respiration is described (Section 3.5) by this chemical equation:

$$C_6H_{12}O_6(aq) + 6\ O_2(g) \rightarrow 6\ CO_2(g) + 6\ H_2O(\ell)$$

Analyze We can determine the limiting reactant from the ratio of O_2 to $C_6H_{12}O_6$ in the chemical equation for the reaction. That means we will use the second method described in the preceding discussion in which we compare the ratio of the amounts of reactants with the stoichiometric ratio in the balanced equation to determine whether one of the reactants is limiting.

Solve Convert the given masses of reactants to moles:

and calculate the mole ratio:

This ratio is less than the stoichiometric ratio of 6 moles O_2 to 1 mole $C_6H_{12}O_6$, so oxygen is the limiting reactant, and there is a slight excess of glucose.

Think About It The calculation indicates that when equal masses of glucose and oxygen react, oxygen is the limiting reactant. This makes sense because the mass of 6 moles O_2 is 6 mol × 32 g/mol = 192 g, whereas the mass of 1 mole of glucose is 180 g. Therefore, a larger mass of O_2 is needed to react with a given mass of glucose.

Practice Exercise Any fuel–oxygen mixture that contains more oxygen than is needed to burn the fuel completely is called a *lean mixture*, whereas a mixture containing too little oxygen to allow complete combustion of the fuel is called a *rich mixture*. A high-performance heater that burns propane, $C_3H_8(g)$, is adjusted so that 100.0 g of $O_2(g)$ enters the system for every 26.0 g of propane. Is this mixture lean or rich?

(Answers to Practice Exercises are in the back of the book.)

SAMPLE EXERCISE 3.15 Calculating Theoretical Yield LO5

The results of the Miller–Urey experiments required a chemical reaction to account for the formation of glycine (**Figure 3.25**). The reaction of carbon dioxide, ammonia, and methane that produces glycine, water, and carbon monoxide is described by the following chemical equation:

$$2\ CO_2(g) + NH_3(g) + CH_4(g) \rightarrow C_2H_5NO_2(s) + H_2O(\ell) + CO(g)$$

How much glycine could be expected from the reaction of 21.3 g of

CO_2, 4.53 g of NH_3, and 4.27 g of CH_4? How much of which reactant(s) would remain unreacted?

Collect and Organize We are given a balanced chemical equation and the quantities of three reactants (CH_4, NH_3, and CO_2). We are asked how much glycine can be produced, which will require us to identify which one of the reactants is the limiting reactant and which reactants will be in excess. Because there are three reactants, we must use the first method discussed previously.

Analyze First we calculate the number of moles of each reactant we have available. Then, we calculate the theoretical quantity of glycine that would be produced from completely consuming each reactant. The reactant yielding the smallest amount of glycine is the limiting reactant and determines the theoretical amount of glycine that we can expect from the reaction. To calculate the quantity of the reactants in excess that will be left over, we use the stoichiometry of the reaction to calculate how much of each reactant is consumed during the reaction and then subtract that value from the initial amount present in the reaction mixture.

Solve

1. Using the molar masses of CO_2, NH_3, and CH_4, we calculate the number of moles of each that are available:

$$21.3\ \cancel{\text{g CO}_2} \times \frac{1\ \text{mol CO}_2}{44.01\ \cancel{\text{g CO}_2}} = 0.4840\ \text{mol CO}_2$$

$$4.53\ \cancel{\text{g NH}_3} \times \frac{1\ \text{mol NH}_3}{17.03\ \cancel{\text{g NH}_3}} = 0.2660\ \text{mol NH}_3$$

$$4.27\ \cancel{\text{g CH}_4} \times \frac{1\ \text{mol CH}_4}{16.04\ \cancel{\text{g CH}_4}} = 0.2662\ \text{mol CH}_4$$

Using the mole ratios of $C_2H_5NO_2$ to each reactant and the molar mass of $C_2H_5NO_2$, we calculate the amount of glycine that could be produced from each reactant:

$$0.4840\ \cancel{\text{mol CO}_2} \times \frac{1\ \cancel{\text{mol C}_2\text{H}_5\text{NO}_2}}{2\ \cancel{\text{mol CO}_2}} \times \frac{75.07\ \text{g C}_2\text{H}_5\text{NO}_2}{1\ \cancel{\text{mol C}_2\text{H}_5\text{NO}_2}} = 18.2\ \text{g C}_2\text{H}_5\text{NO}_2$$

$$0.2660\ \cancel{\text{mol NH}_3} \times \frac{1\ \cancel{\text{mol C}_2\text{H}_5\text{NO}_2}}{1\ \cancel{\text{mol NH}_3}} \times \frac{75.07\ \text{g C}_2\text{H}_5\text{NO}_2}{1\ \cancel{\text{mol C}_2\text{H}_5\text{NO}_2}} = 20.0\ \text{g C}_2\text{H}_5\text{NO}_2$$

$$0.2662\ \cancel{\text{mol CH}_4} \times \frac{1\ \cancel{\text{mol C}_2\text{H}_5\text{NO}_2}}{1\ \cancel{\text{mol CH}_4}} \times \frac{75.07\ \text{g C}_2\text{H}_5\text{NO}_2}{1\ \cancel{\text{mol C}_2\text{H}_5\text{NO}_2}} = 20.0\ \text{g C}_2\text{H}_5\text{NO}_2$$

The smallest of the theoretical yields, 18.2 g, represents the maximum quantity of $C_2H_5NO_2$ that could be produced and identifies CO_2 as the limiting reactant.

2. The masses of NH_3 and CH_4 that would be consumed in a reaction in which 0.4840 mol CO_2 is completely consumed are

$$0.4840\ \cancel{\text{mol CO}_2} \times \frac{1\ \cancel{\text{mol NH}_3}}{2\ \cancel{\text{mol CO}_2}} \times \frac{17.03\ \text{g NH}_3}{1\ \cancel{\text{mol NH}_3}} = 4.12\ \text{g NH}_3$$

$$0.4840\ \cancel{\text{mol CO}_2} \times \frac{1\ \cancel{\text{mol CH}_4}}{2\ \cancel{\text{mol CO}_2}} \times \frac{16.04\ \text{g CH}_4}{1\ \cancel{\text{mol CH}_4}} = 3.88\ \text{g CH}_4$$

Therefore, the masses of unreacted NH_3 and CH_4 would be

$(4.53 - 4.12)\ \text{g NH}_3 = 0.41\ \text{g NH}_3$

$(4.27 - 3.88)\ \text{g CH}_4 = 0.39\ \text{g CH}_4$

Think About It The mass of CO_2 in the original mixture is nearly 5 times the mass of each of the other two reactants, yet CO_2 is the limiting reactant. This may not seem reasonable, but it is for two reasons: the molar mass of CO_2 is over 2.5 times the molar masses of NH_3 and CH_4, and 2 moles of CO_2 are consumed for every 1 mole of NH_3 and 1 mole of CH_4.

Practice Exercise One of the intermediates in the synthesis of glycine from ammonia, carbon dioxide, and methane is $C_2H_4N_2$, produced by this reaction:

$3\ CH_4(g) + 5\ CO_2(g) + 8\ NH_3(g) \rightarrow 4\ C_2H_4N_2(g) + 10\ H_2O(\ell)$

How many grams of $C_2H_4N_2$ could be expected from the reaction of

14.2 g of CO_2, 2.27 g of NH_3, and 2.14 g of CH_4?

(Answers to Practice Exercises are in the back of the book.)

Actual Yields versus Theoretical Yields

Recall from the beginning of this section that the theoretical yield is the maximum amount of product possible from the given quantities of reactants, provided the reaction works perfectly. In nature, industry, or the laboratory, the actual yield may be less than the theoretical yield for several reasons. Sometimes reactants combine to form products other than the ones desired. In others, fractions of the reactants remain unreacted no matter how long the reaction runs. For these and other reasons, it is useful to distinguish between the theoretical yield and the actual yield of a chemical reaction and to calculate the percent yield:

Percent yield is a measure of a reaction’s efficiency at forming the desired product.

SAMPLE EXERCISE 3.16 Calculating Percent Yield LO5

The industrial process for making the ammonia used in fertilizer, explosives, and many other products is based on the reaction between nitrogen and hydrogen at high temperature and pressure:

$N_2(g) + 3\ H_2(g) \rightarrow 2\ NH_3(g)$

If 18.20 kg of NH_3 is produced by a reaction mixture that initially contains 6.00 kg of H_2 and an excess of N_2, what is the percent yield of the reaction?

Collect and Organize We know that the actual yield of NH_3 is 18.20 kg. We also know that the reaction mixture initially contained 6.00 kg of H_2 and that H_2 must be the limiting reactant because the problem specifies the presence of excess N_2. We need to find the percent yield.

Analyze We need to use the mass of H_2 to calculate how much NH_3 could have been produced—the theoretical yield. We can then use the theoretical yield and the actual yield to calculate the percent yield. We need the molar masses of H_2 and NH_3 and the stoichiometry of the reaction, which specifies that 2 moles of NH_3 are produced for every 3 moles of H_2 consumed.

Solve The molar masses we need are:

$\mathcal{M}_{\mathrm{H2}} = 2(1.008\ \mathrm{g/mol}) = 2.016\ \mathrm{g/mol}$

$\mathcal{M}_{\mathrm{NH3}} = 14.01\ \mathrm{g/mol} + 3(1.008\ \mathrm{g/mol}) = 17.03\ \mathrm{g/mol}$

Calculating the theoretical yield of NH_3:

Dividing the actual yield by this theoretical yield to determine percent yield:

Think About It In the text preceding this sample exercise we noted that some reactions proceed only partway in converting reactants into products, but no further, leaving reactants unreacted no matter how long the reaction runs. The synthesis of ammonia is such a reaction, with percent yields that are usually much less than 100% and making the calculated value a reasonable one.

Practice Exercise Most of the hydrogen gas used in industry and as fuel is produced in a reaction between methane and high-temperature steam: $CH_4(g) + H_2O(g) \rightarrow 3\ H_2(g) + CO(g)$. If 1.20 kg CH_4 and an excess of steam produces 318 g H_2, what is the percent yield of the reaction?

(Answers to Practice Exercises are in the back of the book.)

SAMPLE EXERCISE 3.17 Effect of Percent Yield on Calculating the

Mass of Reactant Needed LO5

Another way of producing hydrogen gas (see Practice Exercise 3.16) is the water–gas shift reaction:

$$H_2O(g) + CO(g) \rightarrow H_2(g) + CO_2(g)$$

At 200°C, the reaction produces a 96% yield. How many grams of H_2O and CO are needed to generate 176 g of H_2 under these conditions?

Collect and Organize This is a stoichiometry problem like Sample Exercises 3.12 and 3.13, except that the reaction yield is only 96%.

Analyze We need to convert the mass of H_2 we want to make into moles of H_2, and then we use the mole ratios of H_2:CO and H_2:H_2O to find the quantities of reactants we need. To produce 176 g of H_2 (actual yield), we know the percent yield (96%) and must calculate the theoretical yield. Then by analogy to Sample Exercise 3.13, we can calculate the amount of both reactants needed.

Solve

1. The number of moles of H_2 we want to produce is:

$$176\ \cancel{\text{g H}_2} \times \frac{1\ \text{mol H}_2}{2.016\ \cancel{\text{g H}_2}} = 87.30\ \text{mol H}_2$$

This value represents an actual yield value that is only 96% of the theoretical yield. Solving for the theoretical yield using Equation 3.5:

$$\begin{aligned} \text{percent yield} &= \frac{\text{actual yield}}{\text{theoretical yield}} \times 100\% \\ &= 96\% = \frac{87.30\ \text{mol H}_2}{x} \times 100\% \\ x &= 90.9\ \text{mol H}_2 \end{aligned}$$

2. Using the mole ratios of H_2:H_2O and H_2:CO, we find the

number of moles of H_2O and CO:

$$90.9\ \cancel{\text{mol H}_2} \times \frac{1\ \text{mol H}_2\text{O}}{1\ \cancel{\text{mol H}_2}} = 90.9\ \text{mol H}_2\text{O}$$

$$90.9\ \cancel{\text{mol H}_2} \times \frac{1\ \text{mol CO}}{1\ \cancel{\text{mol H}_2}} = 90.9\ \text{mol CO}$$

3. To convert from moles of reactants to the mass of the reactants, we multiply by the molar mass:

$$90.9\ \cancel{\text{mol H}_2\text{O}} \times \frac{18.02\ \text{g H}_2\text{O}}{1\ \cancel{\text{mol H}_2\text{O}}} = 1.64 \times 10^3\ \text{g H}_2\text{O}$$

$$90.9\ \cancel{\text{mol CO}} \times \frac{28.01\ \text{g CO}}{1\ \cancel{\text{mol CO}}} = 2.55 \times 10^3\ \text{g CO}$$

Think About It As a check of our answers, let’s calculate how much H_2 would be produced from 90.9 moles of CO if the reaction proceeded in 100% yield:

The percent yield is

Practice Exercise How much aluminum oxide and how much carbon are needed to prepare 454 g (1 pound) of aluminum by the balanced chemical equation:

$$2\ \text{Al}_2\text{O}_3(s) + 3\ \text{C}(s) \rightarrow 4\ \text{Al}(s) + 3\ \text{CO}_2(g)$$

if the reaction proceeds to 78% yield?

(Answers to Practice Exercises are in the back of the book.)

Glossary

limiting reactant
: a reactant that is consumed completely in a chemical reaction; the amount of product formed depends on the amount of the limiting reactant available.

theoretical yield
: the maximum amount of product possible in a chemical reaction for given quantities of reactants; also called *stoichiometric yield*.

actual yield
: the amount of product obtained from a chemical reaction, which may be less than the theoretical yield.

percent yield
: the ratio, expressed as a percentage, of the actual yield of a chemical reaction to the theoretical yield.

Learning Objectives

3.7 Determining Empirical Formulas from Percent Composition

Natural sources of methane such as swamps, bogs, rice paddies, and animals introduce about 570 million kg CH_4 into the atmosphere every day. Other volatile hydrocarbons are emitted by other natural sources, such as conifers (**Figure 3.26**), which emit a variety of hydrocarbons including pinene, $C_{10}H_{16}$. One way to distinguish between CH_4 and $C_{10}H_{16}$ is in terms of their percent composition: the composition of a compound expressed in terms of the percentages of the masses of the constituent elements with respect to the total mass of the compound. Putting this definition in equation form:

To calculate the percent composition of CH_4 and $C_{10}H_{16}$, we must calculate the carbon content of both compounds. Suppose we have 1 mole of CH_4, which has a molar mass of

$$4(1.008 \text{ g H/mol}) + 12.011 \text{ g C/mol} = 16.043 \text{ g/mol}$$

Of this 16.043 g, carbon accounts for 12.011 g. Therefore, the mass % of carbon in CH_4 is

Similarly, for hydrogen content:

Because CH_4 contains only C and H, we could also determine the percent H by subtracting the percent C from 100%:

$$100.00\% - 74.87\% = 25.13\%$$

The benefit of calculating the percentages separately, instead of by subtraction, is that you can check to make sure your answers sum to 100%.

How does this compare with the percent C in pinene? If we repeat the calculation for $C_{10}H_{16}$, the molar mass is

$$16(1.008 \text{ g H/mol}) + 10(12.01 \text{ g C/mol}) = 136.23 \text{ g/mol}$$

The carbon content of $C_{10}H_{16}$ is

and the hydrogen content is

$$\text{mass \% H} = 100.00\% - 88.16\% = 11.84\%$$

Pinene contains a higher percent carbon by mass and a correspondingly lower percent hydrogen than those of methane. Methane, in fact, has the highest percent hydrogen of all hydrocarbons.

SAMPLE EXERCISE 3.18 Calculating Percent Composition from a Chemical Formula LO6

A compound with the formula $C_2H_2F_4$ is a propellant in the inhalers used by asthma sufferers (**Figure 3.27**). What is the percent composition of $C_2H_2F_4$?

Collect, Organize, and Analyze We are asked to calculate the percent composition of $C_2H_2F_4$. We need the molar masses of each of the elements (C, H, and F) to calculate the molar mass of $C_2H_2F_4$ and the relative contribution of each element to the compound's molar mass. To calculate the percent composition of $C_2H_2F_4$, we must determine the percentage by mass of each element in 1 mole of $C_2H_2F_4$. These percentages can be calculated by dividing the mass of each element in 1 mole of $C_2H_2F_4$ by the molar mass of $C_2H_2F_4$.

Solve The molar mass of $C_2H_2F_4$ is

$2(12.01\ \text{g/mol}) + 2(1.008\ \text{g/mol}) + 4(19.00\ \text{g/mol}) = 102.04\ \text{g/mol}$

Thus, the percent composition of this compound is

Think About It Although C and F have similar molar masses, the observation that the percentage of F is nearly three times the percentage of C makes sense because there are 2 moles of F for every 1 mole of C in $C_2H_2F_4$. It also makes sense that the percentage of the lightest element, hydrogen, is very small.

Practice Exercise Determine the percent composition of tetradecafluorohexane (C_6F_{14}; **Figure 3.28**), which is used to treat patients suffering from smoke inhalation.

(Answers to Practice Exercises are in the back of the book.)

The three mass percentages in Sample Exercise 3.18 sum to 100.00%. Percent composition values should always sum to 100%, or very close to 100%, if we have accounted for all the elements that make up the total mass of the compound. The total may deviate slightly from 100% because of rounding.

We typically determine the percent composition of a substance in the laboratory by measuring the amount of each element in a given mass of the substance. We can use these data to determine the *empirical formula* of the substance. There are four steps to deriving an empirical formula from percent composition data obtained in the laboratory:

1. Assume you have exactly 100 g of the substance, so that the percent composition values are equivalent to the values of the masses of the elements expressed in grams. As an initial check, add the mass percentages given in the problem to make sure they total 100%.
2. Convert the mass of each element into moles.
3. Compute a simple mole ratio by dividing all the mole values by the smallest one.
4. If necessary, convert the ratio from step 3 into a ratio of whole numbers, which will serve as subscripts following the symbols of the elements in the empirical formula of the compound.

CONNECTION We discussed empirical formulas in Chapter 2. *Empirical*, which is related to the word *experiment*, means "derived from experimental data," such as the data from experiments to determine percent composition.

The best way to learn this process is by using it. Let's start with carbon tetrachloride, a compound once widely used as a fire-extinguishing agent and as a solvent in dry cleaning. It is 7.81% C and 92.19% Cl, which means that in exactly 100 g of this substance there are 7.81 g C and 92.19 g Cl. We use these masses to calculate the number of moles of C and Cl in 100 g of the compound:

To calculate a simple ratio of these mole values, we divide both numbers by the smaller of the two:

Both values are whole numbers, so the empirical formula of carbon tetrachloride is CCl_4.

We can use these same steps for substances that contain more than two elements. For example, elemental analysis of a commonly used refrigeration gas gives the following percent composition of a sample: 28.58% C, 3.60% H, and 67.82% F. The sum of these percentages totals 100%, so all elements are accounted for in our analysis. Our calculations are then

28.58% C = 28.58 g C in 100 g

$3.60\%\ \text{H} = 3.60\ \text{g H in } 100\ \text{g}$

$67.82\%\ \text{F} = 67.82\ \text{g F in } 100\ \text{g}$

and the corresponding numbers of moles are

The mole ratio for C:H:F is 2.380:3.57:3.569. To convert this ratio to small whole numbers, we divide all three values by 2.380 mol, which is the smallest value:

To change the mole ratio 1:1.5:1.5 to a ratio of whole numbers, we multiply the numbers by a factor that results in whole numbers. Multiplying 1.5 (or $\frac{3}{2}$) by 2 yields 3, so we multiply all three terms in this ratio by 2 to obtain a C:H:F ratio of 2:3:3. Thus, the empirical formula is $C_2H_3F_3$.

Both CCl_4 and $C_2H_3F_3$ are molecular compounds whose empirical formulas match their molecular formulas (**Figure 3.29a, b**). This is not always the case. Butane, another hydrocarbon found in natural gas and used as a fuel, has a percent composition of 82.66% C and 17.34% H. We can calculate its empirical formula as follows:

The C:H mole ratio is 6.883:17.20, so dividing by 6.883 mol gives

When we multiply both numbers by 2, the whole-number ratio becomes 2:5, so the empirical formula for butane is C_2H_5. The structure of a molecule of butane is shown in **Figure 3.29c**; it has the *molecular* formula C_4H_{10}. It is important to keep in mind that percent composition data are used to determine empirical formulas—the lowest whole-number ratio of atoms in a molecule. Empirical formulas are not necessarily molecular formulas that tell us the actual numbers of atoms in the molecule.

For ionic compounds such as FeO and Fe_2O_3, chemical formulas *are* empirical formulas because the chemical formulas of ionic compounds represent the ratio of the ions in one formula unit of the compound. Samples of ionic compounds contain vast three-dimensional arrays of their component ions: Fe^{2+} and O^{2-} ions in FeO (**Figure 3.30a**), and Fe^{3+} and O^{2-} ions in Fe_2O_3. The arrangement of the Fe^{2+} and O^{2-} ions in FeO is called a *halite structure* because it is also the structure of the mineral halite (NaCl; **Figure 3.30b**). In an ionic compound the chemical formula, the empirical formula, and the formula unit are all the same.

CONCEPT TEST

Which pairs of the following compounds have the same empirical formula and same percent composition?

1. Ethylene (C_2H_4), a gas used to ripen bananas
2. Acetylene (C_2H_2), a gas used in welding
3. Eicosene ($C_{20}H_{40}$), a compound used to attract Japanese beetles to traps
4. Benzene (C_6H_6), a known carcinogen found in gasoline

(Answers to Concept Tests are in the back of the book.)

SAMPLE EXERCISE 3.19 Deriving an Empirical Formula from Percent Composition LO6

Nitrous oxide, the laughing gas used in dentists' offices, is 63.65% N. What is the empirical formula of nitrous oxide?

Collect and Organize We are given the percent composition by mass of N (63.65%) and asked to determine the simplest whole-number ratio of nitrogen and oxygen in the chemical formula.

Analyze We can obtain the percent composition by mass of oxygen in nitrous oxide by subtracting the percent N from 100%. We can use the four steps described previously to determine the empirical formula.

Solve The percent O in the sample is:

$$\%\text{O} = 100.00\% - \%\text{N} = 100.00\% - 63.65\% = 36.35\%$$

Now we have the data we need to determine the empirical formula of nitrous oxide.

1. Convert percent composition values into masses by assuming a sample size of exactly 100 g:

   $$63.65\%\ \text{N} = 63.65\ \text{g N in } 100\ \text{g}$$

   $$36.35\%\ \text{O} = 36.35\ \text{g O in } 100\ \text{g}$$

2. Convert masses into moles:

   $$63.65\ \cancel{\text{g N}} \times \frac{1\ \text{mol N}}{14.01\ \cancel{\text{g N}}} = 4.543\ \text{mol N}$$

   $$36.35\ \cancel{\text{g O}} \times \frac{1\ \text{mol O}}{16.00\ \cancel{\text{g O}}} = 2.272\ \text{mol O}$$

3. Simplify the mole ratio 4.543:2.272 by dividing by the smaller value:

   $$\frac{4.543\ \text{mol N}}{2.272} = 2.000\ \text{mol N} \qquad \frac{2.272\ \text{mol O}}{2.272} = 1.000\ \text{mol O}$$

   The N:O mole ratio is 2:1.

4. Since the mole ratio of N to O is already a ratio of whole numbers, the empirical formula of nitrous oxide is N_2O.

Think About It The molar masses of N and O are similar, so a ≈2:1 ratio of the mass of N to the mass of O is consistent with an empirical formula that is 2:1 nitrogen to oxygen. “Nitrous oxide”—whose molecular formula is also N_2O—is formally named “dinitrogen monoxide” under the rules introduced in Chapter 2.

Practice Exercise A different nitrogen oxide, containing 46.16% N, acts as a vasodilator, lowering blood pressure in the human body (**Figure 3.31**). What is its empirical formula?

(Answers to Practice Exercises are in the back of the book.)

SAMPLE EXERCISE 3.20 Deriving an Empirical Formula of a Compound Containing More than Two Elements LO6

Rechargeable lithium batteries are essential to portable electronic devices and are increasingly important to the automotive industry in gas–electric hybrid and all-electric vehicles (**Figure 3.32**). Analysis of the most common lithium-containing mineral, spodumene, shows it is composed of 3.73% Li, 14.50% Al, 30.18% Si, and 51.59% O. What is the empirical formula of spodumene?

Collect and Organize We are given the percent composition by mass of spodumene and asked to determine the simplest whole-number ratio of the four elements (Li, Al, Si, and O), which defines the empirical formula of spodumene.

Analyze We follow the same steps as in Sample Exercise 3.19, except that here we must calculate more than one mole ratio.

Solve

1. Assuming an exactly 100-g sample of spodumene, we have 3.73 g of Li, 14.50 g of Al, 30.18 g of Si, and 51.59 g of O.
2. Converting the masses into moles, we have

$$3.73\ \cancel{\text{g Li}} \times \frac{1\ \text{mol Li}}{6.941\ \cancel{\text{g Li}}} = 0.5374\ \text{mol Li}$$

$$14.50\ \cancel{\text{g Al}} \times \frac{1\ \text{mol Al}}{26.98\ \cancel{\text{g Al}}} = 0.5374\ \text{mol Al}$$

$$30.18\ \cancel{\text{g Si}} \times \frac{1\ \text{mol Si}}{28.09\ \cancel{\text{g Si}}} = 1.074\ \text{mol Si}$$

$$51.59\ \cancel{\text{g O}} \times \frac{1\ \text{mol O}}{16.00\ \cancel{\text{g O}}} = 3.224\ \text{mol O}$$

3. Dividing each mole value by the smallest value yields a simple ratio of the four elements:

$$\frac{0.5374\ \text{mol Li}}{0.5374} = 1.000 \text{ or } 1\ \text{mol Li} \qquad \frac{0.5374\ \text{mol Al}}{0.5374} = 1.000 \text{ or } 1\ \text{mol Al}$$

$$\frac{1.074\ \text{mol Si}}{0.5374} = 1.999 \text{ or } 2\ \text{mol Si} \qquad \frac{3.224\ \text{mol O}}{0.5374} = 5.999 \text{ or } 6\ \text{mol O}$$

4. All these results are either whole numbers or very close to whole numbers, so no further simplification of terms is needed. Our mole ratio is Li:Al:Si:O = 1:1:2:6, which means the empirical formula of spodumene is $LiAlSi_2O_6$.

Think About It The sum of the mass percentages should be very close to 100%; in this case, 3.73% + 14.50% + 30.18% + 51.59% = 100.00%, so we have accounted for all the elements. Lithium is present in the lowest percentage by mass of all four elements in spodumene, but spodumene remains the most commercially important source of lithium for batteries.

Practice Exercise Spodumene is processed chemically to convert it to a material having the percent composition 18.79% Li, 16.25% C, and 64.96% O. What is the empirical formula of this lithium compound?

(Answers to Practice Exercises are in the back of the book.)

Glossary

percent composition

the composition of a compound expressed in terms of the percentage by mass of each element in the compound.

The bars at much smaller *m/z* values are produced when the ionizing beam also breaks apart the molecules into fragments. The molar masses of C_2H_2 and C_6H_6 are 26 and 78 g/mol, respectively.

3.8 Comparing Empirical and Molecular Formulas

An empirical formula represents the simplest whole-number ratio of the elements contained in a compound, but it is not necessarily the same as the molecular formula of a molecular compound. To further examine the difference between empirical and molecular formulas, let’s consider the organic molecule glycolaldehyde (**Figure 3.33**). About one in 20 of the meteorites that fall to Earth today contains a variety of organic compounds, including glycolaldehyde. Some scientists view the presence of these compounds as evidence that the molecular building blocks of life on Earth may have come from space. Glycolaldehyde is also present in our bodies as a product of the metabolism of sugars and proteins.

Elemental analysis of glycolaldehyde provides the following percent composition data: 40.00% C, 6.71% H, and 53.28% O. We can use this information to calculate the empirical formula of the compound and then compare our result with the molecular structure in Figure 3.33. Using the method developed in Section 3.7, we obtain these results:

The mole ratio of C:H:O is $3.331:6.66:3.330 = 1:2:1$, so the empirical formula is CH_2O.

The molecular formula of the molecule in Figure 3.33 is $C_2H_4O_2$, which represents the actual numbers of C, H, and O atoms in one molecule of glycolaldehyde. This molecular formula is a multiple of the empirical formula, which is consistent with the idea that the empirical formula represents a ratio of the atoms of the elements. In this case, we would multiply each subscript in the empirical formula by 2 to obtain the molecular formula.

Occasionally, empirical and molecular formulas are identical. For example, formaldehyde—which, like glycolaldehyde, is 40.00% C, 6.71% H, and 53.28% O—has the molecular formula CH_2O, which is the same as its empirical formula (**Figure 3.34**). Many other compounds also have the empirical formula CH_2O. Each subscript in these molecular formulas is a multiple of the corresponding subscript in the empirical formula. For example, a multiplier (*n*) of 6 converts the empirical formula, CH_2O, into the molecular formula of many sugars, including $C_6H_{12}O_6$:

CONCEPT TEST

Which of the following compounds have empirical formulas that are identical to their molecular formulas?

1. $C_2H_6O_2$ (ethylene glycol), used in antifreeze
2. C_3H_8O (isopropanol), also known as rubbing alcohol
3. $C_6H_{12}O_6$ (glucose), also known as “blood sugar” and the primary source of energy for our body’s cells

(Answers to Concept Tests are in the back of the book.)

The key to translating empirical formulas into molecular formulas is to determine the value of *n*, and the key to determining the value of *n* is knowing the molar mass. For example, suppose elemental analysis determines that the empirical formula of a liquid hydrocarbon is C_4H_5. Using the mole ratio given by this formula and the average atomic masses of the two elements, we can calculate the molar mass corresponding to the empirical formula:

$$4(12.01\ \text{g/mol}) + 5(1.008\ \text{g/mol}) = 53.08\ \text{g/mol}$$

Each molecule of this hydrocarbon consists of either the number of atoms in the empirical formula or a multiple of those atoms. Additional analysis of the compound reveals its molar mass to be 106 g/mol. What multiple of 53.08 g/mol (the mass of 4 moles of carbon atoms and 5 moles of hydrogen atoms) has a mass of 106 g/mol? Do the following calculation to find out:

Thus, 2 is the value of the multiplier, *n*, and the molecular formula of the compound is

$$(C_4H_5)_n = (C_4H_5)_2 = C_8H_{10}$$

SAMPLE EXERCISE 3.21 Deriving a Molecular Formula from an Empirical Formula LO7

Lycopene (molar mass 536.88 g/mol) and cymene (134.22 g/mol) are natural products found in tomatoes and cumin (a common spice), respectively (**Figure 3.35**). Lycopene in the diet has been shown to reduce the risk of prostate cancer, whereas cumin is a home remedy for stomach ailments. Both compounds are 89.49% C and 10.51% H by mass. What are the empirical and molecular formulas of lycopene and cymene?

Collect, Organize, and Analyze The problem gives the percent composition and molar masses of two compounds. We want to determine both the empirical and molecular formulas of lycopene and cymene. Percent composition data can be used to derive empirical formulas as described in Section 3.7 and illustrated in Sample Exercises 3.19 and 3.20.

Solve Assuming a 100-g sample, we have 89.49 g of C and 10.51 g of H, which we can convert to moles:

The mole ratio of C to H is 7.451:10.43, or 1.000:1.400. We can convert the fractional mole ratio to a ratio of whole numbers by multiplying by 5:

$$\text{C:H} = 5 \times (1:1.4) = 5:7$$

which means the empirical formula is C_5H_7.

To determine the molecular formula, we first determine the mass of the empirical formula, C_5H_7:

$$5(12.01\ \text{g/mol}) + 7(1.008\ \text{g/mol}) = 67.11\ \text{g/mol}$$

Next, we divide the molar masses for lycopene and cymene by this empirical formula mass to determine the values of the multiplier, *n*:

The molecular formula of lycopene is

$$(C_5H_7)_n = (C_5H_7)_8 = C_{40}H_{56}$$

and the molecular formula of cymene is

$$(C_5H_7)_n = (C_5H_7)_2 = C_{10}H_{14}$$

Think About It The percent composition of a compound reveals only the empirical formula. All compounds with the same empirical formula *must* have the same percent composition.

Practice Exercise *Pheromones* are chemical substances secreted by members of a species to stimulate a response in other individuals of the same species. For example, females of a species secrete certain pheromones to attract males for mating. The percent composition of eicosene (280 g/mol), a compound like the Japanese beetle mating pheromone, is 85.63% C and 14.37% H. Determine its molecular formula.

(Answers to Practice Exercises are in the back of the book.)

CONCEPT TEST

Lycopene and cymene (Sample Exercise 3.21) have the same percent composition. Are they isomers?

(Answers to Concept Tests are in the back of the book.)

Molecular Mass and Mass Spectrometry

How do chemists who isolate an unknown molecular compound from reaction mixtures or biological systems determine the molecular mass of the compound? They often use a powerful analytical technique called *mass spectrometry*.

CONNECTION The positive-ray analyzer that Francis Aston built and used to separate two of the isotopes of neon (see Section 2.3) was the forerunner of today's mass spectrometers.

Mass spectrometers ionize molecules and then separate the ions by the ratio of their masses (m) to their electric charges (z). In many mass spectrometers, samples are vaporized and then bombarded with a beam of high-energy electrons (**Figure 3.36**). These electrons smash into gas-phase molecules with such force that they knock electrons off the molecules, forming positively charged ions known as the molecular ions (M^+):

$$M + e^- \rightarrow M^+ + 2\,e^-$$

Sometimes the collisions are so forceful that they break molecules into fragments and ionize the fragments. The charged fragments and molecular ions are ejected into a second region of the mass spectrometer where they are separated based on their m/z ratios. Then they pass into a detector and are counted. The resulting data are displayed as a mass spectrum (plural *spectra*) in which the horizontal axis is m/z and the spectrum is a displayed as a series of vertical bars at various m/z values. The heights of the bars indicate the number of ions reaching the detector with that m/z value. The bar with the highest m/z value in the spectrum is usually the molecular ion (M^+) peak. If the ions are singly charged ions ($z = 1+$), then the m/z value of that bar is simply m, the molecular mass of the compound.

Figure 3.37 shows the mass spectra of acetylene and benzene. In both spectra, the tall bar with the greatest m/z value (at 26 u in the acetylene spectrum and at 78 u in the benzene spectrum) is the molecular ion. The bars at lower m/z values represent fragments. Distinctive fragmentation patterns help scientists confirm molecular structures.

CONCEPT TEST

Does the molecular ion in a mass spectrum correspond to the mass associated with the empirical formula or the molecular formula of a compound?

(Answers to Concept Tests are in the back of the book.)

Glossary

mass spectrometer	an instrument that separates and counts ions according to their mass-to-charge ratios.
mass spectrum	a graph of the data from a mass spectrometer.
molecular ion (M^+)	the peak of highest mass in a mass spectrum; it has the

same mass as the molecule from which it came.

$$\frac{0.117\ \text{mol N}}{0.117} = 1\ \text{mol N}$$

$$\frac{1.639\ \text{mol O}}{0.117} = 14\ \text{mol O}$$

$$3 \times 10^{6}\ \cancel{\text{g Taxol}} \times \frac{1\ \cancel{\text{mol Taxol}}}{853.88\ \cancel{\text{g Taxol}}} \times \frac{1\ \cancel{\text{mol camphor}}}{1\ \cancel{\text{mol Taxol}}} \times \frac{152.23\ \text{g camphor}}{1\ \cancel{\text{mol camphor}}} = 5 \times 10^{5}\ \text{g camphor}$$

3.9 Combustion Analysis

In combustion analysis, the complete combustion (defined in Section 3.4) of a compound, followed by an analysis of the products, enables chemists to determine the chemical composition of that compound. To ensure that combustion is complete, the process is carried out in excess oxygen, which means more oxygen is present than the stoichiometric amount. Combusting an organic compound means converting all the carbon in the compound to CO_2 and all the hydrogen in the compound to H_2O:

C_aH_b + excess $O_2(g) \rightarrow a\ CO_2(g) + b/2\ H_2O(g)$

Consider burning a hydrocarbon of unknown composition in a chamber through which a stream of pure oxygen flows (**Figure 3.38**). The $CO_2(g)$ and $H_2O(g)$ produced flow first through a tube packed with $Mg(ClO_4)_2(s)$, which selectively absorbs the $H_2O(g)$, and then through a tube containing $NaOH(s)$, which absorbs the $CO_2(g)$. The masses of these tubes are measured before and after combustion. Suppose the mass of the tube that traps $CO_2(g)$ increases by 1.320 g, and the mass of the tube that traps $H_2O(g)$ increases by 0.540 g. How can we use these results to determine the empirical formula of the hydrocarbon?

First, let's establish what we know about the hydrocarbon in this example:

1. Hydrocarbons contain only carbon and hydrogen.
2. Complete conversion of its carbon into CO_2 produces 1.320 g of CO_2.
3. Complete conversion of its hydrogen into H_2O produces 0.540 g of H_2O.

To derive an empirical formula for the hydrocarbon, we must determine the number of moles of carbon in 1.320 g of carbon dioxide and the number of moles of hydrogen in 0.540 g of water vapor, because these quantities are equal to the number of moles of carbon and hydrogen in the sample that was combusted. Converting the mass of carbon dioxide to moles of carbon and the mass of water to moles of hydrogen:

The empirical formula is based on the mole ratio of C and H. If we divide both mole values by the smaller of the two, we get

---

We obtain CH_2 for the empirical formula of the hydrocarbon.

If we want to extend this analysis to determine a molecular formula, we need to know the molecular mass of the hydrocarbon. Suppose its mass spectrum has a molecular ion with a mass of 84 u. This means the molar mass of the compound is 84 g/mol. The empirical formula mass of CH_2 is 14 g/mol. Dividing the molar mass by the empirical formula mass, we get the multiplier, *n*:

The molecular formula is therefore

$$(CH_2)_6 = C_6H_{12}$$

We did not need to know the initial mass of the sample to determine its empirical formula. We only needed to know that the sample was a hydrocarbon and that it was completely converted into the stated amounts of CO_2 and H_2O.

What if we knew that our sample was *not* a hydrocarbon? What if we had isolated a pharmacologically promising compound from a tropical plant, and we knew that its molecules contained atoms of carbon, hydrogen, and oxygen? We would need to determine the proportion of oxygen in it, but there is no simple way of measuring that directly when the compound is burned in excess oxygen. Combustion analyses yield the percentages by mass of all atoms in a sample *except* oxygen. When given the percentages of atoms by mass from a combustion analysis, always check to see whether the percentages add up to 100%. If they do, all the elements in the sample are accounted for in the results. If they do not, oxygen may be responsible for the missing mass.

SAMPLE EXERCISE 3.22 Combustion Analysis of a Hydrocarbon LO8

Limonene is a hydrocarbon that contributes to the odor of citrus fruits, including lemons (**Figure 3.39**). Combustion of 0.671 g of limonene yielded 2.168 g of CO_2 and 0.710 g of H_2O. What is the empirical formula of limonene? If the molar mass of limonene is 136.24 g/mol, then what is its molecular formula?

Collect and Organize We know the masses of CO_2 and H_2O

produced during the combustion of a hydrocarbon sample, and we are asked to determine its empirical formula and then, from its molecular mass, its molecular formula.

Analyze First we determine the number of moles of C and H in the CO_2 and H_2O produced during combustion. These values are equal to the number of moles of C and H in the combusted sample. Then we calculate the C:H mole ratio and convert it into a ratio of small whole numbers to obtain the empirical formula. Next, we calculate the mass of the empirical formula and divide this mass into the molar mass to obtain the multiplier, *n*, which allows us to convert the empirical formula to a molecular formula.

Solve The moles of C and H in the CO_2 and H_2O collected during combustion are

The mole ratio of the two elements in the sample is

0.04926 mol C:0.07880 mol H

Dividing through by the smallest value (0.04926 mol) gives a mole ratio of 1.000:1.600. We can convert this ratio to whole numbers by multiplying by 5, making the empirical formula of the sample C_5H_8.

The molar mass of limonene is 136.24 g/mol. The mass of the empirical formula of limonene is 5(12.01 g/mol) + 8(1.008 g/mol) = 68.11 g/mol, so the multiplier *n* is

and the molecular formula is

$(C_5H_8)_n = (C_5H_8)_2 = C_{10}H_{16}$

Think About It One way to check the accuracy of the empirical formula determination is to convert the moles of C and H into grams of C and H, add the masses together and compare their sum to the mass of the original sample: 0.04926 mol C × 12.01 g C/mol C = 0.5916 g C; 0.07880 mol H × 1.008 g H/mol H = 0.07943 g H. Summing these two mass: 0.5916 g C + 0.07943 g H = 0.671 g, which exactly matches the mass of the sample that was analyzed.

Practice Exercise Cembrene A ($\mathscr{M} = 272.47$ g/mol) is another naturally occurring hydrocarbon, extracted from coral (**Figure 3.40**). Combustion of 0.0341 g of cembrene A yields 0.1101 g of CO_2 and 0.0360 g of H_2O. What are the empirical and molecular formulas of cembrene A?

(Answers to Practice Exercises are in the back of the book.)

SAMPLE EXERCISE 3.23 Combustion Analysis for Compounds Containing Oxygen LO8

Eugenol is an ingredient in several spices, including bay leaves and cloves (**Figure 3.41**). Eugenol contains carbon, hydrogen, and oxygen. Combustion of 21.80 mg of eugenol yields 58.5 mg of CO_2 and 14.4 mg of H_2O. What is the empirical formula of eugenol? If the mass spectrum of eugenol shows a molecular ion at 164 u, what is the molecular formula of eugenol?

Collect and Organize We are given the masses of CO_2 (58.5 mg) and H_2O (14.4 mg) produced by the combustion of 21.80 mg of eugenol and are asked to determine its empirical formula. We also know its molar mass, and we need to determine its molecular formula.

Analyze First we determine the number of moles of C and H in the CO_2 and H_2O produced during combustion. These values are equal to the number of moles of C and H in the combusted sample. Multiplying these mole values by the atomic masses of C and H yields the mass of these elements in the original sample, which we then subtract from the total mass of the sample to obtain the mass of O in the sample. This mass can then be converted into moles of O in the sample:

The mole ratio of C:H:O is then calculated and reduced to a ratio of small whole numbers to obtain the empirical formula. We then divide the mass of the empirical formula into the molar mass to obtain the multiplier, *n*, which makes it possible to convert the empirical formula to a molecular formula.

Solve The moles of C and H in the CO_2 and H_2O collected during combustion are

The masses of C and H are calculated in milligrams to match the original sample:

The sum of these two masses (15.96 mg C + 1.611 mg H = 17.57 mg) is less than the mass of the sample (21.80 mg). The difference must be the mass of oxygen in the sample:

(21.80 − 17.57) mg O = 4.23 mg O

The number of moles of O in the sample is

The mole ratio of the three elements in the sample is

1.329×10^{-3} mol C:1.598×10^{-3} mol H:2.644×10^{-4} mol O

1.329×10^{-3} mol C:1.598×10^{-3} mol H:2.64×10^{-4} mol O

Dividing through by the smallest value (2.64×10^{-4} mol) gives a mole ratio of 5.03:6.04:1, or 5:6:1, making the empirical formula of the sample C_5H_6O. The empirical formula mass is

5(12.01 g/mol) + 6(1.008 g/mol) + 16.00 g/mol = 82.10 g/mol

The molecular ion identifies the molecular mass of eugenol as 164 u, so the molar mass of eugenol is 164 g/mol. Therefore, the multiplier, *n*, to convert the empirical formula into a molecular formula is

and the molecular formula is

$(C_5H_6O)_n = (C_5H_6O)_2 = C_{10}H_{12}O_2$

Think About It Our answer makes sense because we have a simple whole-number ratio of the elements.

Practice Exercise Vanillin is a compound containing carbon, hydrogen, and oxygen that gives vanilla beans their distinctive flavor (**Figure 3.42**). The combustion of 30.4 mg of vanillin produces 70.4 mg of CO_2 and 14.4 mg of H_2O. The mass spectrum of vanillin shows a molecular ion at 152 u. Use this information to determine the molecular formula of vanillin.

(Answers to Practice Exercises are in the back of the book.)

SAMPLE EXERCISE 3.24 Integrating Concepts: Taxol

Taxol, known generically as paclitaxel, is a molecular compound used in the treatment of cancer. It was originally isolated from the bark of the Pacific yew tree (**Figure 3.43**), but subsequently has been synthesized in the laboratory.

1. The yew tree provides about 100 mg of Taxol for every 1.00 kg of bark. If 1 tree has about 3 kg of bark and 9000 trees were needed to isolate enough Taxol for its first clinical trial, how many grams of Taxol were used for those initial tests?
2. One of the laboratory syntheses of Taxol begins with camphor (78.89% C; 10.59% H; $\mathcal{M} = 152.23$ g/mol) and requires 23 different chemical reactions to convert it into Taxol (66.11% C; 6.02% H; 1.64% N; $\mathcal{M} = 853.88$ g/mol). The overall yield of the process to produce 1 mole of Taxol, starting with 1 mole of camphor, is 0.10%. (i) What are the molecular formulas of camphor and Taxol? (ii) How much camphor must be used to make the amount of Taxol extracted from 9000 trees?

Collect and Organize We are given information about the amount of Taxol in bark, the percent composition and molar mass of camphor and Taxol, and the yield of the laboratory synthesis. Using dimensional analysis and other methods from this chapter, we can answer the questions posed.

Analyze The percent compositions given for both substances do not add to 100%. We may assume that both compounds contain oxygen.

Solve

1. We begin by calculating the amount of Taxol in 9000 trees:

   $$9000\ \cancel{\text{trees}} \times \frac{3\ \cancel{\text{kg bark}}}{1\ \cancel{\text{tree}}} \times \frac{0.100\ \text{g Taxol}}{1.00\ \cancel{\text{kg bark}}} = 3 \times 10^{3}\ \text{g Taxol}$$

2. (i) The percent carbon in camphor added to the percent hydrogen is less than 100%:

   $$78.89\% + 10.59\% = 89.48\%$$

Because the reported percentages do not add up to 100%, the camphor most likely contains oxygen, the percent of which we cannot find in a combustion analysis. We can assume the percent oxygen in camphor is 100% − 89.48% = 10.52%. We can now determine the empirical formula of camphor by assuming we have 100.00 g of camphor, which would contain 78.89 g of C, 10.59 g of H, and 10.52 g of O. The first step is to determine how many moles of C, H, and O that is:

Dividing by the smallest number of moles:

The empirical formula of camphor is $C_{10}H_{16}O$. The corresponding mass is [(10 × 12.01 g/mol) + (16 × 1.008 g/mol) + (16.00 g/mol)] = 152.23 g/mol, which matches the molar mass of camphor. Therefore, the molecular formula of camphor is the same as its empirical formula.

Carrying out the same procedure for Taxol:

$66.11\% + 6.02\% + 1.64\% = 73.77\%$

$100\% - 73.77\% = 26.23\%$ oxygen

Calculating the empirical formula:

Dividing by the smallest number of moles:

The empirical formula of Taxol is $C_{47}H_{51}NO_{14}$, which has a mass of $[(47 \times 12.01\ \text{g/mol}) + (51 \times 1.008\ \text{g/mol}) + (1 \times 14.01\ \text{g/mol}) + (14 \times 16.00\ \text{g/mol})] = 853.88\ \text{g/mol}$. This value is the same as the molar mass of Taxol, so $C_{47}H_{51}NO_{14}$ is also the molecular formula.

(ii) We need 3×10^3 g of Taxol from a process that has a yield of 0.10%. The molar ratio in the process is 1 mole of camphor produces 1 mole of Taxol.

$3 \times 10^3\ \text{g} = \text{Taxol} = 0.10\%$ of the theoretical yield

The theoretical yield for the process is

$3 \times 10^3\ \text{g} = 0.0010x \quad x = 3 \times 10^6\ \text{g}$

Starting with that amount of Taxol as the theoretical yield:

Thus, we need 500 kg of camphor to synthesize as much Taxol as there is in 9000 Pacific yew trees.

Think About It The 0.10% yield of the laboratory synthesis of Taxol probably seems strangely low but remember that there were 23 steps in the synthesis. If the average yield of each of them was 74%, the overall yield of the synthesis would be $(0.74)^{23}$ or 0.1%.

Glossary

combustion analysis

a laboratory procedure for determining the composition of a substance by burning it completely in excess oxygen to produce known compounds whose masses are used to determine the composition of the original material.

Learning Objectives

- Use data from combustion analysis to determine the empirical formula of a substance **Return to Sample Exercises 3.22, 3.23**

- Use data from combustion analysis to determine the empirical formula of a substance **Return to Sample Exercises 3.22, 3.23**

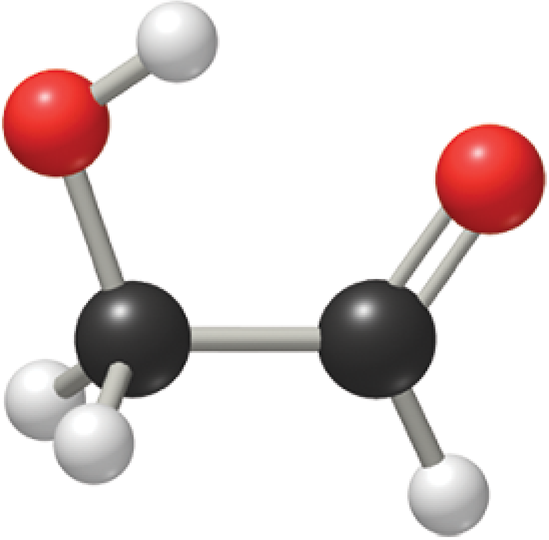
SUMMARY

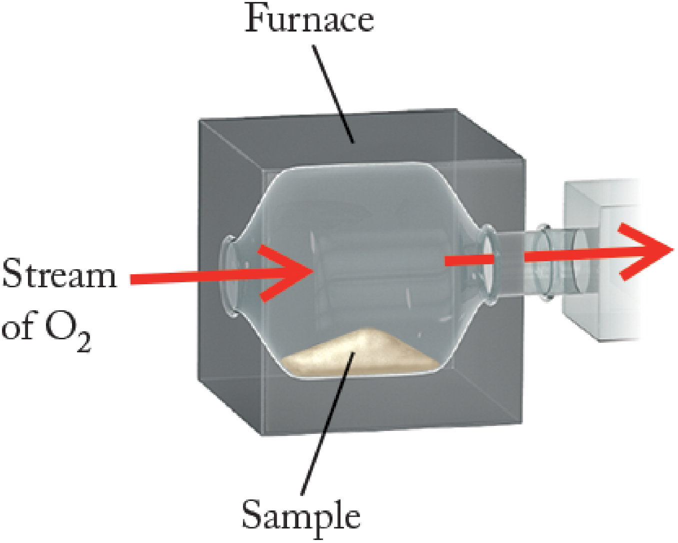
LO1 The Avogadro constant ($N_A = 6.022 \times 10^{23}$ particles) and the mole (the amount of a material that contains this many particles) can be used to convert among grams of a substance, moles of a substance, and number of particles. One mole of any substance has a mass equal to the sum of the molar masses of the elements in its formula. (Section 3.2)

- LO2 Balanced chemical equations are essential tools to describe chemical reactions. Correct equations indicate the quantitative relationship in terms of moles between reactants, whose formulas appear first in the equation, and products, whose formulas appear after the reaction arrow. In a balanced chemical equation, the number of atoms of each element is the same on the reactant side and on the product side. (Sections 3.1–3.4)

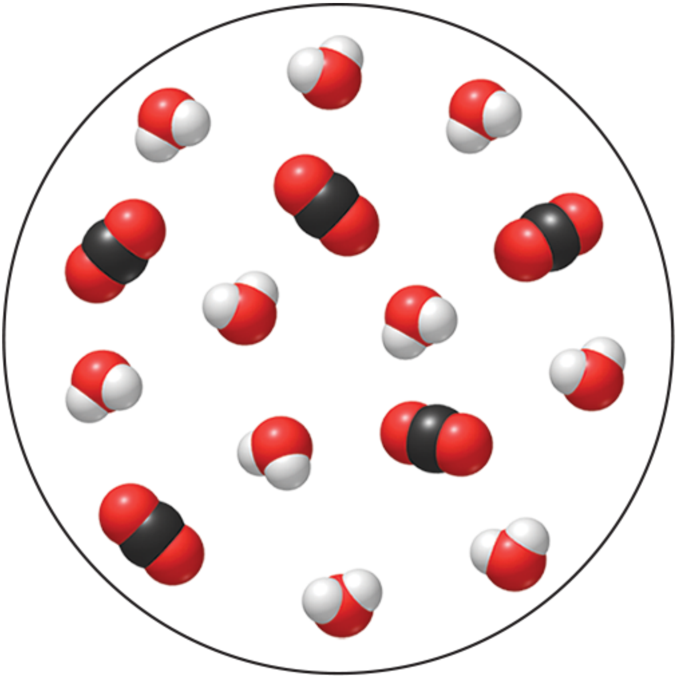
- LO3 Mole ratios from balanced chemical equations can be used to relate the masses of reactants consumed and the masses of products formed in a chemical reaction. (Section 3.5)
- LO4 Balanced equations and stoichiometric calculations can be used to determine which substances are limiting reactants. (Section 3.6)
- LO5 The actual yield (often expressed as percent yield) of a chemical reaction is frequently less than the theoretical yield predicted by the stoichiometry of the balanced chemical equation. If we know the amounts of reactants consumed and products formed in a chemical reaction, we can calculate the percent yield as the ratio of actual yield to theoretical yield, expressed as a percentage. (Section 3.6)
- LO6 Writing balanced chemical equations requires knowing the correct formulas for substances. Empirical formulas for substances can be determined from their percent composition by mass. (Section 3.7)



- LO7 The molecular formula of a compound may or may not be the same as the empirical formula. The molecular formula can be determined from the empirical formula and the molecular mass of the compound. (Section 3.8)



- LO8 Empirical formulas of organic compounds can be determined from the combustion analysis. Production of CO_2, H_2O, and other oxides can provide the percent by mass of all elements in the compound except oxygen, which can be determined by applying the law of conservation of mass. (Sections 3.8 and 3.9)



PARTICULATE PREVIEW WRAP-UP

Ten oxygen molecules will completely combust the five methane molecules to produce five carbon dioxide molecules and ten water molecules.

PROBLEM-SOLVING SUMMARY

Type of Problem	Concepts	Equations	Sample Exercises
Convert number of particles into number of moles (or vice versa)	Convert number of particles to moles by dividing by the Avogadro constant ($N_A = 6.022 \times 10^{23}$ particles/mol). Convert number of moles to particles by multiplying by the Avogadro constant ($N_A = 6.022 \times 10^{23}$ particles/mol).		3.1, 3.2, 3.6
Convert mass of substance into number of moles (or vice versa)	Convert mass of substance to moles by dividing by the molar mass ($\mathscr{M}$) of the substance. Convert moles of substance to mass by multiplying by		3.3, 3.4, 3.6, 3.7

		the molar mass ($\mathscr{M}$) of the substance.
3.5, 3.6, 3.7	**Calculate molar mass of a compound**	Multiply the molar mass of each element by its subscript in the compound's formula, then sum the resulting values.
3.8, 3.9, 3.10	**Write a balanced chemical equation**	Using integers, adjust the coefficients in the chemical equation so that the numbers of atoms of each element are the same on both sides of the reaction arrow.
3.11	**Write a balanced chemical equation for a combustion reaction**	The C and H in organic compounds react with O_2 to form CO_2 and H_2O, for example: $CH_4(g) + 2\ O_2(g) \rightarrow CO_2(g) + 2\ H_2O(g)$ Balance moles of C first, then H, then O.
3.12, 3.13	**Calculate mass of a product from mass of a reactant**	Use $\mathscr{M}_{\text{reactant}}$ to convert mass into moles of reactant, use reaction stoichiometry to calculate moles of product, and then use $\mathscr{M}_{\text{product}}$ to calculate mass of product.
3.14, 3.15	**Identify the limiting reactant**	Method 1: Calculate how much product each reactant could make; the reactant making the *least* amount of product is the limiting reactant. Method 2: Convert given masses of reactants into moles. Compare the mole ratio of reactants to the corresponding mole ratio in the stoichiometric equation. If $\left(\frac{\text{mol A}}{\text{mol B}}\right)_{\text{calculated}} > \left(\frac{\text{mol A}}{\text{mol B}}\right)_{\text{stoichiometric}} \quad (3.3)$ then B is the limiting reactant. If $\left(\frac{\text{mol A}}{\text{mol B}}\right)_{\text{calculated}} < \left(\frac{\text{mol A}}{\text{mol B}}\right)_{\text{stoichiometric}} \quad (3.4)$ then A is the limiting reactant.
3.16, 3.17	**Calculate percent yield**	Calculate the theoretical yield of product using the mass of limiting reactant. Divide actual yield (given) by theoretical yield: $\text{percent yield} = \frac{\text{actual yield}}{\text{theoretical yield}} \times 100\% \quad (3.5)$
3.18	**Calculate percent composition from a chemical formula**	Calculate the molar mass of the compound represented by the chemical formula and divide it into the mass of each element in 1 mole of the compound: $\text{mass \% of an element} = \frac{\text{mass of element in 1 mole of compound}}{\text{molar mass of compound}} \quad (3.6)$
3.19, 3.20	**Determine an empirical formula from percent composition**	Assume a 100.00 g sample, assign the mass (g) of each element to equal its percentage. Divide the mass of each element by its molar mass to get moles. Simplify mole ratios to lowest whole numbers and use those

numbers as subscripts in the empirical formula of the compound.

3.41 Relate empirical and molecular formulas

Calculate the multiplier *n* by dividing the compound's molecular mass by its empirical formula mass. Multiply the subscripts in the empirical formula by this conversion factor.

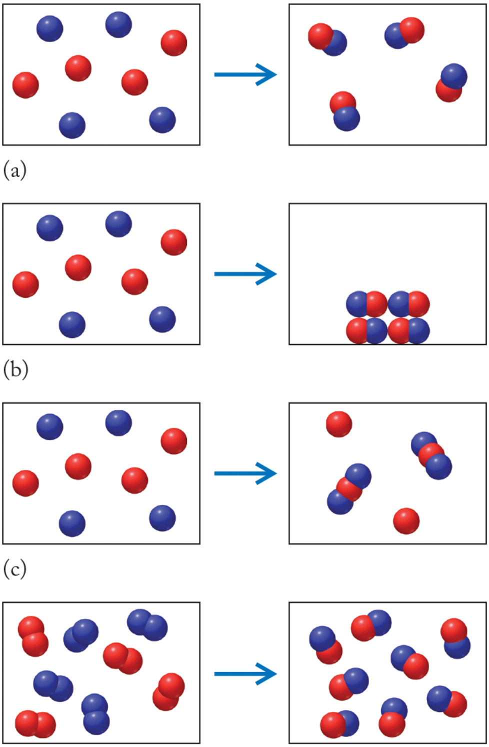
3.22, 3.23 Determine an empirical formula from combustion analysis

Convert the masses of CO_2 and H_2O into moles of CO_2 and H_2O, and then to moles of C and H. For compounds containing O, convert moles of C and H into masses of C and H and subtract the sum of these values from the sample mass to calculate mass of O. Convert mass of O to moles of O. Simplify the mole ratio of C to H to O.

VISUAL PROBLEMS

(Answers to boldface end-of-chapter questions and problems are in the back of the book.)

Each of the pairs of containers pictured in Figure P3.1 contains substances composed of elements X (red spheres) and Y (blue spheres). For each pair, write a balanced chemical equation describing the reaction that takes place. Be sure to indicate the physical states of the reactants and products, using the appropriate symbols in parentheses.



(a)

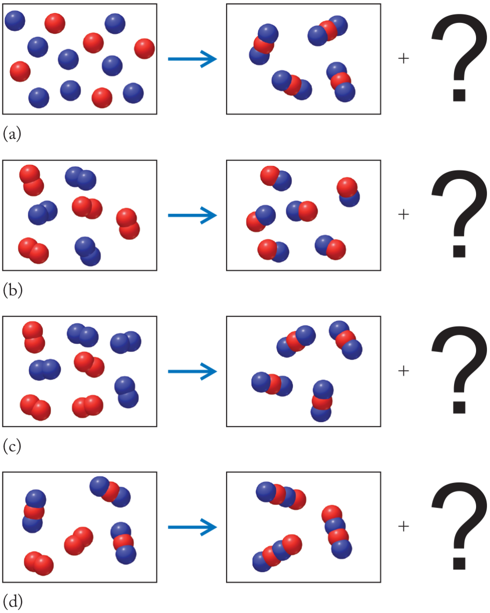
(b)

(c)

(d)

FIGURE P3.1

Identify the limiting reactant in each of the pairs of containers pictured in Figure P3.2. The red spheres represent atoms of element X, whereas the blue spheres represent atoms of element Y. Each question mark means that there is unreacted reactant left over. Identify which reactant is represented by the question



mark.

FIGURE P3.2

Which of the drawings in Figure P3.3 best illustrates the 100% reaction between N_2 and O_2 to produce N_2O? The red spheres represent atoms of oxygen, whereas the blue spheres represent atoms of nitrogen.

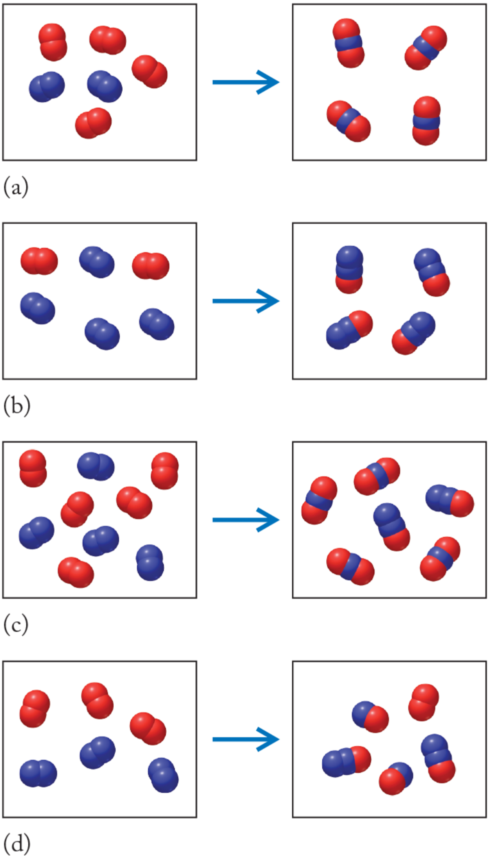


FIGURE P3.3

Is there a limiting reactant in any of the reactions depicted in Figure P3.3? If so, what is it, and how much of the excess reactant remains?

Which of the molecules in Figure P3.5 have the same empirical formulas?

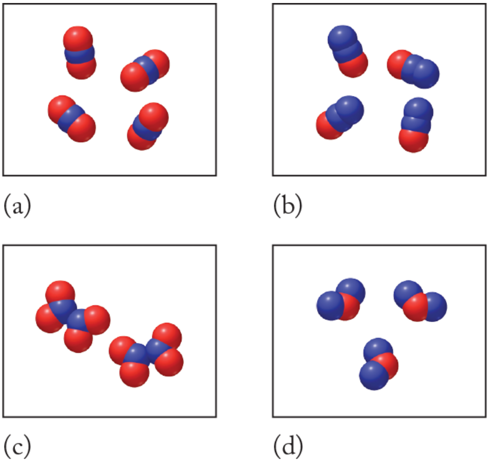

FIGURE P3.5

Which of the pairs of particulate images in Figure P3.6 represent balanced chemical equations? Write balanced chemical equations for any pairs of particulate images that are unbalanced as drawn. The red spheres represent oxygen, black represent carbon, blue represent nitrogen, and yellow represent sulfur.

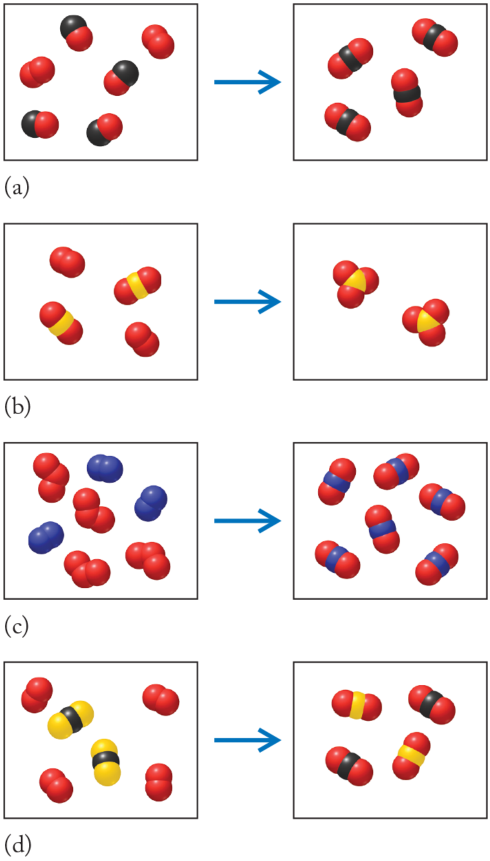

FIGURE P3.6

The two major products of combustion are CO_2 and H_2O. Figure P3.7 shows two mass spectra. Which belongs to water, and which belongs to carbon dioxide?

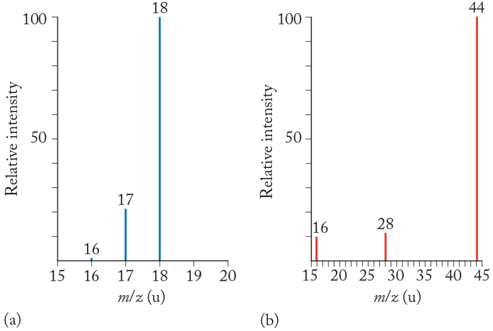

FIGURE P3.7

Figure P3.8 shows the mass spectrum of a simple hydrocarbon that is a widely used fuel for heating and electricity generation. What is the molecular formula of this hydrocarbon?

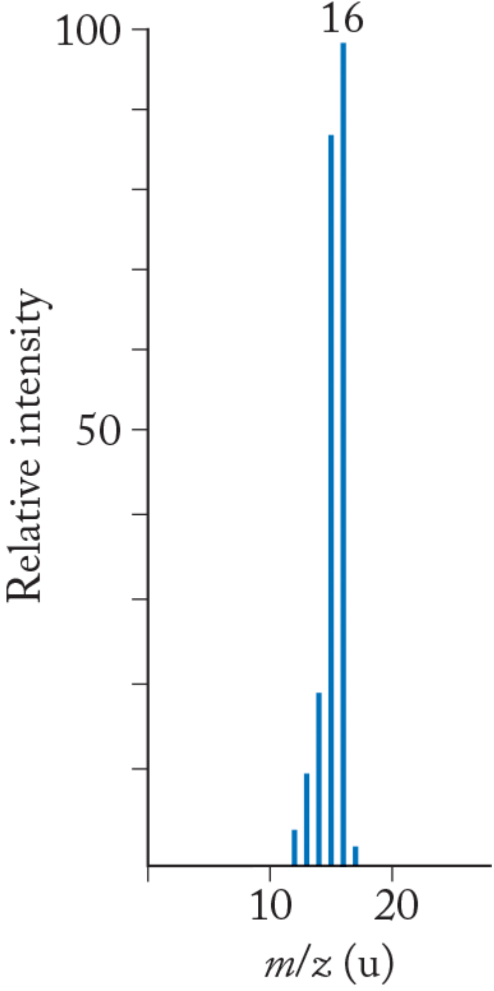

FIGURE P3.8

What is the percent yield of NH_3 for the reaction depicted in Figure P3.9? The blue spheres represent nitrogen, whereas the white spheres are hydrogen.

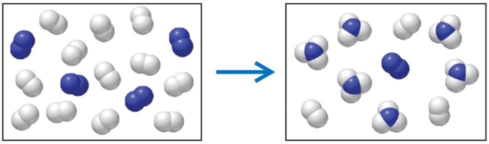

FIGURE P3.9

Use representations [A] through [I] in Figure P3.10 to answer questions (a)–(f).

1. Which two different compounds have the same empirical formula?
2. Which compound has a molecular mass of 180 u?
3. Which compound might have a molar mass of 180 g?
4. Which compound has the largest percent oxygen by mass?
5. The mass of one gold bar in [D] is 12.4 kg. The mass of one silver bar in [E] is 31 kg. Which contains more atoms—the gold bar or the silver bar?
6. When completely combusted, which compound will produce more moles of carbon dioxide—benzene [A] or table sugar [C]?

FIGURE P3.10

QUESTIONS AND PROBLEMS

Air, Life, and Molecules

Concept Review

In a combination reaction, can the reactants be two elements? Two compounds? One compound and one element?

Based on the compositions and physical states of Earth's various layers (Figure 3.3), does Al_2O_3 or Ni have the higher melting point?

Based on the distribution of the elements in Earth's layers (see Figure 3.3), which of the following substances should be the densest? (a) $SiO_2(s)$; (b) $Al_2O_3(s)$; (c) $Fe(\ell)$

The proportions of the elements that make up the asteroid 433 Eros are like those that make up Earth. Scientists believe that this similarity means that 433 Eros and Earth formed around the same time. If another asteroid formed *after* Earth formed a solid crust, and if this asteroid was the product of a collision between Earth and an even larger asteroid, how would the new asteroid's composition differ from that of 433 Eros?

The Mole

Concept Review

In principle we could use the more familiar unit *dozen* in place of mole when expressing the quantities of particles (atoms, ions, or molecules) in chemical reactions. What would be the disadvantage in doing so?

In what way are the molar mass of an ionic compound and its formula mass the same, and in what ways are they different?

Do molecular compounds containing three atoms per molecule always have a molar mass greater than that of molecular compounds containing two atoms per molecule? Explain.

Without calculating their molar masses (though you may consult the periodic table), predict whether NO_2 or N_2O has the larger molar mass.

Problems

Earth's atmosphere contains many volatile substances that are present in trace amounts. The following quantities of these trace gases were found in a 1.0 mL sample of air. Calculate the number of moles of each gas in the sample.

1. 4.4×10^{14} atoms of Ne(*g*)
2. 4.2×10^{13} molecules of CH_4(*g*)
3. 2.5×10^{12} molecules of O_3(*g*)
4. 4.9×10^{9} molecules of NO_2(*g*)

The following quantities of trace gases were found in a 1.0 mL sample of air. Calculate the number of moles of each compound in the sample.

1. 1.4×10^{13} molecules of H_2(*g*)
2. 1.5×10^{14} atoms of He(*g*)
3. 7.7×10^{12} molecules of N_2O(*g*)
4. 3.0×10^{12} molecules of CO(*g*)

How many atoms of titanium are there in 0.125 mol of each of the following?

1. ilmenite, $FeTiO_3$
2. titanium(IV) chloride

3. Ti_2O_3
4. Ti_3O_5

How many atoms of iron are there in 2.5 moles of each of the following?

1. wolframite, $FeWO_4$
2. pyrite, FeS_2
3. magnetite, Fe_3O_4
4. hematite, Fe_2O_3

Which substance in each of the following pairs of quantities contains more moles of sulfur?

1. 3 moles of Al_2S_3 or 4 moles of Fe_2S_3
2. 3 moles of Li_2SO_4 or 4 moles of CaS
3. 2 moles of SO_3 or 2 moles of SO_2

Which substance in each of the following pairs of quantities contains more moles of nitrogen?

1. 2 moles of Li_3N or 0.5 mole of $Ca(NO_3)_2$
2. 1 mole of NO or 0.4 mole of NO_2
3. 3 moles of NF_3 or 1 mole of N_2O_5

Elemental Composition of Amino Acids Carbon, hydrogen, nitrogen, and oxygen are the most prevalent components of amino acids, the fundamental building blocks of proteins in living systems. How many moles of oxygen atoms are in 1.50 moles of the following compounds?

1. Glycine, the smallest amino acid: $C_2H_5NO_2$
2. Lysine, essential in the diet of humans: $C_6H_{14}N_2O_2$
3. Asparagine, produced in our bodies: $C_4H_8N_2O_3$

Composition of Uranium Ores The uranium used for nuclear fuel exists in nature in several minerals. Calculate how many moles of uranium are in 1 mole of the following:

1. carnotite, $K_2(UO_2)_2(VO_4)_2$
2. uranophane, $CaU_2Si_2O_{11}$
3. autunite, $Ca(UO_2)_2(PO_4)_2$

How many moles of carbon are there in 500.0 g of carbon?

How many moles of gold are there in 2.00 ounces of gold?

Cancer Therapy with Iridium Metal When iridium-192 is used in cancer treatment, a small cylindrical piece of ^{192}Ir, 0.6 mm in diameter and 3.5 mm long, is surgically inserted into the tumor. If the density of iridium is 22.42 g/cm^3, how many iridium atoms are present in the sample?

Gold Nanoparticles The product shown in Figure P3.30 contains gold nanoparticles in water. The manufacturer claims that drinking this beverage improves human health. How many gold atoms are in a gold nanoparticle with a diameter of 2.00 nm (d = 19.3 g/mL, 1 u = 1.66054×10^{-24} g)?

SEALED FOR YOUR PROTECTION
MESOGOLD®
COLLOIDAL GOLD
MINERAL SUPPLEMENT
.9999 PURE GOLD PARTICLES

FIGURE P3.30

Calculate the molar masses of the following molecules found in Earth's atmosphere: (a) SO_2; (b) O_3; (c) CO_2; (d) N_2O_5.

Determine the molar masses of the following minerals:

1. rhodonite, $MnSiO_3$
2. scheelite, $CaWO_4$
3. ilmenite, $FeTiO_3$
4. magnesite, $MgCO_3$

Flavoring Additives Calculate the molar masses of the following common flavors in food:

1. vanillin, $C_8H_8O_3$
2. oil of cloves, $C_{10}H_{12}O_2$
3. anise oil, $C_{10}H_{12}O$
4. oil of cinnamon, C_9H_8O

Sweeteners Calculate the molar masses of the following common sweeteners:

1. sucrose, $C_{12}H_{22}O_{11}$
2. saccharin, $C_7H_5NO_3S$
3. aspartame, $C_{14}H_{18}N_2O_5$
4. fructose, $C_6H_{12}O_6$

How many grams of iron are there in 1 mole of the following compounds? (a) FeO; (b) Fe_2O_3; (c) $Fe(OH)_3$; (d) Fe_3O_4

How many grams of sodium are there in 1 mole of the following compounds? (a) NaCl; (b) Na_2SO_4; (c) Na_3PO_4; (d) $NaNO_3$

How many moles of SiO_2 are there in a quartz crystal (SiO_2) that has a mass of 45.2 g?

How many moles of NaCl are there in a crystal of halite that has a mass of 6.82 g?

Early Atmosphere I In Urey and Miller's experiments, some of the gases they reacted were H_2O, H_2S, SO_2, and SO_3. Suppose four balloons are each filled with 10.0 g of one of these gases. Which balloon contains the most molecules?

Early Atmosphere II Which contains more atoms? (a) 0.1 mol H_2O or 0.1 mol H_2S; (b) 0.1 mol SO_3 or 0.2 mol

SO_2

What is the mass of 0.122 mol $MgCO_3$?

What is the volume of 1.00 mol benzene (C_6H_6) at 20°C? The density of benzene is 0.879 g/mL.

The density of uranium (U; 19.05 g/cm^3) is more than five times greater than that of diamond (C; 3.514 g/cm^3). If you have a cube (1 cm on a side) of each element, which cube contains more atoms?

Aluminum ($d = 2.70$ g/mL) and strontium ($d = 2.64$ g/mL) have nearly the same density. If we manufacture two cubes, each containing 1 mole of one element or the other, which cube will be smaller? What are the dimensions of this cube?

Writing Balanced Chemical Equations

Concept Review

In a balanced chemical equation, does the number of moles of reactants always equal the number of moles of products?

In a balanced chemical equation, does the sum of the coefficients for the reactants always equal the sum of the coefficients for the products?

In a balanced chemical equation, must the sum of the masses of all the gaseous reactants always equal the sum of the masses of the gaseous products?

In an unbalanced chemical equation, can the equation be balanced by changing subscripts in formulas rather than changing coefficients?

Problems

Using different-colored spheres to represent C and O, sketch the reaction between four C atoms and the necessary number of O_2 molecules that forms an equal number of CO and CO_2 molecules.

Using different-colored spheres to represent N and O, sketch the reaction between three molecules of N_2 and sufficient O_2 to produce a mixture in which there are an equal number of NO_2 and N_2O_4 molecules.

Ammonia (NH_3) can be formed by the reaction of two elements. What is the coefficient of $NH_3(g)$ in the balanced chemical equation?

Aluminum reacts with elemental oxygen at high temperatures to give pure aluminum oxide. What is the coefficient of $O_2(g)$ in the balanced chemical equation?

Chemical Weathering of Rocks and Minerals Write balanced chemical equations for the following chemical reactions, which contribute to weathering of the iron–silicate minerals ferrosilite ($FeSiO_3$), fayalite (Fe_2SiO_4), and greenalite [$Fe_3Si_2O_5(OH)_4$]:

1. $FeSiO_3(s) + H_2O(l) \rightarrow Fe_3Si_2O_5(OH)_4(s) + H_4SiO_4(aq)$
2. $Fe_2SiO_4(s) + CO_2(g) + H_2O(l) \rightarrow FeCO_3(s) + H_4SiO_4(aq)$
3. $Fe_3Si_2O_5(OH)_4(s) + CO_2(g) + H_2O(l) \rightarrow FeCO_3(s) + H_4SiO_4(aq)$

Chemistry of Geothermal Vents Some scientists believe that life on Earth may have originated near deep-ocean vents. Write balanced chemical equations describing the following reactions, which are among those taking place near such vents:

1. $CH_3SH(aq) + CO(aq) \rightarrow CH_3COSCH_3(aq) + H_2S(aq)$

2. $H_2S(aq) + CO(aq) \rightarrow CH_3CO_2H(aq) + S_8(s)$

Physiologically Active Nitrogen Oxides The oxides of nitrogen are biologically reactive substances. NO is a powerful agent for dilating blood vessels; N_2O is the anesthetic known as laughing gas; NO_2 has an acrid odor and is corrosive to lung tissue. Write balanced chemical equations describing the following reactions for the formation of nitrogen oxides:

1. $N_2(g) + O_2(g) \rightarrow NO(g)$
2. $NO(g) + O_2(g) \rightarrow NO_2(g)$
3. $NO(g) + NO_3(g) \rightarrow NO_2(g)$
4. $N_2(g) + O_2(g) \rightarrow N_2O(g)$

Purifying Natural Gas If natural gas contains significant amounts of sulfur as H_2S, it is called sour natural gas. For the gas to be commercially useful as a fuel, the H_2S must be removed. Once it is separated from the natural gas, it is reacted with oxygen in two different processes to yield either elemental sulfur (S_8), a commercial material that can be sold, or sulfur dioxide (SO_2). This sulfur dioxide product can be reacted with more H_2S to make additional elemental sulfur. Write balanced chemical equations describing the following reactions linked to the production of elemental sulfur.

1. $H_2S(g) + O_2(g) \rightarrow S_8(s) + H_2O(g)$
2. $H_2S(g) + O_2(g) \rightarrow SO_2(g) + H_2O(g)$
3. $H_2S(g) + SO_2(g) \rightarrow S_8(s) + H_2O(g)$

Write a balanced chemical equation for each of the following reactions:

1. Dinitrogen pentoxide reacts with sodium metal to produce sodium nitrate and nitrogen dioxide.
2. A mixture of nitric acid and nitrous acid is formed

when water reacts with dinitrogen tetroxide.

3. At high pressure, nitrogen monoxide reacts to form dinitrogen monoxide and nitrogen dioxide.
4. Acetylene (C_2H_2) burns and becomes carbon dioxide and water vapor.

Write a balanced chemical equation for each of the following reactions:

1. Carbon dioxide reacts with carbon to form carbon monoxide.
2. Potassium reacts with water to give potassium hydroxide and hydrogen gas.
3. Phosphorus (P_4) burns in air to give diphosphorus pentoxide.
4. Octane (C_8H_{18}) burns and becomes carbon dioxide and water vapor.

Combustion Reactions; Stoichiometric Calculations and the Carbon Cycle

Concept Review

Does the sum of the masses of the products always equal the sum of the masses of the reactants in a balanced chemical equation?

There are two ways to write the equation for the combustion of ethane:

$$C_2H_6(g) + \tfrac{7}{2}\,O_2(g) \rightarrow 3\,H_2O(g) + 2\,CO_2(g)$$

$$2\,C_2H_6(g) + 7\,O_2(g) \rightarrow 6\,H_2O(g) + 4\,CO_2(g)$$

Do these two different ways of writing the equation affect the calculation of how much CO_2 is produced from a known quantity of C_2H_6?

Problems

The manufacture of aluminum includes the production of cryolite (Na_3AlF_6) from the following reaction:

$6\ HF(g) + 3\ NaAlO_2(s) \rightarrow Na_3AlF_6(s) + 3\ H_2O(\ell) + Al_2O_3(s)$

How much $NaAlO_2$ (sodium aluminate) is required to produce 1.00 kg of Na_3AlF_6?

Chromium metal can be produced from the high-temperature reaction of Cr_2O_3 [chromium(III) oxide] with silicon or aluminum by each of the following reactions:

$Cr_2O_3(s) + 2\ Al(\ell) \rightarrow 2\ Cr(\ell) + Al_2O_3(s)$

$2\ Cr_2O_3(s) + 3\ Si(\ell) \rightarrow 4\ Cr(\ell) + 3\ SiO_2(s)$

1. Calculate the number of grams of aluminum required to prepare 400.0 g of chromium metal by the first reaction.
2. Calculate the number of grams of silicon required to prepare 400.0 g of chromium metal by the second reaction.

When $NaHCO_3$ is heated above 80°C, it decomposes as described by this chemical equation:

$2\ NaHCO_3(s) \rightarrow Na_2CO_3(s) + H_2O(g) + CO_2(g)$

How many grams of Na_2CO_3 are produced from the decomposition of 50.0 g $NaHCO_3$?

Egyptian Cosmetics $Pb(OH)Cl$, one of the lead compounds used in ancient Egyptian cosmetics, was prepared from PbO according to the following recipe:

$PbO(s) + NaCl(aq) + H_2O(\ell) \rightarrow Pb(OH)Cl(s) + NaOH(aq)$

How many grams of PbO and how many grams of NaCl would be required to produce 10.0 g of $Pb(OH)Cl$?

Suppose the fuel for an electric power plant is coal that contains 3.0% sulfur by mass. During combustion, the sulfur is converted into sulfur dioxide. How many grams of sulfur dioxide are produced for every kilogram of coal that is burned to produce electricity?

The uranium minerals found in nature must be refined and enriched in ^{235}U before the uranium can be used as a fuel in nuclear reactors. One procedure for enriching uranium relies on the reaction of UO_2 with HF to form UF_4, which is then converted into UF_6 by reaction with fluorine:

$$UO_2(g) + 4\ HF(aq) \rightarrow UF_4(g) + 2\ H_2O(\ell)$$

$$UF_4(g) + F_2(g) \rightarrow UF_6(g)$$

1. How many kilograms of HF are needed to completely react with 5.00 kg of UO_2?
2. How much UF_6 can be produced from 850.0 g of UO_2?

In Brazil automobiles use ethanol (C_2H_6O) as fuel, whereas in the United States we rely on gasoline. Using C_8H_{18} (octane) to represent gasoline, write balanced chemical equations for the complete combustion of ethanol and octane. Which fuel produces more CO_2 per gram of fuel?

Driving 1000 miles a month is not unusual for a short-distance commuter. If your vehicle gets 25 mpg, you would use 40 gallons (~150 L) of gasoline every month. If gasoline is approximated as C_8H_{18} (d = 0.703 g/mL), how much carbon dioxide does your vehicle emit every month?

Chalcopyrite ($CuFeS_2$) is an abundant copper mineral that can be converted into elemental copper. How much Cu could be produced from 1.00 kg of $CuFeS_2$?

Mining for Gold Unlike most metals, gold is found in nature as the pure element. Miners in California in 1849 searched for gold nuggets and gold dust in streambeds, where the denser gold could be easily separated from sand and gravel. However, larger deposits of gold are found in veins of rock and can be separated chemically in a two-step process:

(1) $4\ Au(s) + 8\ NaCN(aq) + O_2(g) + 2\ H_2O(\ell) \rightarrow 4\ NaAu(CN)_2(aq) + 4\ NaOH(aq)$

(2) $2\ NaAu(CN)_2(aq) + Zn(s) \rightarrow 2\ Au(s) + Na_2[Zn(CN)_4](aq)$

If a 1.0×10^3 kg sample of rock is 0.019% gold by mass, how much Zn is needed to react with the gold extracted from the rock? Assume that reactions (1) and (2) are 100% efficient.

Limiting Reactants and Percent Yield

Concept Review

If a reaction vessel contains equal masses of Fe and S, a mass of FeS corresponding to which of the following could theoretically be produced?

1. the sum of the masses of Fe and S
2. more than the sum of the masses of Fe and S
3. less than the sum of the masses of Fe and S

Can the percent yield of a chemical reaction ever exceed 100%?

Give two reasons that the actual yield from a chemical reaction is usually less than the theoretical yield.

A chemical reaction produces less than the expected amount of product. Is this result a violation of the law of conservation of mass?

Laboratory Errors A student conducting an experiment based on the thermal decomposition of $NaHCO_3$ (see Problem 3.63) accidentally spills some of the reactant after determining its mass and before placing it in an oven set at 110°C. The student decides to carry out the decomposition reaction on what is left. How will the lost $NaHCO_3$ affect the results of the experiment, including the mass of the decomposed sample and the calculated values of the actual yield and percent yield?

Consider the reaction of 10 g A with 10 g B in the combination reaction $A + B \rightarrow C$. How do the theoretical yield, actual yield, and percent yield change (or not change) if 20 g A are reacted with 20 g B?

Problems

Making Hollandaise Sauce A recipe for 1 cup of hollandaise sauce calls for $\frac{1}{2}$ cup of butter, $\frac{1}{4}$ cup of hot water, 4 egg yolks, and the juice of a medium-sized lemon. How many cups of this sauce can be made from a pound (2 cups) of butter, a dozen eggs, 4 medium lemons, and an unlimited supply of hot water?

A factory making toy wagons has 13,466 wheels, 3360 handles, and 2400 wagon beds in stock. What is the maximum number of wagons the factory can make?

Given the amounts of reactants shown, calculate the theoretical yield in grams of the product of each of these *unbalanced* descriptions of chemical reactions.

1. $Li(s) + N_2(g) \rightarrow Li_3N(s)$

5.0 g 2.0 g ? g

2. $P_2O_5(s) + H_2O(\ell) \rightarrow H_3PO_4(aq)$

25.0 g 36.0 g ? g

3. $SO_2(g) + O_2(g) \rightarrow SO_3(g)$

6.4 g 4.0 g ? g

Given the amounts of reactants shown, calculate the theoretical yield in grams of the product indicated by the question mark for each of these *unbalanced* descriptions of chemical reactions.

1. $Cu_2O(s) + H_2(g) \rightarrow Cu(s) + H_2O(\ell)$

30.0 g 12.0 g ? g

2. $Mg(s) + HCl(g) \rightarrow MgCl_2(s) + H_2(g)$

24.3 g 10.0 g ? g

3. $CuCl_2(aq) + Zn(s) \rightarrow Cu(s) + ZnCl_2(aq)$

11.6 g 10.0 g ? g

Ammonia rapidly reacts with hydrogen chloride, making ammonium chloride. Write a balanced chemical equation for the reaction and calculate the number of grams of excess reactant when 3.0 g of NH_3 reacts with 5.0 g of HCl.

Sulfur trioxide dissolves in water, producing H_2SO_4. How much sulfuric acid can be produced from 10.0 mL of water ($d = 1.00$ g/mL) and 25.6 g of SO_3?

Phosgenite, a lead compound with the formula $Pb_2Cl_2CO_3$, is found in ancient Egyptian cosmetics. Phosgenite was prepared by the reaction of PbO, NaCl, H_2O, and CO_2. An unbalanced description of the reaction is

$$PbO(s) + NaCl(aq) + H_2O(\ell) + CO_2(g) \rightarrow Pb_2Cl_2CO_3(s) + NaOH(aq)$$

1. Write a balanced chemical equation describing the reaction.
2. How many grams of phosgenite can be obtained from 10.0 g of PbO and 10.0 g of NaCl in the presence of excess water and CO_2?
3. If 2.72 g of phosgenite is produced in the laboratory from the amounts of starting materials stated in part (b), what is the percent yield of the reaction?

Potassium superoxide (KO_2) reacts with carbon dioxide to form potassium carbonate and oxygen:

$$4\ KO_2(s) + 2\ CO_2(g) \rightarrow 2\ K_2CO_3(s) + 3\ O_2(g)$$

This reaction makes potassium superoxide useful in a self-contained breathing apparatus. How much O_2 could be produced from 2.50 g of KO_2 and 4.50 g of CO_2?

The reaction of 5.0 g of pentane (C_5H_{12}) with 5.0 g of oxygen gas produces 20.4 g of CO_2. What is the percent yield of this reaction?

Baking soda ($NaHCO_3$) can be made in large quantities by the following reaction:

$$NaCl(aq) + NH_3(aq) + CO_2(aq) + H_2O(\ell) \rightarrow NaHCO_3(s) + NH_4Cl(aq)$$

If 10.0 g of NaCl reacts with excesses of the other reactants and 4.2 g of $NaHCO_3$ is isolated, what is the percent yield of the reaction?

Chemistry of Fermentation Yeast converts glucose ($C_6H_{12}O_6$) into ethanol ($d = 0.789$ g/mL) in a process called fermentation. An equation for the reaction can be written as follows:

$$C_6H_{12}O_6(aq) \rightarrow C_2H_5OH(\ell) + CO_2(g)$$

1. Write a balanced chemical equation for this fermentation reaction.
2. If 100.0 g of glucose yields 50.0 mL of ethanol, what is the percent yield for the reaction?

Composition of Seawater A 1 liter sample of seawater contains 19.4 g of Cl^-, 10.8 g of Na^+, and 1.29 g of Mg^{2+}.

1. How many moles of each ion are present?
2. If we evaporated the seawater, would there be enough Cl^- present to form the chloride salts of all the sodium and magnesium present?

Determining Empirical Formulas from Percent Composition; Comparing Empirical and Molecular Formulas

Concept Review

What is the difference between an empirical formula and a molecular formula?

Why is the empirical formula of an ionic compound represented by a formula unit? Why is the term molecular formula inappropriate to use when describing ionic compounds?

Do the empirical and molecular formulas of a compound always have the same percent composition values? Explain your answer.

Is the element with the largest atomic mass always the element present in the highest percentage by mass in a compound? Explain your answer.

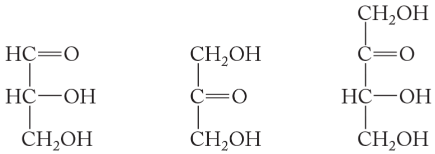
Among the naturally occurring hydrocarbons emitted by plants are three compounds named camphene, carene, and thujene. If all three of these compounds have the same percent composition and the same molar mass, do they have the same empirical formula? Do they have the same molecular formula? Are they isomers?

How might the compounds in Problem 3.93 differ from each other if they have the same molar mass and percent composition?

Problems

Gasoline consists primarily of a mixture of the hydrocarbons C_6H_{14}, C_7H_{16}, C_8H_{18}, and C_9H_{20}. What is the empirical formula of each compound?

The biosynthesis of carbohydrate includes the molecules shown below. What is the empirical formula of each compound shown in Figure P3.96?



Glyceraldehyde Dihydroxyacetone Erythrulose **FIGURE P3.96**

Calculate the percent composition of (a) Na_2O, (b) NaOH, (c) $NaHCO_3$, and (d) Na_2CO_3.

Calculate the percent composition of (a) sodium sulfate, (b) dinitrogen tetroxide, (c) strontium nitrate, and (d) aluminum sulfide.

Organic Compounds in Space The following compounds have been detected in space. Which of them contains the greatest percentage of carbon by mass? Do any two of the following compounds have the same empirical formula?

1. naphthalene, $C_{10}H_8$
2. chrysene, $C_{18}H_{12}$
3. pentacene, $C_{22}H_{14}$
4. pyrene, $C_{16}H_{10}$

Of the nitrogen oxides—N_2O, NO, N_2O_3, N_2O_2, NO_2, and N_2O_4—which are more than 50% oxygen by mass? Which, if any, have the same empirical formula?

Methane (CH_4) and tetrafluoromethane (CF_4) both contain 20% carbon per mole. Which one has the greater percent C by mass?

Silane (SiH_4) is used in the electronics industry to manufacture thin films of silicon. What is the percent Si by mass in SiH_4? Does silane have the same percent Si by mass as disilane (Si_2H_6)?

Surgical-Grade Titanium Medical implants and high-quality jewelry items for body piercings are frequently made of a material known as G23Ti, or surgical-grade titanium. The percent composition of the material is 64.39% titanium, 24.19% aluminum, and 11.42% vanadium. What is the empirical formula for surgical-grade titanium?

A sample of an iron-containing compound is 22.0% iron, 50.2% oxygen, and 27.8% chlorine by mass. What is the empirical formula of this compound?

Sour Candy Tartaric acid ($C_4H_6O_6$) and citric acid ($C_6H_8O_7$) are both used commercially to give sour candies (Figure P3.105) their characteristic sour taste. Which compound has the larger percent C by mass?

FIGURE P3.105

Chlorofluorocarbons CFCs (chlorofluorocarbons) are molecules used as refrigerants, but they also contribute to the destruction of the ozone layer. One CFC consists of two carbon atoms, two fluorine atoms, and four chlorine atoms. What is the empirical formula of this CFC? What is its molecular formula?

Asbestosis Asbestosis is a lung disease caused by inhaling asbestos fibers. In addition, fiber from a form of asbestos called chrysotile is considered to be a human carcinogen by the U.S. Department of Health and Human Services. Chrysotile's composition is 26.31% magnesium, 20.20% silicon, and 1.45% hydrogen, with the remainder of the mass as oxygen. Determine the empirical formula of chrysotile.

Chemistry of Soot A candle flame produces easily seen specks of soot near the edges of the flame, especially when the candle is moved. A piece of glass held over a candle flame will become coated with soot, which is the result of the incomplete combustion of candle wax. Elemental analysis of a compound extracted from a sample of this soot gave these results: 92.26% C and 7.74% H by mass. Calculate the empirical formula of the compound.

Making the DNA Bases Adenine (135.14 g/mol; 44.44% C, 3.73% H, and 51.84% N) was detected in mixtures of HCN, ammonia, and water under conditions that simulate early Earth. This observation suggests a possible origin for one of the bases found in DNA. What are the empirical and molecular formulas for adenine?

Making Sugars for RNA Ribose, the sugar found in RNA, has been detected in experiments designed to mimic the conditions of early Earth. If ribose contains 40.00% C, 6.71% H, and 53.28% O, with a molar mass of 150.13 g/mol, what are the empirical and molecular formulas for ribose?

Combustion Analysis

Concept Review

Explain why it is important for combustion analysis to be carried out in an excess of oxygen.

Why is the quantity of CO_2 obtained in a combustion analysis not a direct measure of the oxygen content of the starting compound?

What additional information is needed to determine a molecular formula from the results of an elemental analysis of an organic compound?

If a compound containing sulfur is subjected to combustion analysis in excess oxygen, what is the most likely molecular formula for the sulfur-containing product?

If a compound containing nitrogen is subjected to combustion analysis in excess oxygen, what is the most likely molecular formula for the nitrogen-containing product?

Suppose an insufficient amount of oxygen is used for a combustion analysis of a hydrocarbon, and some of the carbon is converted to CO rather than to CO_2. Will the empirical formula determined from the results of this analysis be too low or too high in carbon?

Problems

The combustion of 135.0 mg of a hydrocarbon produces 440.0 mg of CO_2 and 135.0 mg of H_2O. The molar mass of the hydrocarbon is 270 g/mol. Determine the empirical and molecular formulas of this compound.

A 0.100-g sample of a compound containing C, H, and O is burned in oxygen, producing 0.1783 g of CO_2 and 0.0734 g of H_2O. Determine the empirical formula of the compound.

GRAS List for Food Additives The compound geraniol ($\mathcal{M} = 154.25$ g/mol) is on the Food and Drug Administration's GRAS (generally recognized as safe) list and can be used in foods and personal care products. By itself, geraniol smells like roses, but it is frequently blended with other fragrances on the GRAS list and then added to products to produce a pleasant peachlike or lemonlike aroma. In an analysis, the complete combustion of 175 mg of geraniol produced 499 mg of CO_2 and 184 mg of H_2O. What are the empirical and molecular formulas of geraniol?

The combustion of 40.5 mg of a compound containing C, H, and O, and extracted from the bark of the sassafras tree, produces 110.0 mg of CO_2 and 22.5 mg of H_2O. The molar mass of the compound is 162 g/mol. Determine its empirical and molecular formulas.

Ethnobotany One of the ingredients in the Native American stomachache remedy derived from common chokecherry is caffeic acid ($\mathscr{M} = 180.16$ g/mol). Combustion of 1.00×10^2 mg of caffeic acid yielded 220 mg of CO_2 and 40.3 mg of H_2O. What are the empirical and molecular formulas of caffeic acid?

Coniine ($\mathscr{M} = 127.23$ g/mol), a substance isolated from poison hemlock, contains only carbon, hydrogen, and nitrogen. Combustion of 5.024 mg of coniine yields 13.90 mg CO_2 and 6.048 mg of H_2O. What are the empirical and molecular formulas of coniine?

Additional Problems

As a solution of copper sulfate slowly evaporates, beautiful blue crystals made of copper(II) and sulfate ions form such that water molecules are trapped inside the crystals. The overall formula of the compound is $CuSO_4 \cdot 5H_2O$.

1. What is the percent by mass of water in this compound?
2. At high temperatures, the water in the compound is driven off as steam. What mass percentage of the original sample of the blue solid is

lost as a result?

Production of Aluminum Aluminum is mined as the mineral bauxite, which consists primarily of Al_2O_3 (alumina).

1. How much aluminum is produced from 1 metric ton (1 metric ton = 10^3 kg) of Al_2O_3?

$2\ Al_2O_3(s) \rightarrow 4\ Al(s) + 3\ O_2(g)$

2. The oxygen produced in part (a) can react with carbon to produce carbon monoxide:

$O_2(g) + 2\ C(s) \rightarrow 2\ CO(g)$

Write a balanced chemical equation describing the reaction involving the following reactants and products:

$Al_2O_3(s) + C(s) \rightarrow Al(s) + CO(g)$

3. How much CO can be produced from the O_2 made in part (a)?

Chemistry of Copper Production “Native,” or elemental, copper can be found in nature, but most copper is mined as oxide or sulfide minerals. Chalcopyrite ($CuFeS_2$) is one copper mineral that can be converted to elemental copper in a series of chemical steps. Reacting chalcopyrite with oxygen at high temperature produces a mixture of copper sulfide and iron oxide. The iron oxide is separated from CuS by reaction with sand. CuS is converted to Cu_2S, and the Cu_2S is then burned in air to produce Cu and SO_2:

(1) $2\ CuFeS_2(s) + 3\ O_2(g) \rightarrow 2\ CuS(s) + 2\ FeO(s) + 2\ SO_2(g)$

(2) $FeO(s) + SiO_2(s) \rightarrow FeSiO_3(s)$

(3) $2\ CuS(s) \rightarrow Cu_2S(s) + \frac{1}{8}S_8(s)$

(4) $Cu_2S(s) + O_2(g) \rightarrow 2\ Cu(s) + SO_2(g)$

An average copper penny minted in the 1960s has a mass of about 3.0 g.

1. How much chalcopyrite had to be mined to produce one dollar’s worth of pennies?
2. How much chalcopyrite had to be mined to produce one dollar’s worth of pennies if reaction 1 above had a percent yield of 85% and reactions 2, 3, and 4 had percent yields of essentially 100%?
3. How much chalcopyrite had to be mined to produce one dollar’s worth of pennies if each reaction involving copper proceeded with an 85% yield?

Mining for Gold Gold can be extracted from the surrounding rock by using a solution of sodium cyanide. Although effective for isolating gold, toxic cyanide finds its way into watersheds, causing environmental damage and harming human health.

$4\ Au(s) + 8\ NaCN(aq) + O_2(g) + 2\ H_2O(l) \rightarrow 4\ NaAu(CN)_2(aq) + 4\ NaOH(aq)$

$2\ NaAu(CN)_2(aq) + Zn(s) \rightarrow 2\ Au(s) + Na_2[Zn(CN)_4](aq)$

1. If a sample of rock contains 0.009% gold by mass, how much NaCN is needed to extract the gold from 1 metric ton (1 metric ton $= 10^3$ kg) of rock as $NaAu(CN)_2$?
2. How much zinc is needed to convert the $NaAu(CN)_2$ from part (a) to metallic gold?
3. The gold recovered in part (b) is manufactured into a

gold ingot in the shape of a cube. The density of gold is 19.3 g/cm^3. How big is the cube of gold?

Preparing Nuclear Reactor Fuel Uranium oxides used in the preparation of fuel for nuclear reactors are separated from other metals in minerals by converting the uranium to $UO_x(NO_3)_y(H_2O)_z$, where uranium has a positive charge ranging from 3+ to 6+.

1. Roasting $UO_x(NO_3)_y(H_2O)_z$ at 400°C leads to loss of water and decomposition of the nitrate ion to nitrogen oxides, leaving behind a product with the formula U_aO_b that is 83.22% U by mass. What are the values of a and b? What is the charge on U in U_aO_b?
2. Higher temperatures produce a different uranium oxide, U_cO_d, with a higher uranium content, 84.8% U. What are the values of c and d? What is the charge on U in U_cO_d?
3. The values of x, y, and z in $UO_x(NO_3)_y(H_2O)_z$ are found by gently heating the compound to remove all the water. In a laboratory experiment, 1.328 g of $UO_x(NO_3)_y(H_2O)_z$ produced 1.042 g of $UO_x(NO_3)_y$. Continued heating generated 0.742 g of U_nO_m. Using the information in parts (a) and (b), calculate x, y, and z.

Fate of Fertilizer Large quantities of fertilizer are washed into the Mississippi River from agricultural land in the Midwest. The excess nutrients collect in the Gulf of Mexico, promoting the growth of algae and endangering other aquatic life.

1. One commonly used fertilizer is ammonium nitrate. What is the chemical formula of ammonium nitrate?

2. Corn farmers typically use 5.0×10^3 kg of ammonium nitrate per square kilometer of cornfield per year. Ammonium nitrate can be prepared by the following reaction:

$NH_3(aq) + HNO_3(aq) \rightarrow NH_4NO_3(aq)$

How much nitric acid would be required to make the fertilizer needed for 1 km^2 of cornfield per year?

3. The ammonium ions can be converted into NO_3^- by bacterial action.

$NH_4^+(aq) + 2\ O_2(g) \rightarrow NO_3^-(aq) + H_2O(\ell) + 2\ H^+(aq)$

If 10% of the ammonium component of 5.0×10^2 kg of fertilizer ends up as nitrate, how much oxygen would be consumed?

Composition of Over-the-Counter Medicines Calculate the number of molecules or formula units of compound in each of the following common, over-the-counter medications:

1. ibuprofen, a pain reliever and fever reducer that contains 200.0 mg of the active ingredient, $C_{13}H_{18}O_2$
2. an antacid containing 500.0 mg of calcium carbonate
3. an allergy tablet containing 4 mg of chlorpheniramine ($C_{16}H_{19}ClN_2$)

Chemistry of Pain Relievers The common pain relievers aspirin ($C_9H_8O_4$), acetaminophen ($C_8H_9NO_2$), and naproxen sodium ($C_{14}H_{13}O_3Na$) are all available in tablets containing 200.0 mg of the active ingredient. Which compound contains the greatest number of molecules per tablet? How many molecules of the active ingredient are present in each tablet?

Some catalytic converters in automobiles contain the manganese oxides Mn_2O_3 and MnO_2.

1. What are the names of Mn_2O_3 and MnO_2?
2. Calculate the percent manganese by mass in Mn_2O_3 and MnO_2.
3. Explain how Mn_2O_3 and MnO_2 are consistent with the law of multiple proportions.

Several chemical reactions have been proposed for the formation of organic compounds from inorganic precursors. Here is one of them:

$$H_2S(g) + FeS(s) + CO_2(g) \rightarrow FeS_2(s) + HCO_2H(\ell)$$

1. Identify the ions in FeS and FeS_2. Give correct names for each compound.
2. How much HCO_2H is obtained by reacting 1.00 g of FeS, 0.50 g of H_2S, and 0.50 g of CO_2 if the reaction results in a 50.0% yield?

The formation of organic compounds by the reaction of iron(II) sulfide with carbonic acid is described by the following chemical equation:

$$2\ FeS(s) + H_2CO_3(aq) \rightarrow 2\ FeO(s) + 1/n\ (CH_2O)_n(s) + 2\ S(s)$$

1. How much FeO is produced starting with 1.50 g of FeS and 0.525 mol of H_2CO_3 if the reaction results in a 78.5% yield?
2. If the carbon-containing product has a molar mass of 3.00×10^2 g/mol, what is the chemical formula of the product?

Marine Chemistry of Iron On the seafloor, iron(II) oxide reacts with water to form Fe_3O_4 and hydrogen in a process called serpentization.

1. Write a balanced chemical equation describing serpentization using these reactants and products:

$FeO(s) + H_2O(\ell) \rightarrow Fe_3O_4(s) + H_2(g)$

2. When CO_2 is present, the product is methane, not hydrogen. Write a balanced chemical equation based on these reactants and products:

$FeO(s) + H_2O(\ell) + CO_2(g) \rightarrow Fe_3O_4(s) + CH_4(g)$

Composition of Solar Wind The solar wind is made up of ions, mostly protons, flowing out from the Sun at about 400 km/s. Near Earth, each cubic kilometer of interplanetary space contains, on average, 6×10^{15} solar-wind ions. How many moles of ions are in a cubic kilometer of near-Earth space?

The Hope Diamond at the Smithsonian National Museum of Natural History has a mass of 45.52 carats (Figure P3.136). Diamond is a crystalline form of carbon.

1. How many moles of carbon are in the Hope Diamond (1 carat = 200.0 mg)?
2. How many carbon atoms are in the diamond?

FIGURE P3.136

E-85 is an alternative fuel for automobiles and light trucks that consists of 85% (by volume) ethanol (CH_3CH_2OH) and 15% gasoline. The density of ethanol is 0.79 g/mL. How many moles of ethanol are in a gallon of E-85?

A 100.00-g sample of white powder A is heated to 550°C. At that temperature the powder decomposes, giving off colorless gas B, which is denser than air and is neither flammable nor does it support combustion. The products also include 56 g of a second white powder C. When gas B is bubbled through a solution of calcium hydroxide, substance A reforms. What are the identities of substances A, B, and C?

You are given a 0.6240-g sample of a substance with the generic formula $MCl_2(H_2O)_2$. After complete drying of the sample (which means removing the 2 moles of H_2O per mole of MCl_2), the sample has a mass of 0.5471 g. What is the identity of element M?

A compound found in crude oil consists of 93.71% C and 6.29% H by mass. The molar mass of the compound is 128 g/mol. What is its molecular formula?

A reaction vessel for synthesizing ammonia by reacting nitrogen and hydrogen is charged with 6.04 kg of H_2 and excess N_2. A total of 28.0 kg of NH_3 is produced. What is the percent yield of the reaction?

If a cube of table sugar, which is made of sucrose ($C_{12}H_{22}O_{11}$) is added to concentrated sulfuric acid, the acid “dehydrates” the sugar, removing the hydrogen and oxygen from it and leaving behind a lump of carbon. What percentage of the initial mass of sugar is carbon?

A power plant burns 1.0×10^2 metric tons of coal that contains 3.0% (by mass) sulfur (1 metric ton $= 10^3$ kg). The sulfur is converted to SO_2 during combustion.

1. How many metric tons of SO_2 are produced?
2. When SO_2 escapes into the atmosphere, it may combine with O_2 and H_2O, forming sulfuric acid (H_2SO_4). Write a balanced chemical equation describing this reaction.
3. How many metric tons of sulfuric acid, a component of acid rain, could be produced from the quantity of SO_2 calculated in part (a)?

Reducing SO_2 Emissions With respect to the previous question, one way to reduce the formation of acid rain involves trapping the SO_2 by passing smokestack gases through a spray of calcium oxide and O_2. The product of this reaction is calcium sulfate.

1. Write a balanced chemical equation describing this reaction.
2. How many metric tons of calcium sulfate would be produced from each ton of SO_2 that is trapped?

In the early 20th century, Londoners suffered from severe air pollution caused by burning high-sulfur coal. The sulfur dioxide that was emitted into the air mixed with London fog, forming sulfuric acid. For every gram of sulfur that was burned, how many grams of sulfuric acid could have formed?

Gas Grill Reaction The burner in a gas grill mixes 24 volumes of air for every one volume of propane (C_3H_8) fuel. Like all gases, the volume that propane occupies is directly proportional to the number of moles of it at a given temperature and pressure. Air is 21% (by volume) O_2. Is the flame produced by the burner fuel-rich (excess propane in the reaction mixture), fuel-lean (not enough propane), or stoichiometric (just right)?

If you had equal masses of the substances in the following pairs of compounds, which of the two would contain the greater number of ions? (a) NaBr or KCl; (b) NaCl or $MgCl_2$; (c) $BaCl_2$ or Li_2CO_3

Ozone Generators Some indoor air-purification systems work by converting a little of the oxygen in the air to ozone, which oxidizes mold and mildew spores and other biological air pollutants. The chemical equation for the ozone generation reaction is

$3\ O_2(g) \rightarrow 2\ O_3(g)$

It is claimed that one such system generates 4.0 g of O_3 per hour from dry air passing through the purifier at a flow of 5.0 L/min. If 1 liter of indoor air contains 0.28 g of O_2,

1. what fraction of the molecules of O_2 is converted to O_3 by the air purifier?
2. what is the percent yield of the ozone generation reaction?

Rebreathing Devices In the first episode of George Lucas's *Star Wars* series, Qui-Gon Jinn and Obi-Wan Kenobi can visit the underwater world of the Gungans only by using A99 Aquata Breathers, which allow them to survive underwater for up to two hours. Although the tiny devices may be from the farfetched world of science fiction, current technology exists for transforming carbon dioxide to oxygen. These self-contained rebreathers are used by a select group of underwater cave explorers and can act as self-rescue devices. The chemistry is based on the following chemical reactions, using either potassium superoxide or sodium peroxide:

$4\ KO_2(s) + 2\ CO_2(g) \rightarrow 2\ K_2CO_3(s) + 3\ O_2(g)$

$2\ Na_2O_2(s) + 2\ CO_2(g) \rightarrow 2\ Na_2CO_3(s) + O_2(g)$

1. The respiratory rate at rest for an average, healthy adult is 12 breaths per minute. If the average breath takes in 0.500 L of O_2 (d = 1.429 g/L) into the lungs, how many grams of KO_2 are needed to produce enough oxygen for 2 hours underwater?
2. Would you need more or less Na_2O_2 to produce an equivalent amount of oxygen?
3. Given the densities of KO_2 (d = 2.14 g/mL) and Na_2O_2 (d = 2.805 g/mL), which solid material would occupy less volume in a rebreather device?

Smelly Socks Socks containing silver nanoparticles embedded in the fabric are currently marketed as an antidote to smelly socks. Silver is known to have antimicrobial properties, and silver ions are toxic to aquatic life. A study at Arizona State University found that much of the silver particles are lost upon laundering the socks in mild acid.

1. Each sock in the study began with 1360 µg of silver. How many moles of silver are contained in each sock?
2. As much as 650 µg of silver was lost after four washings. What percent of the silver was lost?

Glossary

mole (mol)

the SI base unit for expressing quantities of substances. One mole contains $6.02214076 \times 10^{23}$ particles: atoms, molecules, or formula units.

reactant

a substance consumed during a chemical reaction.

product

a substance formed during a chemical reaction.

limiting reactant

a reactant that is consumed completely in a chemical reaction; the amount of product formed depends on the amount of the limiting reactant available.

actual yield

the amount of product obtained from a chemical reaction, which may be less than the theoretical yield.

percent yield

the ratio, expressed as a percentage, of the actual yield of a chemical reaction to the theoretical yield.

theoretical yield

the maximum amount of product possible in a chemical reaction for given quantities of reactants; also called *stoichiometric yield*.

percent composition

the composition of a compound expressed in terms of the percentage by mass of each element in the compound.

combustion analysis

a laboratory procedure for determining the composition of a substance by burning it completely in excess oxygen to produce known compounds whose masses are used to determine the composition of the original material.

Avogadro constant (N_A)

the fundamental constant representing the number of characteristic particles in 1 mole of a substance: $6.02214076 \times 10^{23}$ particles/mol.

SURVIVING IN SEAWATER Marine mammals such as this humpback whale have the ability to regulate the concentrations of dissolved salts in their bodies to about one-third that of the seawater they live in.

Reactions in Solution Aqueous Chemistry in Nature

PARTICULATE REVIEW

Ionic or Covalent in Solution?

In Chapter 4 we examine what happens to ionic and molecular compounds when they dissolve in water and the reactions that result from collisions of the dissolved particles. The beaker on the left contains 0.1 moles of ethylene glycol dissolved in water; the beaker on the right contains 0.1 moles of sodium sulfate dissolved in water. Answer the following questions about these two aqueous solutions.

- Is ethylene glycol a molecular compound or an ionic compound? Are its bonds covalent or ionic?
- Is sodium sulfate a molecular compound or an ionic compound? Are its bonds covalent or ionic?
- What features of the particles help you answer these questions?

  (Review Figures 1.7, 2.18, and 2.19 if you need help.)

(Answers to Particulate Review questions are in the back of the book.)

PARTICULATE PREVIEW

Products and Leftover Reactants

This picture shows 25 mL of 0.5 *M* NH_4Cl about to be poured into 75 mL of 0.1 *M* $AgNO_3$. As you read Chapter 4, look for ideas that will help you answer these questions:

- What are the possible products when these solutions mix? Will the ions remain dissolved in water or form a precipitate?
- Which is the limiting reactant? Will any nitrate ions remain in solution? Why or why not?
- Sketch a drawing of the particulate contents after pouring all the aqueous NH_4Cl solution into the aqueous $AgNO_3$ solution.

Learning Outcomes

- LO1 Express the concentrations of solutions in different units, including molarity

  Sample Exercises 4.1, 4.2, 4.3

- LO2 Calculate the mass of a solute or the volume of a highly concentrated solution required to make a solution of specified volume and concentration

Sample Exercises 4.4, 4.5

- LO3 Use Beer’s law and absorbance data to determine the concentration of an unknown solution

  Sample Exercise 4.6

- LO4 Write molecular, overall ionic, and net ionic equations for reactions in aqueous solution

  Sample Exercises 4.7, 4.10, 4.11, 4.12

- LO5 Classify substances as soluble or only slightly soluble in aqueous solution and identify strong electrolytes, weak electrolytes, nonelectrolytes, and Brønsted–Lowry acids and bases based on their properties

  Sample Exercise 4.8

- LO6 Calculate the concentration of a solution from titration data

  Sample Exercises 4.9, 4.10

- LO7 Use solubility rules to predict the products of precipitation reactions and to quantify results from precipitation reactions

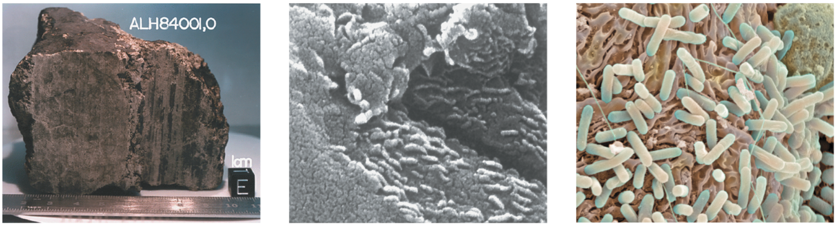
  Sample Exercises 4.11, 4.12, 4.13, 4.14, 4.15

- LO8 Determine oxidation numbers and use them to identify redox reactions, oxidizing agents, and reducing agents. Use the activity series to explain redox reactions between metals and metal ions

  Sample Exercises 4.16, 4.17, 4.19, 4.20

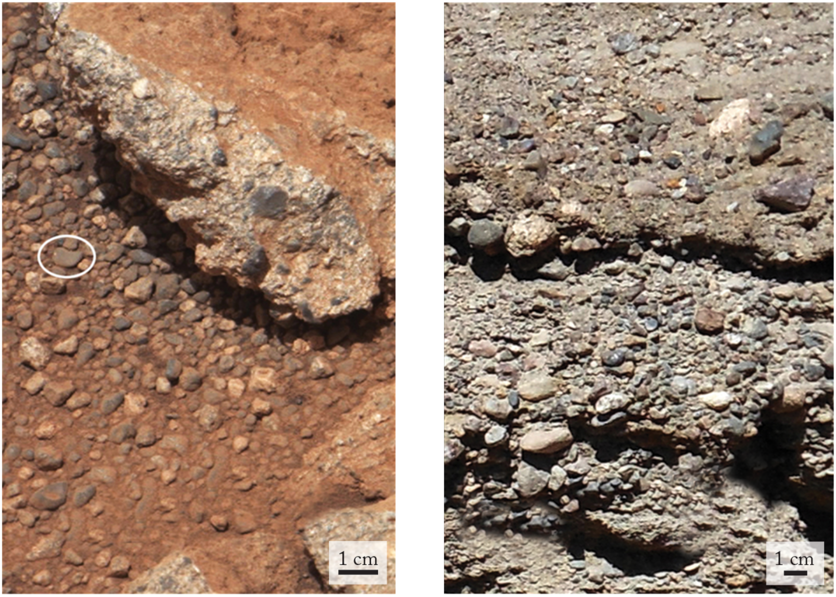
- LO9 Use half-reactions to write balanced equations for redox reactions

Sample Exercises 4.18, 4.21



(a) (b) (c)

FIGURE 4.1 (a) Meteorite ALH84001, thought to have originated from Mars, contains (b) microscopic features that some scientists believe to be fossilized bacteria. (c) An Earth-grown colony of the bacterium *Escherichia coli*, for comparison.



(a) Mars (b) Earth

FIGURE 4.2 (a) Rocks on the Martian surface are similar in size and shape to (b) rocks on Earth in an area where a fast-moving stream of water once flowed.

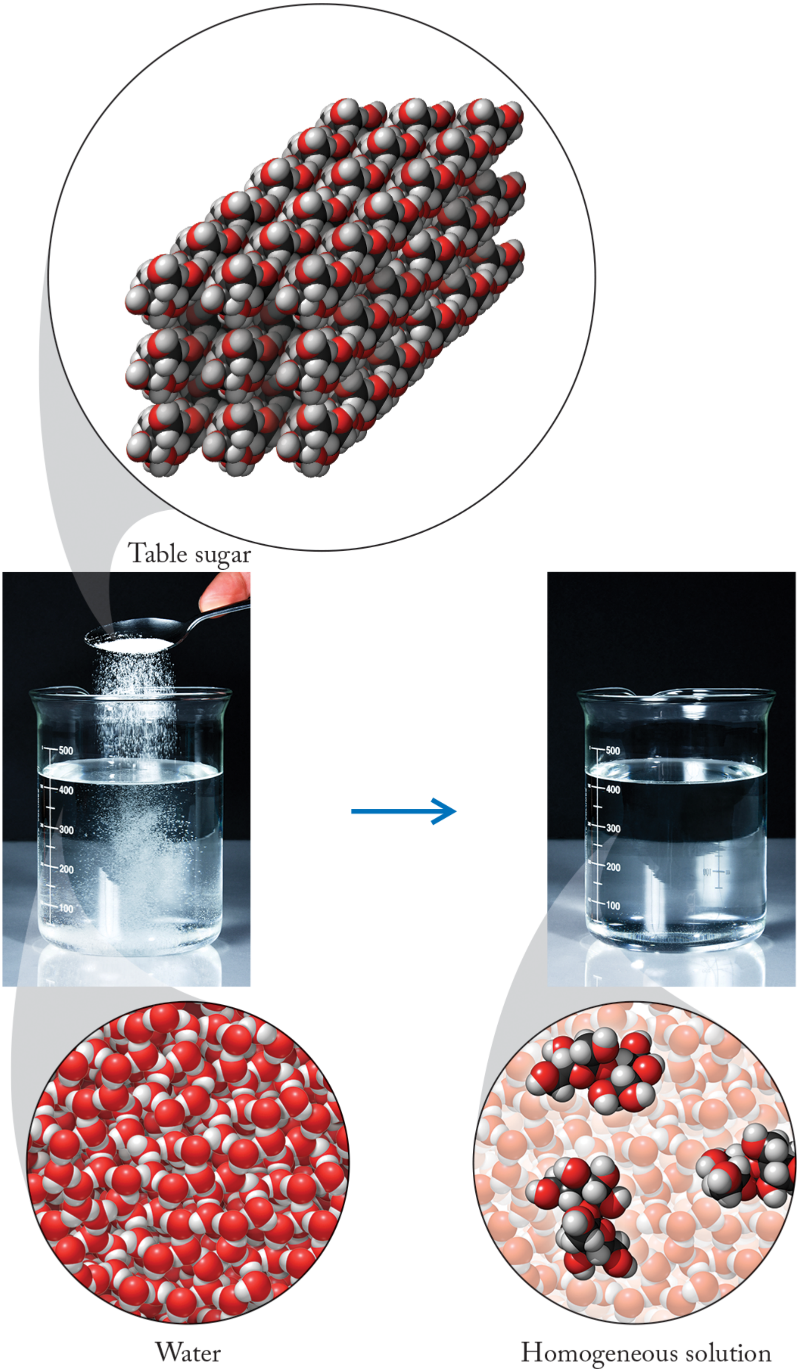


Table sugar
Water
Homogeneous solution

FIGURE 4.3 Adding table sugar (the solute) to water (the solvent)

produces a solution of sugar molecules evenly distributed among water molecules. The covalent bonds in the sugar molecules (shown here as space-filling models) do not break upon dissolving, and the particles of solute in the solution are neutral molecules.

4.1 Ions and Molecules in Oceans and Cells

Chapter 3 began with a description of how Earth formed about 4.6 billion years ago: as a hot, molten sphere that gradually cooled and formed a solid crust surrounded by an atmosphere of gases. Further cooling allowed one of the atmosphere's principal components, water vapor, to condense. The resultant torrential rain ran down from the crust's highlands and collected in its depressions, forming the first oceans. Life on Earth may have begun in these oceans. According to one theory, life originated deep beneath the surface of the oceans at hydrothermal vents, where hot, mineral-laden seawater emerging from Earth's crust mixed with cold seawater, forming mineral-rich deposits. Others have argued that only shallow ponds, not the marine environment, provided the appropriate concentrations of ions for cells to arise. Whether either theory is correct or not, water is essential for life as we know it on Earth. On early Earth, water provided the medium in which dissolved molecules and ions moved about, collided with one another, and participated in chemical reactions that led to the formation of more complex molecules, and eventually to assemblies of molecules capable of reproduction.

CONNECTION Recall from Chapter 1 that solutions are mixtures that are homogeneous: the substances making up the mixture are distributed uniformly.

Debate over the existence of life elsewhere in the universe hinges on the prospect of liquid water on other planets. The controversial claim that Martian meteorites collected in Antarctica contain fossilized life-forms (**Figure 4.1**) is consistent with evidence that water flowed on the surface of Mars in the distant past. Some Martian rocks and pebbles photographed by the *Curiosity* rover are round and smooth like streambed deposits on Earth, suggesting that they were formed by similar processes (**Figure 4.2**). Furthermore, analysis by *Curiosity* has revealed that some samples of Martian surface soil contain 2% water by weight. These and other observations support the idea that liquid water may now exist just under the surface of Mars, and where there is water, there could be life.

Understanding the chemistry of the biosphere requires understanding the principles of chemical reactions between substances dissolved in water. When one element or compound dissolves in another, a *solution* forms—a homogeneous mixture of two or more substances (**Figure 4.3**). The substance present in the greatest number of moles is called the solvent, and the other substances in the solution are called solutes. When the solvent is water, the solution is an *aqueous solution*, and here in Chapter 4 you may assume all the solutions we discuss are aqueous. (It bears noting, however, that in the most general case, a solvent does not have to be a liquid. Many materials in Earth's crust, for example, are *solid solutions*, which are uniform mixtures of solid substances. Moreover, Earth's atmosphere can be thought of as a *gaseous solution*; gases are the subject of Chapter 5.)

CONCEPT TEST

Which, if any, of the following are solutions? (a) muddy river water; (b) helium gas; (c) clear cough syrup; (d) filtered dry air

(Answers to Concept Tests are in the back of the book.)

Dissolved ionic and molecular compounds are present in all the waters on Earth's surface. The amounts of these dissolved compounds in a given volume range from very low (in the water from melting glaciers) to very high (in seawater). The liquids in the cells of all living things are also saline solutions, though not as salty as seawater. For example, the most abundant ionic solutes in our cells and in our blood plasma—Na^+, Cl^-, HCO_3^-, K^+, Ca^{2+}, HPO_4^{2-}, and Mg^{2+} ions—are even more abundant in seawater. The proportions of these ions present in the blood of healthy people are remarkably constant, as are the principal molecular solutes: CO_2, $C_6H_{12}O_6$ (glucose), and hemoglobin. Therefore, clinical assessments of a patient's well-being often include tests of whether these solutes are within their normal quantitative ranges. Departures from normal ranges may indicate problems, such as kidney disease or drug abuse.

Dissolved particles are involved in several major classes of chemical reactions that are essential to the proper function of all living cells. Molecules of CO_2, produced when our bodies metabolize food to produce energy, combine with molecules of H_2O, forming hydrogen ions and bicarbonate ions:

$$CO_2(aq) + H_2O(\ell) \rightarrow H^+(aq) + HCO_3^-(aq)$$

The H^+ ions produced in this reaction combine with additional molecules of water, forming hydronium ions, **H_3O^+**:

$$H^+(aq) + H_2O(\ell) \rightarrow H_3O^+(aq)$$

Reactions such as these that involve the transfer of H^+ ions are called *acid–base reactions*. Acid–base reactions are a major class of aqueous-phase reactions that we explore in this chapter.

A second class of reactions involves pairs of dissolved cations and anions that collide to form only slightly soluble ionic compounds that precipitate from (settle out of) solution. Such a *precipitation reaction* occurs when Ca^{2+} and HPO_4^{2-} ions combine with water molecules to form a mineral that has the common name hydroxyapatite, which is the principal component in tooth enamel:

$$10\ Ca^{2+}(aq) + 6\ HPO_4^{2-}(aq) + 2\ H_2O(\ell) \rightarrow Ca_{10}(PO_4)_6(OH)_2(s) + 8\ H^+(aq)$$

In this chapter we examine trends in the solubility of ionic compounds that enable you to predict whether precipitates form when solutions of different ionic compounds are mixed.

Much of a cell's energy comes from a process we discussed in Chapter 3, in which glucose reacts with O_2 (conveyed in the blood by hemoglobin), forming carbon dioxide and water:

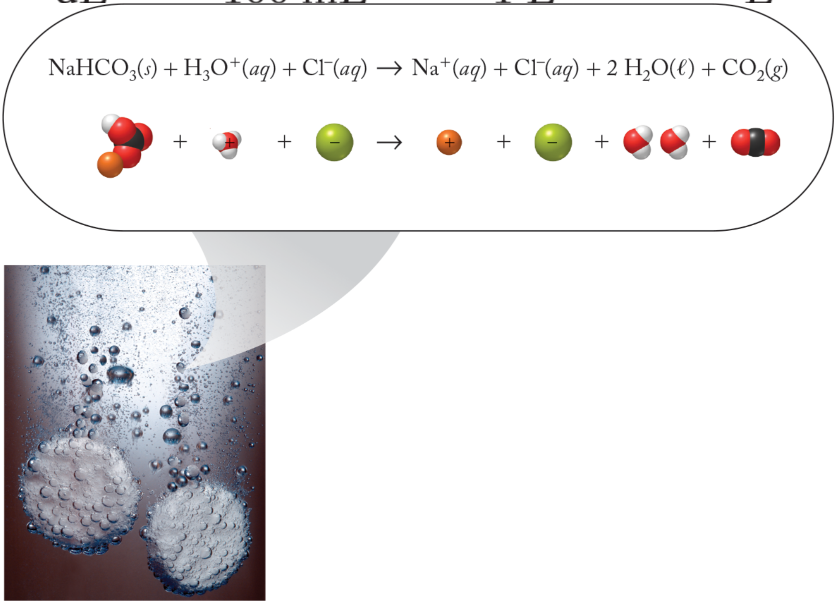
$$C_6H_{12}O_6(aq) + 6\ O_2(g) \rightarrow 6\ CO_2(g) + 6\ H_2O(\ell)$$

This reaction is an example of a third important class of reactions, called *redox* reactions, in which elements (oxygen in this case) are *red*uced, which means that their atoms gain electrons, while others (the carbon in glucose) are *ox*idized, which means that their atoms lose electrons. We explore redox reactions in Section 4.8.

Glossary

solvent	the component of a solution that is present in the largest number of moles.
solute	any component in a solution other than the solvent; a solution may contain one or more solutes.
hydronium ion (H_3O^+)	a H^+ ion bonded to a molecule of water, H_2O; the chemical form of a hydrogen ion in an aqueous solution.

$$\frac{200\text{ mg}}{\cancel{\text{dL}}} \times \frac{1.0\ \cancel{\text{dL}}}{100\ \cancel{\text{mL}}} \times \frac{1000\ \cancel{\text{mL}}}{1\text{ L}} = \frac{2000\text{ mg}}{\text{L}}$$



$$\text{NaHCO}_3(s) + \text{H}_3\text{O}^+(aq) + \text{Cl}^-(aq) \longrightarrow \text{Na}^+(aq) + \text{Cl}^-(aq) + 2\ \text{H}_2\text{O}(\ell) + \text{CO}_2(g)$$

FIGURE 4.4 The reaction between a base (sodium bicarbonate) and stomach acid generates bubbles of carbon dioxide and provides relief for an upset stomach. (Solvent water molecules have been omitted in the particle representation for clarity.)

$$\text{molarity } (M) = \frac{\text{moles } (n) \text{ of solute}}{\text{volume } (V) \text{ of solution in liters}}$$

or

$$M = \frac{n}{V} \qquad (4.1)$$

$$n = V \times M \qquad (4.2)$$

$$\text{moles} = \frac{\text{mass (g)}}{\text{molar mass (g/mol)}}$$

$$\frac{\text{mass (g)}}{\text{molar mass (g/mol)}} = V \times M$$

$$m_{\text{solute}} = (V \times M)\,\mathcal{M} \tag{4.3}$$

$$\text{g} = \left(\cancel{\text{L}} \times \frac{\cancel{\text{mol}}}{\cancel{\text{L}}}\right) \times \frac{\text{g}}{\cancel{\text{mol}}}$$

$$1\text{ ppm} = \frac{1\ \cancel{\mu\text{g solute}}}{1\ \cancel{\text{g solution}}} \times \frac{1\text{ mg solute}}{10^3\ \cancel{\mu\text{g solute}}} \times \frac{10^3\ \cancel{\text{g solution}}}{1\text{ kg solution}} = \frac{1\text{ mg solute}}{1\text{ kg solution}}$$

$$\frac{0.00130\ \cancel{\text{g F}^-}}{1\text{ kg seawater}} \times \frac{10^3\text{ mg F}^-}{1\ \cancel{\text{g F}^-}} = \frac{1.30\text{ mg F}^-}{1\text{ kg seawater}} = 1.30\text{ ppm F}^-$$

$$1\text{ ppb} = \frac{1\text{ ppm}}{1000} = \frac{0.001\ \mu\text{g solute}}{1\ \cancel{\text{g solution}}} \times \frac{10^3\ \cancel{\text{g solution}}}{1\text{ kg solution}} = \frac{1\ \mu\text{g solute}}{1\text{ kg solution}}$$

$$250\text{ ppm} = 250\ \frac{\cancel{\text{mg}}}{\text{kg}} \times \frac{1\text{ g}}{1000\ \cancel{\text{mg}}} = 0.250\ \frac{\text{g}}{\text{kg}}$$

$$\frac{19.353\ \dfrac{\cancel{\text{g}}}{\cancel{\text{kg}}}}{0.250\ \dfrac{\cancel{\text{g}}}{\cancel{\text{kg}}}} = 77.4$$

$$19.353\ \frac{\text{g}}{\text{kg}} \times \frac{1000\text{ mg}}{1\ \text{g}} = 19{,}353\ \frac{\text{mg}}{\text{kg}} = 19{,}353\text{ ppm} \qquad \text{and} \qquad \frac{19{,}353\ \cancel{\text{ppm}}}{250\ \cancel{\text{ppm}}} = 77.4$$

4.2 Expressing Concentrations

In Chapter 3 we used the ideas of the mole and the stoichiometric relationship between reactants and products to deal with macroscopic quantities of materials involved in chemical reactions. In this section we develop additional tools that enable us to apply the concepts of stoichiometry to reactions taking place in solutions. **Figure 4.4** shows a common acid–base reaction: an antacid tablet containing sodium bicarbonate is added to stomach acid, releasing bubbles of $CO_2(g)$ and neutralizing some of the $HCl(aq)$ in gastric fluid. How does a manufacturer of antacid tablets determine the quantity of sodium bicarbonate needed to neutralize a portion of stomach acid? The answer lies in part in knowing both the balanced equation that describes the reaction and the *concentration* of the solution.

Concentration Units

The concentration of any solution, or the amount of solute in a given amount of solvent or solution, can be expressed in a variety of ways. Qualitatively, solutions are described as *concentrated* or *dilute* if they contain relatively high or low ratios of solute to solvent.

To be more specific, we need to be able to quantify the concentration of a solution. Some quantitative measures of concentration are based on *mass-to-volume ratios*, such as milligrams of solute per liter of solution. When clinical laboratories report the concentration of substances in blood plasma, a common unit is milligrams per deciliter (dL; $1\ \text{dL} = 0.10\ \text{L} = 100\ \text{mL}$) of plasma (solution). For example, the reference concentration for total cholesterol is <200 mg/dL, which is the same as <2000 mg/L:

Most scientists interested in studying chemical processes in natural waters or laboratory solutions prefer to work with concentrations based on moles of solute. For these scientists, the preferred concentration unit is moles of solute per liter of solution. This ratio is called molarity (M):[1]

Molarity

If we know the volume and molarity for any solution, we can readily calculate the mass of solute in the solution. First, we rearrange Equation 4.1:

Remember from Chapter 3 that the moles (n) of a substance can also be calculated from its mass (m) and molar mass ($\mathscr{M}$):

Setting these two expressions for calculating the number of moles of solute equal to each other:

Solving for the mass of solute:

To check that Equation 4.3 is correct, note how the units cancel out:

Equation 4.3 is useful when we want to calculate the mass of a solute needed to prepare a solution of a desired volume and molarity or when we have a solution of known molarity and want to know the mass of solute in a given volume of the solution.

In many environmental and biological systems, solute concentrations are often much less than $1.0\ M$. **Table 4.1** lists the major ions in seawater and in human serum and their average concentrations, using three common units. For instance, the concentration units in column 4 are not moles per liter but *millimoles* per liter, which means we are describing concentration in terms of *millimolarity* ($\text{m}M$; $1\ \text{m}M = 10^{-3}\ M$) rather than molarity. On an even smaller scale, the concentrations of minor and trace elements in seawater are often expressed in terms of *micromolarity* (μM; $1\ \mu M = 10^{-6}\ M$), *nanomolarity* ($\text{n}M$; $1\ \text{n}M = 10^{-9}\ M$), and even *picomolarity* ($\text{p}M$; $1\ \text{p}M = 10^{-12}\ M$). The concentration ranges of many biologically active substances in blood, urine, and other biological liquids are also so small that they are often expressed in units such as these.

CONCEPT TEST

Which of the following aqueous sodium chloride solutions is the least concentrated? (a) 0.0053 *M* NaCl; (b) 54 m*M* NaCl; (c) 550 µ*M* NaCl; (d) 56,000 n*M* NaCl

(Answers to Concept Tests are in the back of the book.)

Some concentration units are not mass-to-volume ratios like molarity but rather are *mass-to-mass ratios*. Two such mass-to-mass concentration units are *parts per million* (ppm) and *parts per billion* (ppb). These units are convenient for expressing the very small concentrations frequently encountered in environmental samples: the Safe Drinking Water Act passed by the U.S. Congress in 1974 uses these units to identify safe maximum levels for contaminants in our drinking water, from harmful substances such as lead to helpful substances such as fluoride, which prevents dental cavities. A solution with a concentration of 1 ppm contains 1 part solute for every million parts of solution, which means 1 g of solute for every million (10^6) grams of solution. Put another way, each gram of a 1 ppm solution contains one-millionth of a gram (10^{-6} g = 1 µg) of solute. A 1 ppm solution is also the same as 1 mg of solute per kilogram of solution:

Let’s express the smallest seawater concentration in Table 4.1 (0.00130 g F^-/kg seawater) in parts per million. To do so, we convert grams of F^- into milligrams of F^- because 1 mg of solute per kilogram of solution is the same as 1 ppm:

Thus, parts per million is a particularly convenient unit for expressing the concentration of F^- ions in seawater because it avoids the use of exponents or lots of zeroes to set the decimal place.

Some substances are so harmful that a concentration of less than 1 ppm can still be cause for concern. For example, the maximum concentration of copper ions in drinking water in the United States is 1.3 mg/L or 1.3 ppm (assuming the density of drinking water is 1.00 kg/L). However, the maximum concentration of cadmium ions in drinking water is 0.005 mg/L. For these substances, ppb is a more appropriate unit. A concentration of 1 ppb is 1/1000 as concentrated as 1 ppm. Because 1 ppm is the same as 1 mg of solute per kilogram of solution, 1 ppb is equivalent to 1 μg of solute per kilogram of solution:

Thus, a 0.005 mg/L solution of Cd^{2+} is equivalent to 5 ppb.

SAMPLE EXERCISE 4.1 Comparing Ion Concentrations in Aqueous Solutions LO1

The average concentration of chloride ion in seawater is 19.353 g/kg solution. The World Health Organization (WHO) recommends that the concentration of Cl^- ions in drinking water not exceed 250 ppm (2.50×10^2 ppm). How many times greater is the Cl^- ion concentration in seawater than the WHO limit for Cl^- ions in drinking water?

Collect, Organize, and Analyze We are asked to compare concentrations that are expressed in two sets of units: g/kg and ppm. To facilitate the comparison, let’s convert the drinking water standard from ppm (or mg/kg) into g/kg using a conversion factor based on the equality 1 g = 1000 mg.

Solve

The maximum chloride ion concentration in drinking water is

Dividing this drinking water maximum into the concentration of Cl^- ions in seawater:

Therefore, the concentration of Cl^- ions in seawater is 77.4 times greater than the maximum acceptable concentration of these ions in drinking water.

Think About It Common sense says that seawater is much saltier than drinking water. Drinking seawater induces nausea and vomiting, and it may even cause death. We could also have converted the seawater concentration into ppm and compared that value to the drinking water standard. Doing so:

gives the same concentration ratio, confirming the results of the first calculation.

Practice Exercise The WHO drinking water standard for arsenic is <10.0 μg/L. Arsenic concentrations in water from some wells in Bangladesh are as high as 1.2 mg/L. How many times above the WHO standard is this level?

(Answers to Practice Exercises are in the back of the book.)

CONNECTION In Chapter 1 we discussed distilling seawater to separate the sea salts from the water, thereby generating fresh drinking water.

SAMPLE EXERCISE 4.2 Calculating Molarity from Mass and Volume LO1

Pipes made of polyvinyl chloride (**Figure 4.5**) are widely used in homes and office buildings, though their use is restricted because vinyl chloride (CH_2CHCl, $\mathscr{M} = 62.49$ g/mol) may leach from them. The maximum concentration of vinyl chloride allowed in drinking water in the United States is 0.002 mg/L. What molarity is this?

Collect and Organize We are given a concentration in milligrams of solute per liter of solution, and we are asked to convert it to units of molarity (moles of solute per liter of solution). The molar mass (g/mol) of a substance relates the mass and number of moles of a given quantity of the substance.

Analyze The solute mass is given in milligrams, so we need to convert this mass first to grams and then to moles to calculate molarity. The mass/volume concentration value is small; the molarity value should be smaller still.

Solve The molarity of vinyl chloride in a 0.002 mg/L solution is

Think About It As predicted, the molar concentration equivalent to the drinking water standard is very low, reflecting the danger that exposure to vinyl chloride poses to human health.

Practice Exercise When 1.00 L of water from the surface of the Dead Sea is evaporated, 179 g of $MgCl_2$ is recovered. What was the molarity of $MgCl_2$ in the original sample?

(Answers to Practice Exercises are in the back of the book.)

SAMPLE EXERCISE 4.3 Calculating Molarity from Density LO1

The concentration of Na^+ ions in a sample of water from the Great Salt Lake in Utah is 83.6 mg/g. What is the molarity of Na^+ ions if the density of the water is 1.160 g/mL solution?

Collect and Organize We are asked to convert a concentration value expressed in mg/g to one expressed in mol/L. We are given the density of the sample, and the molar mass of Na is 22.99 g/mol.

Analyze We need to convert mg Na^+ ions to an equivalent number of moles:

and use the density of the sample to convert milligrams of it to liters:

Dividing the results of the first calculation by the results of the second will give us the moles of Na^+ ions in one liter of sample, that is, molarity.

Solve Calculating moles of Na^+ ions in 1 g of lake water:

The volume of exactly 1 g of lake water is

The molarity of Na^+ ions in the sample is

Think About It Let's compare the initial (83.3 mg/g = 83.3 g/kg) and calculated (4.22 *M*) concentrations of Na^+ ions in water from the Great Salt Lake with Na^+ ion concentrations in seawater in Table 4.1, column 2 (10.781 g/kg) and column 4 (480.57 m*M* = 0.48057 *M*). Both the lake water samples are much higher than the comparable seawater values, though the ratio is greater for the molarity concentrations, 4.22 *M*/0.48057 *M* = 8.78, than the mass-based concentrations, (83.3 g/kg)/(10.781 g/kg) = 7.73. This difference makes sense because the density of the lake water sample (1.160 g/mL) is over 13% higher than the average density of seawater (1.025 g/mL). Therefore, concentrations based on sample volume, such as one liter, will be proportionately greater than those based on sample mass, such as one kilogram. Compare the values in columns 3 and 4 of Table 4.1 to gain another perspective on this difference.

Practice Exercise If the density of ocean water at a depth of 10,000 m is 1.071 g/mL and if 25.0 g of water at that depth contains 190 mg of potassium chloride, what is the molarity of potassium chloride in the water?

(Answers to Practice Exercises are in the back of the book.)

CONNECTION Density, first introduced in Chapter 1, is the ratio of the mass of a quantity of material to its volume, or $d = m/V$. Density is an intensive physical property, so its value is independent of the quantity of material present.

SAMPLE EXERCISE 4.4 Calculating the Quantity of Solute Needed to Prepare a Solution of Known Concentration LO2

An aqueous solution called *Kalkwasser* [German for “limewater”; 0.0225 M $Ca(OH)_2$] may be added to saltwater aquaria to reduce acidity and add Ca^{2+} ions. How many grams of $Ca(OH)_2$ do you need to make 500.0 mL of Kalkwasser?

Collect, Organize, and Analyze We know the volume and molarity of the solution we must prepare. We also know the identity of the solute, which enables us to calculate its molar mass. We can use Equation 4.3 to calculate the mass of $Ca(OH)_2$ needed. We also must convert the volume from milliliters to liters to obtain the mass, in grams, of solute required.

The molar mass of $Ca(OH)_2$ is

$$40.08\ \text{g/mol} + 2(16.00\ \text{g/mol}) + 2(1.008\ \text{g/mol}) = 74.10\ \text{g/mol}$$

Solve Equation 4.3 can be used to calculate the mass of $Ca(OH)_2$ needed:

Figure 4.6 shows the technique for making this solution. A key feature in the preparation is that we suspend 0.834 g of solute in 200–300 mL of water and then add additional water until the final solution has the volume specified.

Think About It To complete an exercise like this one requires that we remember the definition of molarity: moles of solute per liter of solution. The solution we want has a concentration of 0.0225 *M*, or 0.0225 mol/L. Because we need only 0.5000 L of this solution, we do not need 0.0225 mol of $Ca(OH)_2$, but only half that amount (0.0112 mol). Finally, we calculate the number of grams of calcium hydroxide in 0.0112 mol of calcium hydroxide (0.834 g). The amount of $Ca(OH)_2$ needed is less than a teaspoon.

Practice Exercise An aqueous solution known as Ringer's lactate is administered intravenously to trauma victims suffering from blood loss or severe burns. The solution contains the chloride salts of sodium, potassium, and calcium and is 4.00 m*M* in sodium lactate ($NaC_3H_5O_3$; **Figure 4.7**). How many grams of sodium lactate are needed to prepare 10.0 L of Ringer's lactate?

(Answers to Practice Exercises are in the back of the book.)

Glossary

concentration

the amount of a solute in a given mass or volume of solvent or solution.

molarity (*M*)

the concentration of a solution expressed in moles of solute per liter of solution ($M = n/V$).

Endnotes

- Note that molarity is symbolized by M, whereas molar mass is $\mathscr{M}$ throughout this text. Return to reference 1
- g/kg = grams of solute per kilogram of solution.Return to reference a
- mmol/kg = millimoles of solute per kilogram of solution. (Oceanographers prefer this unit to one based on solution volume because the volume of a given mass of water varies with changing temperature and pressure, whereas its mass remains constant.)Return to reference b
- mmol/L = mM = millimoles of solute per liter of solution.Return to reference c
- mmol/L = mM = millimoles of solute per liter of solution.Return to reference c

(c) The red line represents a calibration curve for Beer's law, plotting absorbance versus concentration for a series of standard samples. The horizontal dashed blue line represents the absorbance of a solution of unknown concentration. By extending the line to where it meets the calibration curve and following the vertical dashed blue line down to the x-axis, we can determine the concentration of the unknown solution.

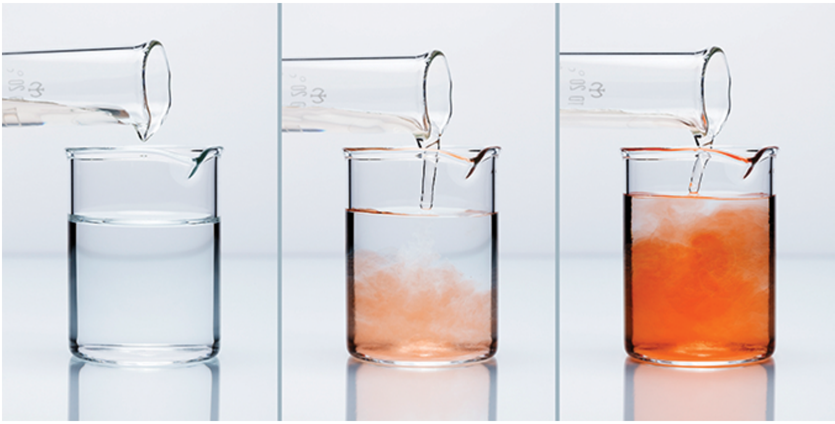

FIGURE 4.10 Adding a colorless solution of phenanthroline to a colorless solution of Fe^{2+} forms an orange-red solution when the phenanthroline molecules bond to the Fe^{2+} ions.

4.3 Dilutions

In laboratories such as those that test drinking water quality, scientists purchase stock solutions of substances such as pesticides and toxic metals from chemical manufacturers. To make their distribution more efficient, these solutions are packaged and sold in high concentrations—too high to be used directly in analytical procedures. So, to prepare a solution with a solute concentration that is near the substance's expected concentration in the sample of drinking water being tested, the laboratory will *dilute* the stock solution. Dilution is the process of lowering the concentration of a solution by adding solvent to a known volume of the initial solution. The stock solution is concentrated—it contains a much larger solute-to-solvent ratio than does the dilute solution.

Suppose we need to prepare 250.0 mL of an aqueous solution that is 0.0100 M Cu^{2+}, starting with a stock solution that is 0.1000 M Cu^{2+}. We can use Equation 4.2 to calculate the number of moles of Cu^{2+} ions in the diluted solution:

The subscript "diluted" refers to the solution we are preparing, and V refers to the final volume of the solution in liters. Using the same equation, we can calculate the *initial* quantities, that is, the volume of the stock solution we need to deliver 2.50×10^{-3} of Cu^{2+}:

To make the diluted solution, we add water to 25.0 mL of the stock solution to make a final volume of 250.0 mL (**Figure 4.8**).

Because the number of moles of solute (Cu^{2+} ions) is the same in the diluted solution and in the portion of stock solution required ($n_{\text{diluted}} = n_{\text{initial}}$), we can combine these two equations into one that applies to all situations in which we know any three of these four variables: the initial volume (V_{initial}) of stock solution, the initial solute concentration (M_{initial}), the volume (V_{diluted}) of the diluted solution, and the solute concentration (M_{diluted}) in the diluted solution:

$$V_{\text{initial}} \times M_{\text{initial}} = n_{\text{initial}} = n_{\text{diluted}} = V_{\text{diluted}} \times M_{\text{diluted}}$$

or simply

Equation 4.4 works because each side of the equation represents a quantity of solute that does not change because of dilution. Furthermore, this equation can be used for *any* units of volume and concentration if the units used to express the initial and diluted volumes are the same and the units for the initial and diluted concentrations are the same.

Equation 4.4 applies to all systems, even those much larger than a laboratory stock solution to be diluted. In estuaries, for instance, where rivers flow into the sea, seawater is diluted by the freshwater that enters it. Suppose a coastal bay contains 3.8×10^{12} L of ocean water mixed with 1.2×10^{12} L of river water for a total volume of 5.0×10^{12} L. We can calculate the Na^{+} concentration in the bay if the Na^{+} concentration in the open ocean is 0.48 *M* and if we assume that the river water does not contribute significantly to the Na^{+} content in the bay. Using these values to solve Equation 4.4 for M_{diluted}, the Na^{+} concentration in the bay, we have

The bay is less salty than the ocean because it is diluted by the freshwater from the river.

SAMPLE EXERCISE 4.5 Preparing a Dilution LO2

The solution used in hospitals for intravenous infusion—called *physiological saline* or *saline solution*—is 0.155 M in NaCl. It is typically prepared by diluting a stock solution, the concentration of which is 1.76 M, with water. What volume of stock solution and what volume of water are required to prepare 2.00 L of physiological saline?

Collect, Organize, and Analyze We know the volume ($V_{\text{diluted}} = 2.00$ L) and concentration ($M_{\text{diluted}} = 0.155\ M$) of the diluted solution and the concentration of stock solution available ($M_{\text{initial}} = 1.76\ M$). That is, we know three of the four variables in Equation 4.4. We must find V_{initial}, the volume of the stock solution required to make 2.00 L of physiological saline.

Solve Solving Equation 4.4 for V_{initial} and using the values given:

To make 2.00 L of the diluted solution, we need to add: 2.00 L − 0.176 L = 1.82 L of water. If we prepare the dilute solution in a volumetric flask like that in Figure 4.8, rather than add 1.82 L of water, we would add enough water to fill the flask to the mark.

Think About It Because the concentration of the stock solution is about ten times the concentration of the diluted solution, the volume of stock solution required should be about one-tenth the final volume. Our result of 0.176 L of stock solution is reasonable.

Practice Exercise The concentration of Pb^{2+} in a stock solution is 1.000 mg/mL. What volume of this solution should be diluted to 500.0 mL to produce a solution in which the Pb^{2+} concentration is 25.0 mg/L?

(Answers to Practice Exercises are in the back of the book.)

CONCEPT TEST

Why is a stock solution always more concentrated than the solutions made from it?

(Answers to Concept Tests are in the back of the book.)

Determining Concentration

The intensity of the blue color of the Cu^{2+} solution in Figure 4.8 decreases as we dilute the solution. Is there a way of using the intensity of the color to quantify the concentration? The color of the Cu^{2+} solution arises from the absorption of visible light, a topic we explore in more detail in Chapters 7 and 22. For now, it is sufficient to know that the absorbance (A) of a solution is a measure of the intensity of the color. Beer's law (Equation 4.5) relates absorbance to three quantities: concentration (c), the path length that the light travels through the solution (b), and a constant (called the molar absorptivity, or ϵ) characteristic of the dissolved solute.

Absorbance is measured with a spectrophotometer like that shown in **Figure 4.9a**, in which a solution is placed in a sample cell of fixed length b, typically 1.00 cm. The cell is placed in a beam of light (**Figure 4.9b**). The value of A represents how much light is absorbed by the solution. If we express the concentration of the solution, c, in molarity (M), we can calculate ε. A graph of A versus c for solutions of different Cu^{2+} concentration yields a straight line because the amount of light absorbed by a sample is *directly proportional* to the concentration of that sample. Such a graph (**Figure 4.9c**) is called a calibration curve. Once a calibration curve is generated, the concentration of any solution of Cu^{2+} can be determined by measuring its absorbance, finding that value on the y-axis, reading across to where it intersects the calibration curve, and then reading the value on the x-axis below, which is the concentration. We can also use a calibration curve to determine molar absorptivity. If $b = 1.00$ cm, then the slope of the graph is equal to ε in units of $M^{-1}\ \text{cm}^{-1}$. This method of analysis is called *spectrophotometry*. Sample Exercise 4.6 shows how we can apply Beer's law to find the concentration of a solution of iron ions.

SAMPLE EXERCISE 4.6 Applying Beer's Law LO3

One way to determine the concentration of Fe^{2+} in an environmental sample is to add a solution of phenanthroline (phen) molecules that will bond to the metal ions, creating an intensely orange-red solution (**Figure 4.10**). The absorbance of a $5.00 \times 10^{-5}\ M$ solution is measured as 0.55 in a 1.00 cm cell. (a) Calculate the molar absorptivity, e, and (b) determine the concentration of such a solution whose absorbance is 0.36.

Collect and Organize Given the concentration and absorbance of a solution, we are asked to calculate the molar absorptivity (ε).

Analyze (a) We can rearrange Beer's law (Equation 4.5) to solve for ε and then use this value to find the concentration of the unknown solution. (b) Concentration and absorbance are linearly related by Beer's law, so we predict that a smaller absorbance for the unknown solution should correspond to a lower concentration. (In fact, a concentration of zero would correspond to zero absorbance.)

Solve

1. Rearranging Equation 4.5 and substituting for A, b, and c:

$$\varepsilon = \frac{A}{bc} = \frac{0.55}{(1.00\ \text{cm})(5.00 \times 10^{-5}\ M)} = 1.1 \times 10^{4}\ M^{-1}\ \text{cm}^{-1}$$

---

2. Solving Beer's law for concentration and substituting for A, b, and ε:

$$c = \frac{A}{\varepsilon b} = \frac{0.36}{(1.1 \times 10^{4}\ M^{-1} \cdot \cancel{\text{cm}^{-1}})(1.00\ \cancel{\text{cm}})} = 3.3 \times 10^{-5}\ M$$

Think About It As predicted, the concentration of the unknown solution is lower than $5.00 \times 10^{-5}\ M$.

Practice Exercise One analytical method for determining the concentration of copper ions in a sample uses a solution of cuproine molecules to bond to the metal, like the bonds between Fe^{2+} ions and phenanthroline molecules. The following data were collected for four standard solutions of Cu^{2+} with cuproine:

Concentration of Cu^{2+} (M)	Absorbance
1.00×10^{-4}	0.64
1.25×10^{-4}	0.80
1.50×10^{-4}	0.96
1.75×10^{-4}	1.12

Construct a calibration curve based on these data and use it to determine the concentration of a copper solution with an absorbance $A = 0.74$.

(Answers to Practice Exercises are in the back of the book.)

Glossary

stock solution
: a concentrated solution of a substance used to prepare solutions of lower concentration.

dilution
: the process of lowering the concentration of a solution by adding more solvent.

absorbance (A)
: a measure of the quantity of light absorbed by a sample.

Beer's law
: the relation of the absorbance of a solution (A) to concentration (c), the light's path length (b), and the solute's molar absorptivity (ε) by the equation $A = \varepsilon bc$.

molar absorptivity (ϵ)
: a measure of how well a compound or ion absorbs light.

calibration curve

a graph showing how a measurable property, such as absorbance, varies for a set of standard samples of known concentration that can later be used to determine the unknown concentration of a sample from its absorbance.

Learning Objectives

- Calculate the mass of a solute or the volume of a highly concentrated solution required to make a solution of specified volume and concentration **Return to Sample Exercises 4.4, 4.5**
- Use Beer’s law and absorbance data to determine the concentration of an unknown solution **Return to Sample Exercise 4.6**

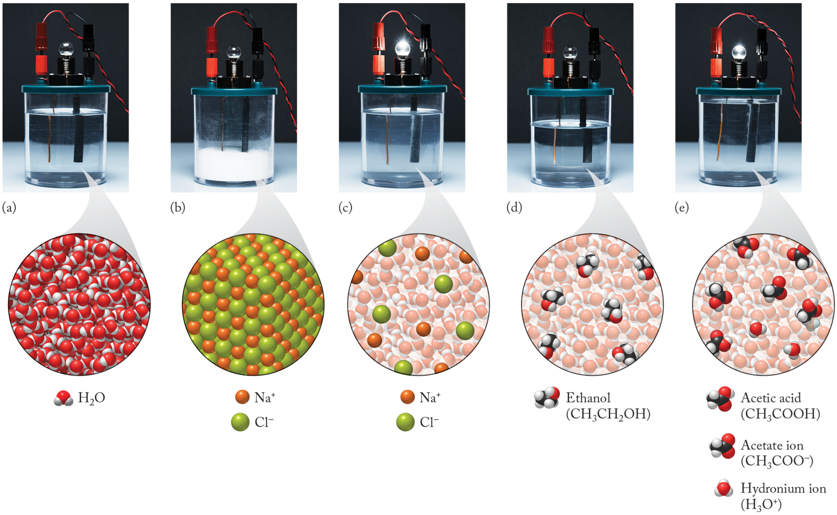

FIGURE 4.11 (a) The unlit light bulb indicates that pure water (H_2O) conducts electricity very poorly; because water is a molecular material, it contains very few ions. (b) The unlit light bulb indicates that solid sodium chloride (NaCl) does not conduct electricity. (c) The brightly lit bulb indicates that a 0.50 *M* solution of NaCl conducts electricity very well. (d) The unlit bulb indicates that a 0.50 *M* solution of ethanol (CH_3CH_2OH) does not conduct electricity any better than pure water. (e) The dimly lit bulb indicates that a 0.50 *M* solution of acetic acid (CH_3COOH) conducts electricity better than pure water or the ethanol solution, but not as well as the NaCl solution.

4.4 Electrolytes and Nonelectrolytes

The high concentrations of NaCl and other salts in seawater (Table 4.1) make it a good conductor of electricity. Suppose we immerse two *electrodes* (solid conductors) in distilled water (**Figure 4.11a**) and connect them to a battery and a light bulb. For electricity to flow and the bulb to light up, the circuit must be completed by mobile charge carriers (ions) in the solution. The light bulb does not light when the electrodes are placed in distilled water because there are very few ions in distilled water. When the electrodes are pressed into solid NaCl (**Figure 4.11b**), no electric current flows and the bulb does not light because the Na^+ and Cl^- ions in solid NaCl are fixed in position. However, when the electrodes are immersed in aqueous 0.50 *M* NaCl (**Figure 4.11c**), the bulb lights because the many mobile ions in the solution act as charge carriers between the two electrodes. The saline solution conducts electricity because Na^+ ions are attracted to and migrate toward the electrode connected to the negative terminal of the battery, and Cl^- ions are attracted to and migrate toward the positive electrode, completing an electric circuit.

Ions in Solution

Any solute that imparts electrical conductivity to an aqueous solution is called an electrolyte. Sodium chloride is categorized as a strong electrolyte because it *dissociates* completely in water, which means it completely breaks up into its component ions when it dissolves, releasing charge-carrying Na^+ cations and Cl^- anions.

Other substances, however, do *not* dissociate when dissolved in water. For instance, a 0.50 *M* solution of ethanol (CH_3CH_2OH) conducts electricity no better than pure water because each CH_3CH_2OH molecule remains intact in the solution and no ions are formed (**Figure 4.11d**). Solutes that do not form ions when dissolved in water are called nonelectrolytes.

In addition to strong electrolytes (complete dissociation into ions) and nonelectrolytes (no dissociation), there are weak electrolytes. Only a small fraction of a weak electrolyte's molecules dissociates into ions. Instead, most of them remain intact as whole, neutral molecules. One example of a weak electrolyte is acetic acid (CH_3COOH). In **Figure 4.11e**, the beaker contains a 0.50 *M* aqueous solution of acetic acid. The molarity of the solution in part (e) is equivalent to that in parts (c) and (d) of the figure, meaning that the same number of moles of acetic acid were dissolved as the number of moles of NaCl or moles of CH_3CH_2OH. Because the bulb connected to the acetic acid solution glows, but not very brightly, we can conclude that there are some ions present, but not as many as are present in the 0.50 *M* NaCl solution (Figure 4.11c). The acetic acid molecules dissociate to some extent, forming hydronium ions and acetate ions, but the process does not go to completion:

$$CH_3COOH(aq) + H_2O(\ell) \rightleftharpoons CH_3COO^-(aq) + H_3O^+(aq)$$

In this case, the arrow with the top half pointing right and the bottom half pointing left indicates that all species (the reactant and both products) are simultaneously present in solution: undissociated CH_3COOH molecules, acetate ions, and hydrogen ions. This type of arrow is used to indicate that the dissociation process is incomplete. It is important to understand that dissolving and dissociating are two different processes. All the acetic acid molecules dissolve in water, but only a tiny fraction of them dissociate into ions. A balance, called a *dynamic equilibrium,* is achieved in solutions of weak electrolytes, at which point the net concentrations of the reactants and the products in the dissociation reaction do not change. Solutions of weak electrolytes, such as weak acids, consist of dissociated ions and undissociated molecules existing together in dynamic equilibrium. For this reason, the arrow used above is called an *equilibrium arrow.*

CONCEPT TEST

Why were equivalent molar concentrations used in the solutions in Figure 4.11?

(Answers to Concept Tests are in the back of the book.)

Glossary

electrolyte	a substance that dissociates into ions when it dissolves in water, enhancing the conductivity of the solvent.
strong electrolyte	a substance that dissociates completely into ions when it dissolves in water.

nonelectrolyte

a substance that does *not* dissociate into ions and therefore does *not* result in conductivity when dissolved in water.

weak electrolyte

a substance that dissolves in water with most molecules staying intact, but with a small fraction dissociating into ions.

4.5 Acid–Base Reactions: Proton Transfer

Although the behavior of acetic acid molecules when dissolved in water is best described as a dynamic equilibrium, not all acids are weak electrolytes. Pure HCl is a molecular compound (called hydrogen chloride) and a gas. When HCl dissolves in water, however, it ionizes completely, producing $H_3O^+(aq)$ and $Cl^-(aq)$. This solution is called hydrochloric acid.

CONCEPT TEST

Which drawing in **Figure 4.12** depicts the particles in an aqueous solution of an acid that is a weak electrolyte, and which drawing depicts the particles in an aqueous solution of an acid that is a strong electrolyte? [The solvent molecules (water) have been omitted.]

(Answers to Concept Tests are in the back of the book.)

CONNECTION We discussed the naming of acids in Section 2.7.

As a molecule of HCl dissolves, it donates a proton (H^+ ion) to a water molecule:

This behavior is consistent with our definition of an acid as a *proton donor*. The water molecule accepts the proton, so water in this case is a *proton acceptor*, which is the corresponding definition of a base. These definitions were originally proposed by chemists Johannes Brønsted (1879–1947) and Thomas Lowry (1874–1936), so they are called Brønsted–Lowry acids and Brønsted–Lowry bases. We develop this concept of proton transfer more completely in Chapter 15, but for now it provides a convenient way to define acids and bases in aqueous solutions.

We often use $H^+(aq)$ to represent the cation produced in aqueous solution by an acid. Hydrogen ions do not have an independent existence in water, however, because each proton combines with a water molecule to form a hydronium ion (H_3O^+):

$$H^+(aq) + H_2O(\ell) \rightarrow H_3O^+(aq)$$

In aqueous acid–base chemistry, the terms hydrogen ion, proton, and hydronium ion all refer to the same species.

In the reaction between aqueous solutions of HCl and NaOH,

the HCl functions as an acid by donating a proton to the hydroxide ion, and the hydroxide ion functions as a base by accepting the proton; the H^+ and OH^- ions combine to form a molecule of water. The remaining two ions—the anion Cl^- and the cation Na^+—form a salt, sodium chloride, which remains dissolved and dissociated in the aqueous solution. This reaction is called a neutralization reaction because the acid and the base no longer exist as a result of the reaction. The products of the neutralization of an acid like HCl with a base like NaOH in solution are always water and a salt. A salt is a substance formed along with water as a product of a neutralization reaction.

Equation 4.7 is written as a molecular equation, meaning each reactant and product is written as a neutral compound. Balanced molecular equations are sometimes the easiest equations to write, so reactions involving substances that dissociate in solution are often written first as molecular equations.

Another equation representing the reaction in Equation 4.7 is one that shows the reactants and products as the particles that exist in solution, which means that any substance that dissociates completely is written as individual ions:

This form, called an overall ionic equation, distinguishes soluble ionic substances from molecular substances in a chemical reaction taking place in solution. Any nonelectrolytes or weak electrolytes are written as neutral molecules.

Notice in Equation 4.8 that chloride ions and sodium ions appear on both sides of the reaction arrow. If this were an algebraic equation, we would remove the terms that are the same on both sides. When we do the same thing in chemistry, the result is a net ionic equation (Equation 4.9). The ions that are removed (in this case, sodium ion and chloride ion) are called spectator ions, and the resulting equation shows only the species taking part in the reaction:

The spectator ions are unchanged by the reaction and remain in solution. The chemical change in a neutralization reaction occurs when a hydrogen ion reacts with a hydroxide ion to produce a molecule of water. The net ionic equation enables us to focus on those species that participate in the reaction. The three ways of depicting the reaction between HCl and NaOH—molecular, overall ionic, and net ionic equations—are summarized in **Figure 4.13**.

SAMPLE EXERCISE 4.7 Writing Neutralization Reaction Equations LO4

Write (a) molecular, (b) overall ionic, and (c) net ionic equations that describe the reaction that takes place when an aqueous solution of nitric acid is neutralized by an aqueous solution of calcium hydroxide.

Collect and Organize Solutions of nitric acid and calcium hydroxide take part in a neutralization reaction. Our task is to write three different equations describing the neutralization reaction.

Analyze We know that calcium hydroxide [$Ca(OH)_2$] is the base and nitric acid (HNO_3) is the acid. The products of a neutralization reaction are water and a salt. (a) All species are written as neutral compounds in the molecular equation. The products are water and calcium nitrate, the salt made from the cation of the base and the anion of the acid. (b) Writing each substance in the balanced molecular equation in terms of the ions it forms when it dissolves in water produces the overall ionic equation. (c) Removing spectator ions from the overall ionic equation yields the net ionic equation.

Solve

1. The molecular equation is

$$HNO_3(aq) + Ca(OH)_2(aq) \rightarrow Ca(NO_3)_2(aq) + H_2O(\ell) \qquad \text{(unbalanced)}$$

$$2\ HNO_3(aq) + Ca(OH)_2(aq) \rightarrow Ca(NO_3)_2(aq) + 2\ H_2O(\ell) \qquad \text{(balanced)}$$

2. The overall ionic equation is

$$2\ H^+(aq) + 2\ NO_3^-(aq) + Ca^{2+}(aq) + 2\ OH^-(aq) \rightarrow Ca^{2+}(aq) + 2\ NO_3^-(aq) + 2\ H_2O(\ell)$$

3. The spectator ions are Ca^{2+} and NO_3^-. Removing them gives us the net ionic equation:

$$2\ H^+(aq) + 2\ OH^-(aq) \rightarrow 2\ H_2O(\ell)$$

or

$$H^+(aq) + OH^-(aq) \rightarrow H_2O(\ell)$$

Think About It Both reactants are soluble compounds that form ions in aqueous solutions. Of these ions, only the H^+ ions formed by HNO_3 and the OH^- ions from $Ca(OH)_2$ are no longer ions on the product side, but rather molecules of H_2O. Therefore, it is reasonable that these are the only species in the net ionic equation describing the reaction.

Practice Exercise Write (a) molecular, (b) overall ionic, and (c) net ionic equations for the reaction between an aqueous solution of acetic acid, $CH_3COOH(aq)$, and an aqueous solution of sodium hydroxide. The products are sodium acetate and water. *Note*: Acetic acid is a weak electrolyte.

(Answers to Practice Exercises are in the back of the book.)

For billions of years, neutralization reactions have played key roles in the chemical transformations of Earth's crust that geologists call *chemical weathering*. One type of chemical weathering occurs when carbon dioxide in the atmosphere dissolves in rainwater to create a weakly acidic solution of carbonic acid, $H_2CO_3(aq)$. This solution reacts with calcium carbonate, which occurs as chalk, limestone, and marble, and is only slightly soluble in pure water. The reaction between carbonic acid and calcium carbonate is responsible for the formation of stalactites and stalagmites (**Figure 4.14**). Chemical weathering caused by even more acidic rain is responsible for the degradation of statues and the exteriors of buildings made of marble (**Figure 4.15**). The rain that falls in many regions of North America and Europe contains dilute sulfuric acid, which reacts with structures made of marble and limestone (forms of calcium carbonate, $CaCO_3$) forming calcium sulfate $CaSO_4$, which is more soluble in water than calcium carbonate.

Table 4.2 lists some common nonmetal oxides that are classified as atmospheric pollutants because they produce acid rain.

Nonmetal oxides other than carbon dioxide form solutions that are much more acidic than carbonic acid. Dinitrogen pentoxide, for example, forms nitric acid in water in a hydrolysis reaction.

$$N_2O_5(g) + H_2O(\ell) \rightarrow 2\ HNO_3(aq)$$

Similarly, sulfur trioxide forms sulfuric acid:

$$SO_3(g) + H_2O(\ell) \rightarrow H_2SO_4(aq)$$

Nitric acid and sulfuric acid are categorized as strong acids because they dissociate completely in water.

$$H_2O(\ell) + HNO_3(aq) \rightarrow H_3O^+(aq) + NO_3^-(aq)$$

$$H_2O(\ell) + H_2SO_4(aq) \rightarrow H_3O^+(aq) + HSO_4^-(aq)$$

They are listed in **Table 4.3** along with other common strong acids. Strong acids are strong electrolytes. The arrows in the ball-and-stick figures of the acids point to the bonds that ionize in solution to produce protons. Because one molecule of nitric acid donates one proton, nitric acid is called a *monoprotic acid*. Hydrochloric acid is another strong monoprotic acid. Sulfuric acid can donate up to two protons per molecule, which makes it a *diprotic acid*. In some H_2SO_4 solutions, however, only one of the two H atoms in each molecule ionizes. Sulfuric acid, then, is a strong acid when it comes to donating the first proton. This dissociation results in the formation of the HSO_4^- ion (hydrogen sulfate), which is also an acid because HSO_4^- ions can dissociate in solution into H^+ and SO_4^{2-} ions. Not all HSO_4^- ions may dissociate, however, so the hydrogen sulfate anion is a weak acid—that is, it is an acid in which only a small fraction of all the ions dissociate in water. Acetic acid, the weak electrolyte shown previously in Figure 4.11e, is a weak acid, too.

TABLE 4.2 Volatile Nonmetal Oxides and Their Acids

Oxide	Acid
SO_2	H_2SO_3
SO_3	H_2SO_4
NO_2	HNO_2, HNO_3
N_2O_5	HNO_3
CO_2	H_2CO_3

The two equations for the dissociation of the two protons of sulfuric acid are written differently to reflect these different dissociation behaviors. First, the complete dissociation of the strong acid H_2SO_4:

$$H_2O(\ell) + H_2SO_4(aq) \rightarrow H_3O^+(aq) + HSO_4^-(aq)$$

Second, the dynamic equilibrium and partial dissociation of the weak acid HSO_4^-:

$$H_2O(\ell) + HSO_4^-(aq) \rightleftharpoons H_3O^+(aq) + SO_4^{2-}(aq)$$

TABLE 4.3 Strong Acids

Acid	Formula	Molecule(s)	Ionization in Solution
Hydrochloric acid	HCl		
Hydrobromic acid	HBr		
Hydroiodic acid	HI		
Nitric acid[a]	HNO_3		
Sulfuric acid	H_2SO_4		

		Perchloric acid	$HClO_4$	
Beyond the strong acids listed in Table 4.3, nearly all other acids are weak acids, even if they are *polyprotic acids* such as carbonic acid (H_2CO_3) or phosphoric acid (H_3PO_4). For any diprotic acid, the HX^- anion formed when the first proton dissociates is a weaker acid than the original acid H_2X. This pattern applies to triprotic acids (H_3X) as well. Thus, H_3X is a stronger acid than H_2X^-, and H_2X^- is a stronger acid than HX^{2-}.

Acetic acid (CH_3COOH) is a member of a large group of organic compounds called carboxylic acids because they all contain the –COOH group in their structures. All carboxylic acids, not just acetic acid, are weak acids and hence dissociate only partially in water.

CONCEPT TEST

A molecule called EDTA has four carboxylic acid groups and hence four acidic protons. We can symbolize it as H_4E to highlight this property. Pick the more acidic member of each pair listed: (a) H_2E^{2-} or HE^{3-}; (b) H_4E or H_3E^-.

(Answers to Concept Tests are in the back of the book.)

As with acids, bases are classified as strong or weak depending on the extent to which they dissociate or hydrolyze in aqueous solution. Strong bases are strong electrolytes that dissociate completely, whereas weak bases are weak electrolytes. Strong bases include the hydroxides of group 1 and group 2 metals, which dissociate completely when dissolved in water.

Although substances such as $NaOH(aq)$ and $Ca(OH)_2(aq)$ can be considered bases because they produce hydroxide ions in aqueous solution, Brønsted–Lowry bases are proton acceptors. Hydroxide ions are bases because they can accept protons. This definition permits other substances that do not consist of hydroxide ions to be categorized as bases as well.

Ammonia (NH_3), for example, is a weak base, even though it does not contain hydroxide ions. Ammonia in its molecular form is a gas at room temperature. When NH_3 dissolves in water it produces a solution that conducts electricity weakly, which means that ammonia is a weak electrolyte:

Ammonia is an inorganic molecule, but it can be viewed as the parent in a family of organic molecules that are typically weak bases. These compounds are called amines, and they are characterized by having one or more of the hydrogen atoms in NH_3 replaced by an organic group. We deal with the structure of ammonia in Chapters 8 and 9, but for now you need only to recognize amines as weak bases. They all behave similarly to ammonia in water by accepting a proton from the water molecule and producing a hydroxide ion in solution. The simplest member of this family is methylamine: CH_3NH_2. Because amines are weak bases, only a small fraction of the molecules accept protons in an aqueous solution; this behavior is indicated by an equilibrium arrow, just as we used with ammonia:

$$CH_3NH_2(g) + H_2O(\ell) \rightleftharpoons CH_3NH_3^+(aq) + OH^-(aq)$$

If a second or third hydrogen atom in NH_3 is replaced, whether by the same or different organic group, the compound still behaves as a weak base. For example, dimethyl amine, $(CH_3)_2NH$, contains one nitrogen atom with two CH_3 groups and one hydrogen atom bonded to it. Trimethyl amine has three CH_3 groups (and no hydrogen atoms) bonded to the central nitrogen atom: $(CH_3)_3N$. The most general way of describing amines is to use the symbol R for any organic group. Then the three general types of amines may be symbolized as RNH_2, R_2NH, and R_3N.

Finally, some substances, such as water, can behave as either acids or bases, depending on what other substances are in solution. Water is called an amphiprotic substance because it can function as a proton acceptor (Brønsted–Lowry base) in solutions containing acid solutes or as a proton donor (Brønsted–Lowry acid) in solutions containing basic solutes. In the hydrolysis of HCl (Equation 4.6), water functions as a base; in the hydrolysis of NH_3 (Equation 4.11), water functions as an acid.

CONCEPT TEST

Identify the following compounds as acids or bases or neither in water. If the compound is an acid or base, identify it as weak or strong. (a) CH_3CH_2COOH; (b) CH_3OH; (c) $(CH_3CH_2)_2NH$; (d) HNO_3

(Answers to Concept Tests are in the back of the book.)

SAMPLE EXERCISE 4.8 Comparing Electrolytes, Acids, and Bases LO5

Classify each of the following compounds in aqueous solution as a strong electrolyte, a weak electrolyte, or a nonelectrolyte; and then again as an acid, a base, or neither an acid nor a base: (a) NaCl; (b) HCl; (c) NaOH; (d) CH_3COOH; (e) $CH_3CH_2NH_2$.

Collect, Organize, and Analyze We are given the formulas of five compounds and asked to classify them based on their behavior in an aqueous solution.

Strong electrolytes are substances that dissociate completely into ions when dissolved in water. Weak electrolytes dissociate only partially in water. Nonelectrolytes do not dissociate at all. A Brønsted–Lowry acid is defined as a proton donor, whereas a Brønsted–Lowry base is a proton acceptor. Structures with a –COOH group are weak acids, whereas compounds containing an amine group, –NH_2, are weak bases.

Solve

1. NaCl is an ionic compound that dissociates completely into ions in aqueous solution, as shown in Figure 4.11c. Therefore, NaCl is a strong electrolyte. Sodium chloride has no protons to donate, and neither Na^+ nor Cl^- ions readily accept protons, so NaCl is neither an acid nor a base.
2. HCl dissociates completely into H^+ and Cl^- ions when dissolved in water, making HCl a strong electrolyte. Aqueous HCl is a proton donor, so it is also a Brønsted–Lowry acid.
3. NaOH is an ionic compound that dissociates completely into Na^+ and OH^- ions in aqueous solution. NaOH is a strong electrolyte. The OH^- ion formed upon dissolution of NaOH readily accepts a proton to form water, making NaOH a Brønsted–Lowry base.
4. Some molecules of acetic acid, CH_3COOH, when dissolved in water, dissociate into H^+ and CH_3COO^- ions (Figure 4.11e), creating a weakly conducting solution; thus, CH_3COOH is a weak electrolyte. Since acetic acid is a proton donor, it is a Brønsted–Lowry acid.
5. Some molecules of $CH_3CH_2NH_2$ function as proton acceptors when dissolved in water (which functions as a proton donor) to form $CH_3CH_2NH_2^+$ ions, creating a weakly conducting solution. Therefore, $CH_3CH_2NH_2$ is both a weak electrolyte and a Brønsted–Lowry base.

Think About It Strong acids and bases are also strong electrolytes, and weak acids and bases are weak electrolytes. However some strong electrolytes are neither acidic nor basic, but instead are neutral compounds.

Practice Exercise Classify aqueous solutions of each of the following compounds as a strong electrolyte, weak electrolyte, or nonelectrolyte; and as an acid, a base, or neither: (a) potassium sulfate; (b) HBr; (c) NH_3; (d) ethanol (CH_3CH_2OH).

(Answers to Practice Exercises are in the back of the book.)

Glossary

acid (Brønsted–Lowry acid)
a proton donor.

base (Brønsted–Lowry base)
a proton acceptor.

acid (Brønsted–Lowry acid)
a proton donor.

base (Brønsted–Lowry base)
a proton acceptor.

neutralization reaction
a reaction that takes place when an acid reacts with a base and produces a solution of a salt in water.

salt
the product of a neutralization reaction; it is made up of the cation of the base in the reaction plus the anion of the acid.

molecular equation
an equation describing a reaction in solution in which the reactants and products are written as neutral compounds.

overall ionic equation
an equation describing a reaction in solution that shows all the species, both ionic and molecular, present in the reaction mixture.

net ionic equation
an equation describing a reaction in solution that contains only the species changed by the reaction; it is obtained by eliminating the spectator ions from the overall ionic equation.

spectator ion
an ion present in a reaction mixture in solution that is unchanged by the reaction; spectator ions appear in overall ionic equations but not in net ionic equations.

hydrolysis
the reaction of water with another material. The hydrolysis of nonmetal oxides produces acids.

strong acid

an acid that completely dissociates into ions in aqueous solution.

weak acid

an acid that is a weak electrolyte and so has a limited capacity to donate protons to the medium.

carboxylic acid

an organic compound containing the –COOH group.

strong base

a base that completely dissociates into ions in aqueous solution.

weak base

a base that is a weak electrolyte and so has a limited capacity to accept protons.

amine

an organic compound that functions as a base and has the general formula RNH_2, R_2NH, or R_3N, where R is any organic group.

amphiprotic

describes a substance that can behave as either a proton acceptor or a proton donor.

Learning Objectives

- Write molecular, overall ionic, and net ionic equations for reactions in aqueous solution **Return to Sample Exercises 4.7, 4.10, 4.11, 4.12**
- Classify substances as soluble or only slightly soluble in aqueous solution and identify strong electrolytes, weak electrolytes, nonelectrolytes, and Brønsted–Lowry acids and bases based on their properties **Return to Sample Exercise 4.8**

Endnotes

- The dashed bonds in the model of nitric acid indicate bonds that are part single bond and part double bond in character. We discuss that phenomenon in detail in Chapter 8.Return to reference a

4.6 Titrations

We can use the reactions of acids and bases to analyze solutions and determine the concentrations of dissolved substances. A technique called titration is a common analytical method based on measured volumes of reactants. Acid–base neutralization reactions are frequently the basis of analyses done by titration.

One use of titrations is to analyze water draining from abandoned coal mines. Sulfide-containing minerals called pyrites may be exposed when coal is removed from a site. The ensuing reaction between the minerals and microorganisms in the presence of oxygen produces very acidic solutions of sulfuric acid. To manage these hazardous wastes appropriately, we must know the concentrations of acid present in them. Titrations give us this information.

Suppose we have 100.0 mL of drainage water containing an unknown concentration of sulfuric acid. We can use an acid–base titration in which the sulfuric acid in the water sample is neutralized by reaction with a standard solution of 0.00100 M NaOH. The NaOH solution in this case is called the titrant; it is a standard solution, meaning its concentration is known accurately. The neutralization reaction is

$$H_2SO_4(aq) + 2\ NaOH(aq) \rightarrow Na_2SO_4(aq) + 2\ H_2O(\ell)$$

To determine the concentration of sulfuric acid in the sample, we determine the volume of titrant needed to neutralize a known volume of the sample.

Suppose 22.40 mL of the NaOH solution is required to react completely with the H_2SO_4 in the sample. Because we know the volume and molarity of the NaOH solution, we can calculate the number of moles of NaOH reacted:

We know from the stoichiometry of the reaction that 2 moles of NaOH are required to neutralize 1 mole of H_2SO_4, so the number of moles of H_2SO_4 in the 100.0 mL sample must be

We can combine these two steps into one mathematical expression and do so throughout the rest of the text:

Therefore, the concentration of H_2SO_4 is

Couldn’t we have used Equation 4.4 (i.e., $V_{\text{initial}}M_{\text{initial}} = V_{\text{diluted}}M_{\text{diluted}}$) to solve for the molarity of sulfuric acid given that we knew both the concentration and the volume of the sodium hydroxide solution in addition to the volume of sulfuric acid solution? That may seem possible because Equation 4.4 can be rearranged to solve for a volume when given another volume and two concentrations, but that equation applies only to situations in which the moles of solute remain unchanged as more solvent is added to dilute the solution. In the problem we just worked, we do not have one solution that is diluted but rather a reaction that occurs when two aqueous solutions are mixed together.

How did we determine in the first place that exactly 22.40 mL of the NaOH solution was needed to react with the sulfuric acid in the sample? The glassware required to perform an acid–base titration is illustrated in **Figure 4.16**. The standard solution of NaOH is poured into a *buret*, a narrow glass cylinder with volume markings. The solution is gradually added to the sample until the point in the titration when just enough standard solution has been added to completely react with all the solute in the sample. This is called the equivalence point of the titration.

How do we know when the equivalence point has been reached? Chemists add a small amount of indicator solution to the sample before it is titrated. Indicator solutions contain molecules that change color as the concentration of $H^+(aq)$ ions changes. To detect the end point in our sulfuric acid–sodium hydroxide titration, we might use the indicator *phenolphthalein*, which is colorless in acidic solutions but pink in basic solutions. If the correct indicator has been chosen, the equivalence point is very close to the end point, the point at which the indicator changes color. The part of the titration that requires the most skill is adding just enough NaOH solution to reach the end point, the point at which a pink color first persists in the solution being titrated. To catch this end point precisely, one must add the standard solution no faster than one drop at a time with thorough mixing between drops.

Titration is an effective method for determining solution concentrations; however, it is not applicable in all situations. We have already seen in Section 4.3 how spectrophotometry can be used to determine concentration. We explore yet another method in Section 4.7.

SAMPLE EXERCISE 4.9 Calculating Molarity from Titration Data LO6

Vinegar is an aqueous solution of acetic acid (CH_3COOH) that can be made from any source containing starch or sugar. Apple cider vinegar is made from apple juice that is fermented to produce alcohol, which then reacts with oxygen from the air in the presence of certain bacteria to produce vinegar. Commercial vinegar must contain no less than 4% acetic acid—that is, no fewer than 4 grams of acetic acid per 100 mL of vinegar. Suppose the titration of a 25.00 mL sample of vinegar requires 11.20 mL of a 5.95 *M* solution of NaOH. What is the molarity of the vinegar? Could this be a commercial sample of vinegar?

Collect, Organize, and Analyze We are given the volume and concentration of the titrant and the volume of the sample, and we are asked to calculate the concentration of the sample. We start with the chemical equation for the neutralization reaction:

$$CH_3COOH(aq) + NaOH(aq) \rightarrow CH_3COONa(aq) + H_2O(\ell)$$

The following sequence allows us to calculate the molarity of the acetic acid in the sample, from which we can calculate the grams of acetic acid per 100 mL and determine if the sample could be commercial-grade vinegar.

Solve The stoichiometry of the titration reaction is 1 mol NaOH per mol CH_3COOH. Therefore, number of moles of acetic acid in the sample is

and its concentration is

The number of grams of acetic acid in the sample is

The original sample had a volume of 25.00 mL, so the mass of acetic acid per 100 mL of sample is

At 16.0 g/100 mL, or 16%, acetic acid, the sample has more than enough of the acid to qualify as a commercial vinegar.

Think About It About 11 mL of titrant were needed to neutralize the sample. That is about half the volume of the sample, so the calculated molarity of the vinegar should be about half that of the titrant, which it is. Vinegar this concentrated is typically used for pickling. Table vinegar is usually between 4% and 8% acetic acid.

Practice Exercise Citric acid ($C_6H_8O_7$; **Figure 4.17**), a weak triprotic acid found in lemon juice, is widely used as a flavoring in beverages. What is the molarity of citric acid in commercially available lemon juice if 14.26 mL of 1.751 *M* NaOH is required in a titration to neutralize 20.00 mL of the juice? How many grams of citric acid are in 100.0 mL of the juice?

(Answers to Practice Exercises are in the back of the book.)

SAMPLE EXERCISE 4.10 Using Titration Data to Calculate the Purity of a Sample LO4, LO6

The over-the-counter antacid shown in **Figure 4.18**, contains sodium bicarbonate, which neutralizes excess stomach acid (aqueous HCl). A sample that contains a 650 mg tablet of the antacid dissolved in 25.00 mL of water required 25.27 mL of a 0.3000 *M* solution of HCl to be neutralized. (a) Write a net ionic equation for the reaction between $NaHCO_3$ and HCl. (b) What is the molarity of the antacid solution? (c) Is the tablet pure $NaHCO_3$?

Collect and Organize We are assigned three tasks in this sample exercise. We are given the names of the reactants and asked to write a net ionic equation. We are given the volume and concentration of the titrant and the volume of the sample and asked to calculate the concentration of the solution. Finally, using the results of our calculations, we are asked to assess the purity of the sample.

Analyze (a) The products of the reaction between $NaHCO_3$ and HCl are sodium chloride, water, and carbon dioxide. We need to write a molecular equation and, from that, write overall ionic and net ionic equations. (b) The steps involved in calculating the molarity of the sodium bicarbonate solution (not including liter–milliliter conversions) are

---

(c) The purity of the tablet can be determined by converting the number of moles of $NaHCO_3$ calculated in part (b) into an equivalent number of grams,

---

and comparing the result with the mass of the tablet (650 mg).

Solve

1. The molecular equation for the neutralization reaction is

$$NaHCO_3(aq) + HCl(aq) \rightarrow H_2O(\ell) + CO_2(g) + NaCl(aq)$$

The ionic equation is

$Na^+(aq) + HCO_3^-(aq) + H^+(aq) + Cl^-(aq) \rightarrow H_2O(\ell) + CO_2(g) + Na^+(aq) + Cl^-(aq)$

and the net ionic equation is

$$\cancel{Na^+(aq)} + HCO_3^-(aq) + H^+(aq) + \cancel{Cl^-(aq)} \rightarrow H_2O(\ell) + CO_2(g) + \cancel{Na^+(aq)} + \cancel{Cl^-(aq)}$$
$$HCO_3^-(aq) + H^+(aq) \rightarrow H_2O(\ell) + CO_2(g)$$

2. The number of moles of $NaHCO_3$ in the sample is

$$\begin{aligned} n_{NaHCO_3} &= 0.02527\ \cancel{\text{L HCl}} \times \frac{0.3000\ \cancel{\text{mol HCl}}}{1\ \cancel{\text{L HCl}}} \times \frac{1\ \text{mol NaHCO}_3}{1\ \cancel{\text{mol HCl}}} \\ &= 0.007581\ \text{mol NaHCO}_3 \end{aligned}$$

and the concentration of the HCO_3^- ion is

$$[HCO_3^-] = \frac{0.007581\ \text{mol NaHCO}_3}{0.02500\ \text{L solution}} = 0.3032\ \text{M NaHCO}_3$$

3. To calculate the mass of $NaHCO_3$ in the sample, we first must calculate its molar mass:

$\mathscr{M}_{NaHCO3} = 22.99\ \text{g/mol} + 1.008\ \text{g/mol} + 12.01\ \text{g/mol} + 3(16.00\ \text{g/mol})$

5 84.01 g/mol $NaHCO_3$

and then the mass of sodium bicarbonate in the tablet:

$$m_{NaHCO_3} = 0.007581\ \cancel{\text{mol NaHCO}_3} \times \frac{84.01\ \text{g NaHCO}_3}{1\ \cancel{\text{mol NaHCO}_3}} = 0.637\ \text{g} = 637\ \text{mg NaHCO}_3$$

This mass is slightly less than the mass of the tablet (650 mg), which indicates that the tablet was not pure $NaHCO_3$.

Think About It The experimentally determined mass of $NaHCO_3$ in the tablet corresponded to 637/650 or 98% of the mass of the tablet. The experimental results may mean that the tablet was not pure $NaHCO_3$, though analytical error is another possibility. Additional titrations are needed to assess the variability in the results, and carefully prepared standard solutions should be titrated to assess accuracy.

Practice Exercise What is the molarity of calcium bicarbonate if 9.870 mL of 1.000 *M* HNO_3 is required in a titration to neutralize 50.00 mL of a solution of $Ca(HCO_3)_2$?

(Answers to Practice Exercises are in the back of the book.)

Glossary

titration

an analytical method for determining the concentration of a solute in a sample by reacting the solute with a standard solution of known concentration.

titrant

the standard solution added to the sample in a titration.

standard solution

a solution of known concentration used in titrations.

equivalence point

the point in a titration at which just enough titrant has been added to completely react the substance being analyzed.

end point

the point in a titration that is reached when just enough standard solution has been added to cause the indicator to change color.

4.7 Precipitation Reactions

Some of the most abundant elements in Earth's crust, including silicon (Si), aluminum (Al), and iron (Fe), are not abundant in seawater for the simple reason that most compounds containing these elements are only slightly soluble in water. Earth's crust must be made of compounds with limited water solubility, or else they would never survive as solids in the presence of all the water on our planet. The reasons why some compounds don't readily dissolve in water whereas others do involve many factors. For now, we will rely on the solubility guidelines in **Table 4.4**, which allow us to predict the solubility of common ionic compounds. *Soluble* and *slightly soluble* are qualitative terms. In principle, all ionic compounds dissolve in water to some extent. When ionic compounds dissolve in water, they do so by dissociating into ions.

In practice, we consider a compound to be only slightly soluble in water if the maximum amount that dissolves gives a concentration of less than 0.01 *M*.

TABLE 4.4 Solubility Guidelines for Ionic Compounds in Water

All compounds containing the following ions are soluble: • Cations: Group 1 ions (alkali metals) and NH_4^+ • Anions: NO_3^- and CH_3COO^- (acetate)
Compounds containing the following anions are soluble except as noted: • Cl^-, Br^-, and I^-, except those of Ag^+, Cu^+, Hg_2^{2+}, and Pb^{2+} • SO_4^{2-}, except those of Ba^{2+}, Ca^{2+}, Hg_2^{2+}, Pb^{2+}, and Sr^{2+}
The following compounds are only slightly soluble: • All hydroxides except those of group 1 cations and $Ca(OH)_2$, $Sr(OH)_2$, and $Ba(OH)_2$ • All sulfides except those of group 1 cations and NH_4^+, CaS, SrS, and BaS • All carbonates except those of group 1 cations and NH_4^+ • All phosphates except those of group 1 cations and NH_4^+ • Most fluorides, though not those of group 1 cations and NH_4^+

Precipitate Formation

In Section 4.5, we examined what happens in neutralization reactions such as the addition of aqueous sulfuric acid to aqueous barium hydroxide. When this reaction occurs (**Figure 4.19**), however, a white solid called a precipitate forms at the bottom of the beaker. Such reactions are called precipitation reactions.

We can use Table 4.4 to determine whether a precipitate forms when solutions of ionic solutes are mixed together. For example, does a precipitate form when aqueous solutions of potassium nitrate (KNO_3) and sodium iodide (NaI) are mixed? To answer this question we need to follow two steps:

1. *Recognize that both salts are in solution, which means that they are both soluble in water and therefore have dissociated into their respective cations and anions*. Table 4.4 specifies that all compounds containing cations from group 1 in the periodic table are soluble in water. Potassium and sodium are in group 1, so salts containing them are soluble and dissociate in water into their ions:

    - Solution 1 consists of potassium ions and nitrate ions: $K^+(aq)$ and $NO_3^-(aq)$
    - Solution 2 consists of sodium ions and iodide ions: $Na^+(aq)$ and $I^-(aq)$

    From this information we can set up the reactant side of the overall ionic equation:

    $K^+(aq) + NO_3^-(aq) + Na^+(aq) + I^-(aq) \rightarrow ?$

4. *Determine whether any of the possible combinations of ions produces a slightly soluble product*. In step 1 we determined that there are four kinds of ions present when the two solutions are mixed. When these ions collide with one another, do any of them form a slightly soluble ionic compound, that is, a precipitate? KI and $NaNO_3$ are soluble according to Table 4.4. (The other possible combinations of ions are KNO_3 and NaI, but those are the compounds we started with and we already determined them to be soluble and dissociate.) As a result, no precipitate forms when the two solutions are mixed:

    $K^+(aq) + NO_3^-(aq) + Na^+(aq) + I^-(aq) \rightarrow \text{no reaction}$

Table 4.5 conveniently summarizes these solubility rules. It contains the same information as Table 4.4, but it is organized to show trends across common cations and anions. Does a precipitate form when an aqueous solution of lead(II) nitrate is added to an aqueous solution of sodium iodide? As before, NaI(*aq*) exists in solution as $Na^+(aq)$ and $I^-(aq)$ ions. Because Table 4.4 (and Table 4.5) indicate that all nitrate salts are soluble, $Pb(NO_3)_2$ dissolves in water and forms ions. The ions present in the mixed solutions are

$$Pb^{2+}(aq) + 2\ NO_3^-(aq) + Na^+(aq) + I^-(aq) \rightarrow ?$$

[There is a coefficient of 2 present in front of nitrate because there are 2 moles of nitrate for every mole of $Pb^{2+}(aq)$ ions.] When these ions collide, do ionic bonds form and produce a slightly soluble ionic compound? The solubility guidelines in Table 4.4 indicate that PbI_2 is only slightly soluble, so we predict that $PbI_2(s)$ will precipitate (**Figure 4.20**).

TABLE 4.5 Solubility Matrix for Ionic Compounds in Water

CATION	
[illegible] Ba^{2+}	
ANION [illegible] or CH_3COO^-	
Slightly soluble [illegible]	
Slightly soluble [illegible] S^{2-}	
Slightly soluble [illegible]	
Slightly soluble [illegible] PO_4^{3-}	

Because a reaction takes place, we can write an equation that describes the process, starting with the molecular equation:

Converting the molecular equation into an overall ionic equation:

Removing the spectator ions NO_3^- and Na^+ gives the net ionic equation:

$$Pb^{2+}(aq) + 2\ I^-(aq) \rightarrow PbI_2(s)$$

SAMPLE EXERCISE 4.11 Writing Net Ionic Equations for Precipitation Reactions I LO4, LO7

A precipitate forms when aqueous solutions of ammonium sulfate and barium nitrate are mixed. Write the net ionic equation for this reaction.

Collect, Organize, and Analyze We are to write the net ionic equation describing the precipitation reaction that occurs when solutions of ammonium sulfate and barium nitrate are mixed together. The formulas of the reactants are $(NH_4)_2SO_4$ and $Ba(NO_3)_2$. According to Table 4.4 all ammonium salts and all nitrate salts are soluble in water. Therefore, the precipitate must be $BaSO_4$ and the only other product is soluble NH_4NO_3.

Solve Let's start by writing a preliminary expression containing single formula units of all the reactants and products:

$$(NH_4)_2SO_4(aq) + Ba(NO_3)_2(aq) \rightarrow NH_4NO_3(aq) + BaSO_4(s)$$

This expression is not balanced because there are 2 $NH_4{}^+$ ions and 2 $NO_3{}^-$ ions on the left side but only one of each on the right. To balance them we add a coefficient of 2 in front of the $NH_4NO_3(aq)$ term:

$$(NH_4)_2SO_4(aq) + Ba(NO_3)_2(aq) \rightarrow 2\ NH_4NO_3(aq) + BaSO_4(s)$$

Separating the soluble compounds into their component ions yields the overall ionic equation:

Simplifying by crossing out (equation above) and then removing (equation below) all the spectator ions that appear on both sides of the reaction arrow yields the net ionic equation:

$$Ba^{2+}(aq) + SO_4{}^{2-}(aq) \rightarrow BaSO_4(s)$$

Think About It To identify whether a precipitation reaction will occur when solutions of two ionic compounds are mixed together, check whether switching the cation–anion pairs produces one of the compounds listed in Table 4.5 as slightly soluble.

Practice Exercise Does a precipitate form when you mix aqueous solutions of (a) sodium acetate and ammonium sulfate; (b) calcium chloride and mercury(I) nitrate? (c) If you answered yes in either case, write the net ionic equation for the reaction.

(Answers to Practice Exercises are in the back of the book.)

Precipitation reactions can be used to synthesize slightly soluble salts. For example, barium sulfate, used in medical procedures to image the gastrointestinal tract, can be made by mixing an aqueous solution of any water-soluble barium salt with a solution of a soluble sulfate salt. The precipitate from such a reaction can be collected by filtration, dried, and used for whatever purpose we may have. The soluble compound remaining in solution can also be collected. The ammonium chloride left in solution in Sample Exercise 4.11, for instance, can be isolated by evaporating the water to leave a residue of solid NH_4NO_3.

SAMPLE EXERCISE 4.12 Writing Net Ionic Equations for Precipitation Reactions II LO4, LO7

Write a net ionic equation for the reaction between aqueous sulfuric acid and barium hydroxide as pictured in Figure 4.19. Is this the same net ionic equation as in Sample Exercise 4.11?

Collect and Organize We are asked to write a net ionic equation given the names of the reactants. Figure 4.19 shows that the reaction produces a white precipitate. We then need to write the net ionic equation and compare it with the one from Sample Exercise 4.11.

Analyze First, we need to write a molecular equation for the reaction. Next, we must identify which reactants and products are soluble in water. We write any soluble ionic compounds as ions, leaving any precipitates and molecular compounds unchanged. Finally, we will simplify the overall ionic equation by removing any spectator ions that appear on both sides of the equation to obtain the net ionic equation.

Sulfuric acid is a strong diprotic acid. As mentioned previously in this chapter, its first proton completely dissociates but its second proton does not:

$H_2SO_4(aq) \rightarrow H^+(aq) + HSO_4^-(aq)$ $HSO_4^-(aq) \rightleftharpoons H^+(aq) + SO_4^{2-}(aq)$

Therefore, the correct way to write the ionic species present in solution in an overall ionic equation when sulfuric acid is a reactant is $H^+(aq) + HSO_4^-(aq)$, *not* $2\ H^+(aq) + SO_4^{2-}(aq)$.

Solve

1. Molecular equation:

   $Ba(OH)_2(aq) + H_2SO_4(aq) \rightarrow BaSO_4(s) + 2\ H_2O(\ell)$

2. Overall ionic equation:

   $Ba^{2+}(aq) + 2\ OH^-(aq) + H^+(aq) + HSO_4^-(aq) \rightarrow BaSO_4(s) + 2\ H_2O(\ell)$

3. The equation cannot be simplified any further, so the net ionic equation is the same as the overall ionic equation in this case.

This net ionic equation is *not* the same as for the reaction between ammonium sulfate and barium nitrate in Sample Exercise 4.11, even though both reactions form the same precipitate.

Think About It The reaction between barium hydroxide and sulfuric acid is *both* a neutralization reaction *and* a precipitation reaction. Formation of a slightly soluble salt and water means that all the ions on the reactant side are changed by the reaction, which makes the net ionic equation the same as the overall ionic equation.

Practice Exercise Write a net ionic equation for the reaction between barium hydroxide and phosphoric acid (H_3PO_4) in water.

(Answers to Practice Exercises are in the back of the book.)

CONCEPT TEST

Lead(II) chromate ($PbCrO_4$), is a paint pigment called *chrome yellow* that was used for decades to paint school buses and the lines on highways. Design a synthesis of chrome yellow that uses a precipitation reaction.

(Answers to Concept Tests are in the back of the book.)

Using Precipitation in Analysis

Chemists use the insolubility of ionic compounds to determine concentrations of ions in solution. For example, NaCl (in the form of *rock salt*) is used to melt ice and snow on roads during the winter. However, the resulting NaCl solutions may run off into nearby water supplies, and that water can become contaminated with high levels of sodium and chloride ions. To determine whether sources of drinking water have become contaminated with such runoff, analytical chemists can determine the concentration of chloride ions by reacting a sample of the water with a solution of silver nitrate, $AgNO_3(aq)$. Any chloride ions in the water combine with Ag^+ ions to form a precipitate of AgCl:

$$NaCl(aq) + AgNO_3(aq) \rightarrow AgCl(s) + NaNO_3(aq) \quad (4.12)$$

This precipitate can be filtered and dried, and its mass determined. From its mass, we can calculate the concentration of chloride in the original water sample.

Equation 4.12 is the molecular equation describing the formation of AgCl. Because both reactants are soluble ionic compounds and completely dissociate in solution, the overall ionic equation is

$$Na^+(aq) + Cl^-(aq) + Ag^+(aq) + NO_3{}^-(aq) \rightarrow AgCl(s) + Na^+(aq) + NO_3{}^-(aq)$$

Eliminating the spectator ions $Na^+(aq)$ and $NO_3{}^-(aq)$ yields the net ionic equation:

$Ag^{+}(aq) + Cl^{-}(aq) \rightarrow AgCl(s)$

When performing this analysis, we must add enough Ag^{+} ions to ensure that all the Cl^{-} ions precipitate. Specifically, if we use a molar ratio of $Ag^{+}(aq)/Cl^{-}(aq)$ greater than 1, then the $Ag^{+}(aq)$ is present *in excess*. Precipitation reactions such as this may also include indicators that produce a visual signal (like a color change) that defines when the reaction is complete.

CONNECTION To review limiting reactants and reactants in excess when calculating the yield of reactions, see Chapter 3.

SAMPLE EXERCISE 4.13 Calculating the Mass of a Precipitate LO7

When hydrofluoric acid, HF(*aq*), gets on the skin, it migrates away from the site of exposure and shuts down the microcapillaries that carry blood. The clinical management of burns on the skin from exposure to hydrofluoric acid may include the injection of a soluble calcium salt in the skin near the site of contact to stop the migration of HF(*aq*). As F^{-} ions from the acid move through the skin, they combine with Ca^{2+} ions and form deposits of only slightly soluble CaF_2. If 1.00 mL of a 2.24 *M* aqueous solution of Ca^{2+} is injected, what is the mass of CaF_2 produced if all the calcium ions react with fluoride ions?

Collect and Organize We are given the volume and concentration of a solution of Ca^{2+} ions and asked to determine the maximum amount of CaF_2 precipitate that could be formed upon reaction with F^{-} ions.

Analyze The net ionic reaction for the process involved is

$Ca^{2+}(aq) + 2\,F^{-}(aq) \rightarrow CaF_2(s)$

The problem states that all the calcium ions react, so we can calculate the mass of product assuming Ca^{2+} ions are the limiting reactant by (1) converting the volume × concentration of the Ca^{2+} solution into mol Ca^{2+}, (2) using the stoichiometry of the equation to calculate mol CaF_2, and (3) using $\mathscr{M}_{CaF_2}$ to calculate g CaF_2.

Solve First we need to calculate the molar mass of CaF_2:

$$\mathscr{M}_{CaF2} = 40.08 \text{ g/mol} + 2(19.00 \text{ g/mol}) = 78.08 \text{ g/mol } CaF_2$$

Following the steps described in the Analyze section:

Think About It As a check on the solution to this exercise, consider that 1.0 mL of 2.24 M Ca^{2+} ions contains 1.0 mL × 2.24 mol/L = 2.24 mmoles of Ca^{2+} ions (1 mmol = 0.001 mol). This quantity of Ca^{2+} ions produces the same quantity of CaF_2 whose mass is 2.24 mmol CaF_2 × 78.08 g/mol = 175 mg or 0.175 g CaF_2, which is that answer we obtained above.

Practice Exercise A deep red pigment known as vermilion has been used by artists and craftsmen for thousands of years. The pigment is prepared from the mineral cinnabar, which is a form of mercury(II) sulfide (HgS). Synthetic cinnabar can be prepared by precipitating HgS from mixing solutions containing Hg^{2+} ions and S^{2-} ions. How many grams of cinnabar could be made in the precipitation reaction that occurs when 50.00 mL of 0.0150 M $Hg(NO_3)_2$ is mixed with excess $Na_2S(aq)$?

(Answers to Practice Exercises are in the back of the book.)

SAMPLE EXERCISE 4.14 Calculating Solute Concentration from a Mass of Precipitate LO7

To determine the concentration of chloride ions in a 100.0 mL sample of groundwater, a chemist adds a large enough volume of a solution of $AgNO_3$ to the sample to precipitate the Cl^- ions as AgCl ($\mathscr{M}$ = 143.32 g/mol). The mass of the resulting AgCl precipitate is 71.7 mg. What is the Cl^- ion concentration in the sample in mg/L?

Collect and Organize We are given the mass (71.7 mg) of AgCl formed by precipitating the Cl^- ions from a 100.0 mL sample and asked to calculate the concentration of Cl^- ions in the sample in mg/L. Each mole of AgCl ($\mathcal{M}$ = 143.32 g/mol) precipitate contains 1 mole of Cl^- ions.

Analyze The diagram below outlines a strategy for converting a mass of AgCl into a concentration of Cl^- ions in mg/L. The initial mass of AgCl and final mass of Cl^- ions are both in mg, so the “milli” prefix is carried through the calculation to avoid unnecessary milligram-to-gram and gram-to-milligram conversion steps.

Solve Converting the mass of AgCl precipitate into mg Cl^- ions /L:

Think About It Another way to solve this problem starts by expressing the mass of AgCl precipitated from a 100.0 mL sample as if it were a concentration and then using a ratio of molar masses to calculate an equivalent concentration of Cl^- ions in mg/L:

Practice Exercise The concentration of $SO_4^{2-}(aq)$ in a 50.0 mL sample of river water is determined using a precipitation titration in which $Ba^{2+}(aq)$ is added to precipitate $BaSO_4(s)$. What is the $SO_4^{2-}(aq)$ concentration in molarity if 6.55 mL of a 0.00100 M $Ba^{2+}(aq)$ solution is consumed?

(Answers to Practice Exercises are in the back of the book.)

Saturated Solutions and Supersaturation

A solution containing the maximum amount of solute that can dissolve is a saturated solution (**Figure 4.21**). The maximum amount of solute that can dissolve in a given quantity of solvent at a given temperature is called the solubility of that solute in the solvent. Precipitates form when the solubility of a solute is exceeded.

Solubility depends on temperature; often, the higher the temperature, the greater the solubility of solids in water. The makers of rock candy (**Figure 4.22**), for example, exploit the property that more table sugar dissolves in hot water than in cold. After a large amount of sugar is dissolved in hot water, the solution is slowly cooled. An object with a slightly rough surface (such as a string or a wooden stirrer) suspended in the solution serves as a site for crystallization. As the solution cools below the temperature at which the solubility of sugar is exceeded, crystals of sugar grow on the rough surface. The formation of crystals as the temperature of a saturated solution is lowered is a form of precipitation.

Sometimes, more solute dissolves in a volume of liquid than the amount predicted by the solute's solubility in that liquid, creating a supersaturated solution. This can happen when the temperature of a saturated solution drops slowly or when the volume of an unsaturated solution is reduced through slow evaporation. Slow evaporation of the solvent is partly responsible for the formation of stalactites and stalagmites, as well as of the salt flats in the American Southwest. Sooner or later, usually in response to a disruption such as a change in temperature, a mechanical shock, or the addition of a *seed crystal* (a small crystal of the solute that provides a site for crystallization), the solute in a supersaturated solution rapidly comes out of solution (**Figure 4.23**).

SAMPLE EXERCISE 4.15 Limiting Reactants in Aqueous Phase Reactions LO7

Acid rain in the form of aqueous H_2SO_4 slowly erodes marble statues, as shown in Figure 4.15. Can 16.75 mL of $1.00 \times 10^{-2}\ M$ H_2SO_4 completely dissolve 15.0 mg of $CaCO_3$?

Collect and Organize We are given the quantities of two reactants: the volume and concentration of one and the mass of the other and are essentially being asked to determine which one is the limiting reactant. Equation 4.10 is the molecular equation that describes the reaction between dilute sulfuric acid and solid calcium carbonate.

One mole of $H_2SO_4(aq)$ reacts with 1 mole of $CaCO_3(s)$.

Analyze One way to answer the question is to calculate the mass of $CaCO_3$ that could be consumed by all the H_2SO_4 available. The steps for doing that are:

Solve Calculate the mass of calcium carbonate that could be consumed by 16.75 mL of the sulfuric acid solution:

There is more than enough sulfuric acid to completely dissolve 15.0 mg $CaCO_3$.

Think About It According to Table 4.5, $CaSO_4$ is slightly soluble in water, so perhaps you are wondering why there is an (*aq*) symbol after $CaSO_4$ in Equation 4.10. Actually, the concentration of a saturated solution of $CaSO_4$ is 0.015 *M* at 20°C. In this case, 0.01 *M* H_2SO_4 produces a solution that contains ~0.01 *M* $CaSO_4$, which is $<$ 0.015 *M* and should not precipitate.

Practice Exercise Heavy metal ions such as lead(II) can be precipitated from laboratory wastewater by adding sodium sulfide, Na_2S. Will all of the lead be removed from 15.00 mL of 7.52×10^{-3} *M* $Pb(NO_3)_2$ upon addition of 12.50 mL of 0.0115 *M* Na_2S?

(Answers to Practice Exercises are in the back of the book.)

Glossary

precipitate

a solid product formed from a reaction in solution.

precipitation reaction

a reaction that produces a slightly soluble product upon mixing two solutions.

saturated solution

a solution that contains the maximum concentration of a solute possible at a given temperature.

solubility

the maximum amount of a substance that dissolves in a given volume of solution at a given temperature.

supersaturated solution

a solution that contains more than the maximum quantity of solute predicted to be soluble in a given volume of solution at a given temperature.

Learning Objectives

- Write molecular, overall ionic, and net ionic equations for reactions in aqueous solution **Return to Sample Exercises 4.7, 4.10, 4.11, 4.12**
- Use solubility rules to predict the products of precipitation reactions and to quantify results from precipitation reactions **Return to Sample Exercises 4.11, 4.12, 4.13, 4.14, 4.15**
- Write molecular, overall ionic, and net ionic equations for reactions in aqueous solution **Return to Sample Exercises 4.7, 4.10, 4.11, 4.12**
- Use solubility rules to predict the products of precipitation reactions and to quantify results from precipitation reactions **Return to Sample Exercises 4.11, 4.12, 4.13, 4.14, 4.15**
- Use solubility rules to predict the products of precipitation reactions and to quantify results from precipitation reactions **Return to Sample Exercises 4.11, 4.12, 4.13, 4.14, 4.15**

(c) Increasing concentrations of pale yellow Fe^{3+} ions and faintly pink Mn^{2+} ions combine to give the sample a pale amber color. (d) When all the Fe^{2+} ions have been consumed, the next drop of unreacted purple MnO_4^- ions gives the sample a peach color that signals the end point of the titration.

4.8 Oxidation–Reduction Reactions: Electron Transfer

In the 15th century, Leonardo da Vinci observed: “Where flame cannot live, no animal that draws breath can live.” Although oxygen was not isolated and recognized as an element until the 18th century, da Vinci captured an important property of the substance as a requirement for combustion and metabolism. Oxygen makes up about 50% by mass of Earth’s crust, it is almost 89% by mass of the water that covers 70% of Earth’s surface, and it is about 20% of the volume of Earth’s atmosphere. It is essential for the metabolism of most creatures, just as it is essential for combustion reactions. What type of reaction is involved in metabolism and in the combustion reaction in **Figure 4.24**? Methane and oxygen are neither acids nor bases. No precipitates are formed in the reactions, which produce water and carbon dioxide.

Combination reactions of oxygen with nonmetals such as carbon, sulfur, and nitrogen produce volatile oxides. Combination reactions of O_2 with metals and semimetals produce solid oxides. All of these reactions are examples of oxidation–reduction reactions. *Oxidation* was first defined as a reaction that increased the oxygen content of a substance. Hence, two reactions involving oxygen—with methane to produce $CO_2(g)$ and $H_2O(\ell)$, and with elemental iron to produce $Fe_2O_3(s)$—are both oxidations from the point of view of the CH_4 and the Fe because the products contain more oxygen than the starting materials:

$$CH_4(g) + 2\ O_2(g) \rightarrow CO_2(g) + 2\ H_2O(g)$$

$$4\ Fe(s) + 3\ O2(g) \rightarrow 2\ Fe2O3(s)$$

CONNECTION In Chapter 3 we defined combustion as a heat-producing reaction between oxygen and another element or compound.

Reduction reactions were originally defined in a similar fashion—namely, reactions in which the oxygen content of a substance is reduced. A classic example is the reduction of iron ore (mostly Fe_2O_3) to metallic iron:

$Fe_2O_3(s) + 3\ CO(g) \rightarrow 2\ Fe(s) + 3\ CO_2(g)$

The oxygen content of the iron ore is reduced—Fe_2O_3 is converted into Fe—as a result of its reaction with $CO(g)$. At the same time, though, the carbon in CO is oxidized because the oxygen content of CO increases as it is converted into CO_2.

CONCEPT TEST

The following equation describes the conversion of one iron mineral, called magnetite (Fe_3O_4), into another, called hematite (Fe_2O_3):

$4\ Fe_3O_4(s) + O_2(g) \rightarrow 6\ Fe_2O_3(s)$

Identify which element is oxidized and which is reduced and explain your choices.

(Answers to Concept Tests are in the back of the book.)

Oxidation Numbers

The processes of oxidation and reduction always occur together, which gives rise to the common way of referring to them as *redox reactions*. To distinguish between oxidation and reduction in redox reactions, chemists have developed a system of oxidation numbers to assign to atoms in reactants and products. The oxidation number (O.N.), or oxidation state, of an atom in a molecule or ion may be a positive or negative number or zero. The oxidation number represents the positive or negative character an atom has or appears to have as determined by the following rules:

1. The oxidation numbers of the atoms in a neutral molecule sum to zero; those of the atoms in an ion sum to the charge on the ion.

2. Each atom in a pure element has an oxidation number of zero:

   F_2 O.N. $=$ 0 for each FO_2 O.N. $=$ 0 for each O

   Fe O.N. $=$ 0Na O.N. $=$ 0

3. In monatomic ions, the oxidation number is the charge on the ion:

   F^- O.N. $= -1$$O^{2-}$ O.N. $= -2$

   Fe^{3+} O.N. $= +3$$Na^+$ O.N. $= +1$

   Note that the number comes first when we write the symbol of an ion, Fe^{3+}, but the sign comes first when we write an oxidation number, $+3$.

4. In compounds containing fluorine and one or more other elements, the oxidation number of the fluorine is *always* -1:

   KFO.N. $= -1$ for F, which means O.N. $= +1$ for K (rule 1)

   OF_2O.N. $= -1$ for each F, which means O.N. $= +2$ for O (rule 1)

   CF_4O.N. $= -1$ for each F, which means O.N. $= +4$ for C (rule 1)

5. In most compounds, the oxidation number of hydrogen is $+1$ and that of oxygen is -2. Exceptions include hydrogen in metal hydrides (e.g., LiH), where O.N. $= -1$ for H, and oxygen in peroxides such as H_2O_2, where O.N. $= -1$ for each O atom.
6. Unless combined with oxygen or fluorine, chlorine and bromine have an oxidation number of -1:

   $CaCl_2$O.N. $= -1$ for Cl, which means O.N. $= +2$ for Ca (rule 1)

   $AlBr_3$O.N. $= -1$ for Br, which means O.N. $= +3$ for Al (rule 1), *but*

ClO_4^- O.N. $= -2$ for O (rule 5), which means O.N. $= +7$ for Cl (rule 1)

SAMPLE EXERCISE 4.16 Determining Oxidation Numbers LO8

What is the oxidation number of sulfur in (a) SO_2, (b) Na_2S, and (c) $CaSO_4$?

Collect, Organize, and Analyze To assign the oxidation number of sulfur in three of its compounds, we apply the rules for determining the oxidation numbers of the elements in each compound. SO_2 is the molecule sulfur dioxide. Na_2S is an ionic compound, and the oxidation number of an ion in an ionic compound equals its charge. Sulfur in $CaSO_4$ is part of the sulfate ion, which means its oxidation number added to those of the four O atoms must add up to the charge of the ion; we determine the oxidation number for calcium from rule 1.

Solve

1. From rule 5, O.N. $= -2$ for the O in SO_2. Rule 1 says that the sum of the oxidation numbers for S and the two O in the neutral molecule must be zero. Letting O.N. for S be x:

   $x + 2(-2) = 0$

   $x = +4$ O.N. for S in $SO_2 = +4$

2. Sodium forms only one ion, Na^+, which means that, according to rule 3, O.N. $= +1$. To balance the O.N. values in Na_2S (rule 1), we let y stand for the O.N. of sulfur:

   $2(+1) + y = 0$

   $y = -2$ O.N. for S in $Na_2S = -2$

3. The charge on the calcium ion is always 2+. This means that the charge on the sulfate ion must be 2−. Assigning O.N. $= -2$ for oxygen (rule 5) and z for the O.N. of sulfur:

   $z + 4(-2) = -2$

$z = +6$ O.N. for S in $CaSO_4 = +6$

Think About It We found oxidation numbers for sulfur ranging from -2 for its monatomic ion to $+4$ and $+6$ in its oxoanions. This pattern applies to other nonmetals (except O and F), though their maximum positive values vary with group number: from $+4$ in group 14 to $+7$ in group 17.

Practice Exercise Determine the oxidation number of chromium in (a) $Cr(OH)_3$, (b) $BaCrO_4$, and (c) $K_2Cr_2O_7$.

(Answers to Practice Exercises are in the back of the book.)

Changes in Oxidation Numbers in Redox Reactions

Now that we know how to assign oxidation numbers to atoms in molecules and ions, we can examine how oxidation numbers change during a redox reaction. Let's look at the formation of sodium chloride from its elements:

$2\ Na(s) + Cl_2(g) \rightarrow 2\ NaCl(s)$

First, we assign oxidation numbers to all the atoms in the reactants and the ions in the product:

OXIDATION NUMBERS			
Atoms in Reactants		Ions in Products	
Na:	0	Na^{1+} in NaCl:	
Cl in Cl_2:	0	Cl^{1-} in NaCl:	

The oxidation numbers of the sodium atoms and chlorine atoms change; such a change for any element defines a reaction as redox. The sodium atom on the left changes from O.N. $= 0$ in $Na(s)$ to $+1$ in $NaCl(s)$, and each chlorine atom changes from O.N. $= 0$ in $Cl_2(g)$ to -1 in $NaCl(s)$. Because the oxidation number of sodium *increases*, sodium is said to be *oxidized* in this reaction. Likewise, because the oxidation number of chlorine *decreases*, chlorine is said to be *reduced*. In redox reactions, we can keep track of the oxidation numbers and the electrons transferred by annotating the equation in the following way:

CONCEPT TEST

Determine whether the following are redox reactions. For the redox reactions, identify the atoms that undergo changes in oxidation number.

1. $Sn^{2+}(aq) + Br_2(aq) \rightarrow Sn^{4+}(aq) + 2\ Br^-\ (aq)$
2. $2\ F_2(g) + 2\ H_2O(\ell) \rightarrow 4\ HF(aq) + O_2(g)$
3. $NaHCO_3(aq) + HCl(aq) \rightarrow NaCl(aq) + CO_2(g) + H_2O(\ell)$

(Answers to Concept Tests are in the back of the book.)

Electron Transfer in Redox Reactions

Ultimately, the meanings of oxidation and reduction were expanded, so that oxidation now refers to any chemical reaction in which a substance *loses electrons*, whereas reduction refers to any reaction in which a substance *gains electrons*. If one substance loses electrons, another substance must gain them; that is, if one species is oxidized, another must be reduced. The defining event in oxidation–reduction reactions is the *transfer* of electrons from one substance to another.

For example, when a piece of copper wire [elemental copper, Cu(*s*)] is placed in a colorless solution of silver nitrate [$Ag^+(aq) + NO_3{}^-(aq)$], the solution gradually turns blue, the color of a solution of $Cu^{2+}(aq)$, and branchlike structures of Ag(*s*) form in the medium (**Figure 4.25**). As silver ions (Ag^+) collide with the surface of the solid Cu, electrons transfer from the copper atoms to the silver ions, resulting in a layer of silver atoms depositing on the copper solid. Two electrons transfer, one to each Ag^+ ion, from one copper atom.

Simultaneously, for each two Ag^+ ions that deposit as silver atoms, one copper atom enters solution as a Cu^{2+} ion. The process can be summarized as

Because the silver ion is reduced as the copper atom is oxidized, the silver ion is the oxidizing agent in the redox reaction. We say that “silver ion oxidizes copper.” As an oxidizing agent, the silver ion is reduced. This is always the case: the *oxidizing* agent in any redox reaction is always *reduced* in the process. Any species that is reduced experiences a *reduction in oxidation number*, as is the case for the silver ion, which goes from O.N. $= +1$ to O.N. $= 0$. Likewise, as the copper atom is oxidized, the silver ion is reduced. Copper in this reaction is therefore the reducing agent. The *reducing* agent is always *oxidized* and experiences an *increase in oxidation number*; in this reaction, the copper atom goes from O.N. $= 0$ to O.N. $= +2$. Every redox reaction has both an oxidizing agent and a reducing agent.

SAMPLE EXERCISE 4.17 Identifying Oxidizing Agents and Reducing Agents LO8

Hydrazine is used as rocket fuel, but it is also used to remove dissolved oxygen gas from aqueous solutions:

$$O_2(aq) + N_2H_4(aq) \rightarrow 2\,H_2O(\ell) + N_2(g)$$

Identify the species oxidized, the species reduced, the oxidizing agent, and the reducing agent.

Collect and Organize The reactants are the element oxygen and the compound hydrazine. The products are water and nitrogen.

Analyze The O.N. of the oxygen atoms in O_2 changes from zero to -2 in H_2O. The O.N. of nitrogen changes from -2 in N_2H_4 to zero in N_2. The O.N. $= +1$ of hydrogen is unchanged.

Solve

Oxygen is the oxidizing agent because the oxidation number of nitrogen increases. This means that O_2 is reduced and N_2H_4 is the reducing agent.

Think About It We tend to identify the specific *atoms* that are oxidized or reduced, whereas whole *molecules or ions* are identified as the oxidizing agents or reducing agents. In the equation in this exercise, nitrogen is oxidized but N_2H_4 is the reducing agent.

Practice Exercise In the reaction between $O_2(g)$ and $SO_2(g)$ to make $SO_3(g)$, identify the species oxidized, the species reduced, the oxidizing agent, and the reducing agent.

(Answers to Practice Exercises are in the back of the book.)

Balancing Redox Reactions by Using Half-Reactions

At first glance, the equation for the redox reaction between $Ag^+(aq)$ and $Cu(s)$ may seem balanced—and in a material sense it is: the number of silver and copper atoms or ions is the same on both sides. However, the charges are not balanced: the sum of the charges is $1+$ for the reactants but $2+$ for the products. The reason for this imbalance is that one electron is involved in the reduction reaction but two are involved in the oxidation reaction. Equal numbers of electrons must be lost and gained, so to balance equations describing redox reactions like this one, we must develop a method that accounts for electron transfer.

CONNECTION In Chapter 2 we introduced nuclear equations, which must also be balanced in both mass and charge.

The change in oxidation number reflects the change in the number of electrons associated with an atom or ion. This change in the number of electrons happens because electrons are transferred from one atom or ion to another during a redox reaction. By tracking changes in oxidation numbers, we can gain additional insight into the transfer of electrons as the redox reaction takes place.

Think of this reaction between Cu(*s*) and $AgNO_3(aq)$ as consisting of one oxidation and one reduction. Each of these reactions represents *half* of the overall reaction; hence, each is called a half-reaction. We can write a balanced chemical equation by combining half-reactions following these five steps:

1. *Write one expression for the oxidation half-reaction and a separate one for the reduction half-reaction*:

   $\text{Oxidation:} \text{Cu}(s) \rightarrow \text{Cu}^{2+}(aq)$

   $\text{Reduction:} \text{Ag}^{+}(aq) \rightarrow \text{Ag}(s)$

2. *Balance the number of atoms of each element in each half-reaction.* This example requires no changes at this point because both contain single atoms of one element on both sides of the reaction arrow.
3. *Balance the charges* by adding electrons to the appropriate side. Always *add* electrons; never subtract them. We add 2 electrons to the product side of the Cu half-reaction:

   $\text{Oxidation: } \text{Cu}(s) \rightarrow \text{Cu}^{2+}(aq) + 2\ \text{e}^{-}$

   and 1 electron to the reactant side of the Ag half-reaction:

   $\text{Reduction:} 1\ \text{e}^{-} + \text{Ag}^{+}(aq) \rightarrow \text{Ag}(s)$

4. This gives us a total charge of 0 on both sides of both half-reactions. Note that electrons are added on the reactant side of the reduction equation (reduction is the gain of electrons) and on the product side of the oxidation equation (oxidation is the loss of electrons). This is always the case.
5. *Multiply each equation by the appropriate whole number* to make the number of electrons lost in the oxidation half-reaction equal the number of electrons gained in the reduction half-reaction:

   $\text{Oxidation:} \text{Cu}(s) \rightarrow \text{Cu}^{2+}(aq) + 2\ \text{e}^{-}$

Reduction: $2 \times [1\ e^- + Ag^+(aq) \rightarrow Ag(s)]$

As a result we have the following half-reactions:

Oxidation: $Cu(s) \rightarrow Cu^{2+}(aq) + 2\ e^-$

Reduction: $2\ e^- + 2\ Ag^+(aq) \rightarrow 2\ Ag(s)$

6. *Add the two equations to generate one that represents the overall redox reaction*:

$$\begin{array}{ll} \text{Oxidation:} & Cu(s) \rightarrow Cu^{2+}(aq) + \cancel{2\ e^-} \\ \text{Reduction:} & \cancel{2\ e^-} + 2\ Ag^+(aq) \rightarrow 2\ Ag(s) \\ \hline \text{Overall equation:} & 2\ Ag^+(aq) + Cu(s) \rightarrow 2\ Ag(s) + Cu^{2+}(aq) \end{array}$$

If we have carried out step 4 correctly, the number of electrons in the oxidation half-reaction is the same as the number of electrons in the reduction half-reaction, and they cancel out when we write the overall equation. In redox reactions, we can keep track of the oxidation numbers and the electrons transferred by annotating the equation in the following way:

The equation is now balanced in terms of number of atoms and charge. The equation is a net ionic equation because only species changed by the redox reaction appear in it. The nitrate ions from the silver nitrate solution (Figure 4.25) are spectator ions and are not shown in the Ag half-reaction or the net ionic equation.

We review the methods for balancing chemical equations as described here when we discuss applications of oxidation–reduction reactions in Chapter 18.

SAMPLE EXERCISE 4.18 Balancing Redox Reactions with Half-Reactions LO9

Iodine is slightly soluble in water forming yellow-brown aqueous solutions. When colorless $Sn^{2+}(aq)$ is dissolved in it (**Figure 4.26**), the solution turns colorless as $I^-(aq)$ forms and $Sn^{2+}(aq)$ is converted into $Sn^{4+}(aq)$. (a) Is this a redox reaction? (b) Write the net ionic equation describing the reaction.

Collect and Organize The reactants in this process are molecules of I_2 and Sn^{2+} ions; the products are I^- and Sn^{4+} ions.

Analyze The oxidation number of tin increases from $+2$ in Sn^{2+} ions to $+4$ in Sn^{4+} ions. The oxidation number of iodine is reduced from 0 in molecules of I_2 to -1 in I^- ions. Combining half-reactions is one way to write a net ionic equation for a redox reaction, so we need to write half-reactions based on the oxidation of Sn^{2+} ions to Sn^{4+} ions and on the reduction of I_2 to I^- ions. Tin and iodine are in separate equations when we write the respective half-reactions.

Solve

1. The oxidation numbers of the atoms of two elements change, so this is a redox reaction.
2. Writing the symbols of all reactants and products:

$Sn^{2+}(aq) + I_2(aq) \rightarrow I^-\,(aq) + Sn^{4+}(aq)$

Balancing this expression using the five-step process.

1. Separate the half-reactions.

   Oxidation:$Sn^{2+}(aq) \rightarrow Sn^{4+}(aq)$

   Reduction:$I_2(aq) \rightarrow I^-\,(aq)$

2. Balance the number of atoms of each element.

   Oxidation:$Sn^{2+}(aq) \rightarrow Sn^{4+}(aq)$

   Reduction:$I_2(aq) \rightarrow 2\,I^-\,(aq)$

3. Balance the charges by adding electrons.

   Oxidation:$Sn^{2+}(aq) \rightarrow Sn^{4}+(aq) + 2\,e^-$

   Reduction:$2\,e^- + I_2(aq) \rightarrow 2\,I^-\,(aq)$

4. Balance the numbers of electrons gained and lost. This step is not needed because they're already equal.
5. Combine the two half-reactions.

$$\begin{array}{lr}
\text{Oxidation:} & \mathrm{Sn^{2+}}(aq) \rightarrow \mathrm{Sn^{4+}}(aq) + \cancel{2\,e^-} \\
\text{Reduction:} & \cancel{2\,e^-} + \mathrm{I_2}(aq) \rightarrow 2\,\mathrm{I^-}(aq) \\
\hline
\text{Overall equation:} & \mathrm{Sn^{2+}}(aq) + \mathrm{I_2}(aq) \rightarrow 2\,\mathrm{I^-}(aq) + \mathrm{Sn^{4+}}(aq)
\end{array}$$

Think About It To assess the accuracy of the overall chemical equation,

1. check for atom balance: 1 Sn + 2 I = 2 I + 1 Sn ✓
2. check for charge balance: reactant side 2+, product side 2(1−) + (4+) = 2+ ✓.

Practice Exercise When a nail made of Fe(*s*) is placed in an aqueous solution of a soluble palladium(II) salt [containing Pd^{2+}(*aq*)], it gradually disappears because the iron enters the solution as Fe^{3+}(*aq*), and palladium metal [Pd(*s*)] forms. (a) Is this a redox reaction? (b) Balance the equation that describes this reaction.

(Answers to Practice Exercises are in the back of the book.)

The Activity Series of Metals

If we replaced the $AgNO_3$(*aq*) solution in Figure 4.25a with a $Zn(NO_3)_2$ solution, no reaction between it and Cu metal would be observed. By immersing copper wire in solutions of other metal cations, we would find, for example, that Cu metal reduces Ag^+ and Au^{3+} ions to Ag and Au metal, but it does not reduce Zn^{2+}, Ni^{2+}, and Al^{3+} ions to their metals. Similarly, we could explore the ability of zinc metal to reduce these same cations and find that all except Al^{3+} (and Zn^{2+}) are reduced by Zn metal.

Why do particular metals reduce some metal cations but not others? A detailed explanation awaits in Chapter 18, but for now we can use the activity series in **Table 4.6** to rank the strengths of metals as reducing agents: from the highly reactive group 1 and group 2 metals at the top of the table to the largely inert metals, such as platinum and gold, at the bottom. Metals at the top of the table can reduce the cations of metals below them as the top metal's oxidation half-reaction proceeds as written in the table, whereas the lower metal's cations are reduced to metal atoms as its half-reaction proceeds in reverse—as a reduction half-reaction.

SAMPLE EXERCISE 4.19 Using the Activity Series I LO8

An aluminum wire is dipped into a solution containing Na^+, Sn^{2+}, and Cu^{2+} ions. Which ions will be present in the solution after the reactions are complete?

Collect and Organize We are asked to predict which metal ions in solution will be reduced by aluminum. We use the activity series in Table 4.6 to guide our answer.

Analyze The activity series is arranged based on metals' decreasing strengths as reducing agents. Alternatively, the ease of oxidation of the corresponding metals at the top of the series can reduce the cations of the metals below them.

Solve Aluminum is above copper and tin but below sodium in Table 4.6. Therefore, Al reduces both Cu^{2+} and Sn^{2+} ions, removing them from the solution, but Na^+ ions remain. Aluminum is oxidized as Cu^{2+} and Sn^{2+} ions are reduced, so Al^{3+} ions are also present in the solution when the reaction is over.

Think About It The arrangement of metals in the activity series makes sense from what we know about the chemical reactivity of groups of metals: the highly reactive group 1 and group 2 metals are clustered at the top and many of those that are stable as free metals such as gold, silver, and copper, which are used to make coins, are near the bottom.

Practice Exercise Which substance listed in Table 4.6 is most easily oxidized? Which substance is most easily reduced?

(Answers to Practice Exercises are in the back of the book.)

Why is hydrogen gas listed in Table 4.6? What does its position in the activity series tell us? Table 4.6 allows us to predict which metals will react with strong aqueous acids like HCl. Any metal below H_2 in Table 4.6 will not react with H^+ and hence will be resistant to most strong acids. One reason coins and jewelry made from silver, gold, and platinum last is that they do not react with most acids.

TABLE 4.6 An Activity Series for Metals in Aqueous Solution

Metal	Oxidation Reaction
Lithium	$Li(s) \longrightarrow Li^{+}(aq) + e^{-}$
Potassium	$K(s) \longrightarrow K^{+}(aq) + e^{-}$
Barium	$Ba(s) \longrightarrow Ba^{2+}(aq) + 2e^{-}$
Calcium	$Ca(s) \longrightarrow Ca^{2+}(aq) + 2e^{-}$
Sodium	$Na(s) \longrightarrow Na^{+}(aq) + e^{-}$
Magnesium	$Mg(s) \longrightarrow Mg^{2+}(aq) + 2e^{-}$
Aluminum	$Al(s) \longrightarrow Al^{3+}(aq) + 3e^{-}$
Manganese	$Mn(s) \longrightarrow Mn^{2+}(aq) + 2e^{-}$
Zinc	$Zn(s) \longrightarrow Zn^{2+}(aq) + 2e^{-}$
Chromium	$Cr(s) \longrightarrow Cr^{3+}(aq) + 3e^{-}$
Iron	$Fe(s) \longrightarrow Fe^{2+}(aq) + 2e^{-}$
Cobalt	$Co(s) \longrightarrow Co^{2+}(aq) + 2e^{-}$
Nickel	$Ni(s) \longrightarrow Ni^{2+}(aq) + 2e^{-}$
Tin	$Sn(s) \longrightarrow Sn^{2+}(aq) + 2e^{-}$
Lead	$Pb(s) \longrightarrow Pb^{2+}(aq) + 2e^{-}$
Hydrogen	$H_2(g) \longrightarrow 2H^{+}(aq) + 2e^{-}$
Copper	$Cu(s) \longrightarrow Cu^{2+}(aq) + 2e^{-}$
Silver	$Ag(s) \longrightarrow Ag^{+}(aq) + e^{-}$
Mercury	$Hg(l) \longrightarrow Hg^{2+}(aq) + 2e^{-}$
Platinum	$Pt(s) \longrightarrow Pt^{2+}(aq) + 2e^{-}$

Gold $Au(s) \rightarrow Au^{3+}(aq) + 3\ e^-$	

SAMPLE EXERCISE 4.20 Using the Activity Series II LO8

Use the activity series to predict the products of the reaction between zinc metal and aqueous hydrochloric acid and write a net ionic equation describing the reaction.

Collect, Organize, and Analyze The reactants in this process are $Zn(s)$ and $HCl(aq)$, which is a strong acid that forms $H^+(aq)$ and $Cl^-(aq)$ ions in aqueous solutions. The relevant half-reactions in Table 4.6 are

$Zn(s) \rightarrow Zn^{2+}(aq) + 2\ e^-$ and $H_2(g) \rightarrow 2\ H^+(aq) + 2\ e^-$

Zinc is listed above hydrogen in Table 4.6.

Solve Placement of the half-reactions in the table tells us that zinc metal reduces H^+ ions, producing Zn^{2+} ions (as the Zn half-reaction runs in the forward direction) and H_2 gas (as the H_2 half-reaction runs in reverse).

Writing the two half-reactions in the appropriate directions and combining them:

Think About It The activity series is a list of net ionic equations describing half-reactions, so selecting the two that are related to a redox reaction of interest—and reversing the one that is lower in the series before combining it with the other—is a convenient way to write a net ionic equation for the overall reaction. Knowing that H^+ ions were a reactant was another clue that the H_2 half-reaction ran in reverse as a reduction. Combining the two was made easy because two electrons were gained in one half-reaction and lost in the other.

Practice Exercise Predict the products of the reaction between aluminum metal and silver nitrate. Write a net ionic equation describing the reaction.

(Answers to Practice Exercises are in the back of the book.)

Redox in Nature

Redox processes play a major role in determining the character of Earth's rocks and soils. For example, the orange-red rocks of Bryce Canyon National Park in Utah contain the iron(III) oxide mineral called hematite (**Figure 4.27**). Rocks containing hematite are relatively weak and easily broken, causing the fascinating shapes of such deposits. Iron(III) oxide is also the form of iron known as rust—the crumbly, red-brown solid that forms on iron objects exposed to water and oxygen.

Soil color and mineral content are influenced by moisture content. Wetlands, which are areas that are either saturated or flooded with water during much of the year, are protected environments in many areas of the United States. Defining a given area as a wetland relies in part on the characteristics of the soils, especially their color (**Figure 4.28**), which is strongly influenced by the redox chemistry of iron.

Figure 4.29a shows a solution of iron(II) ammonium sulfate, $(NH_4)_2Fe(SO_4)_2(aq)$, upon addition of $NaOH(aq)$. The pale greenish color of the liquid is characteristic of $Fe^{2+}(aq)$. Addition of $NaOH(aq)$ causes $Fe(OH)_2(s)$ to precipitate as a blue-gray solid, similar in color to the wetland soils shown in Figure 4.28. When this mixture is filtered, the iron(II) hydroxide residue immediately starts to darken (**Figure 4.29b**). After about 20 minutes of exposure to oxygen in the air (**Figure 4.29c**), the precipitate turns the orange-red color of iron(III) hydroxide. The iron(II) has been oxidized—just as the iron(II) compounds in a wetland soil are oxidized when exposed to oxygen.

Redox reactions take place in acidic, neutral, or basic solutions, and

H^+ ions, OH^- ions, or even molecules of water may play roles in these reactions. For example, a method for determining the concentration of $Fe^{2+}(aq)$ involves its oxidation to $Fe^{3+}(aq)$ by intensely purple permanganate, $MnO_4{}^-$ ions (**Figure 4.30**), which are reduced to $Mn^{2+}(aq)$. Thus, the key components of the redox reaction are

---

A chemical equation describing the reaction will be balanced when (a) the number of atoms of each element on both sides of the reaction is the same and (b) the total charges on each side of the reaction arrow are the same. We proceed in the same way as for the previous examples in neutral solutions.

1. Separate iron and manganese into their respective half-reactions.

   Oxidation:$Fe^{2+}(aq) \rightarrow Fe^{3+}(aq)$

   Reduction:$MnO_4{}^-\ (aq) \rightarrow Mn^{2+}(aq)$

2. Balance the atoms of the elements being oxidized or reduced.

    1. a. Oxidation:$Fe^{2+}(aq) \rightarrow Fe^{3+}(aq)$ (Fe atoms balanced)

   Reduction:$MnO_4{}^-\ (aq) \rightarrow Mn^{2+}(aq)$ (Mn atoms balanced, but not O atoms)

   Balance O atoms by adding four molecules of H_2O.

    1. b. Oxidation:$Fe^{2+}(aq) \rightarrow Fe^{3+}(aq)$

   Reduction:$MnO_4{}^-\ (aq) \rightarrow Mn^{2+}(aq) + 4\ H_2O(\ell)$

   (O atoms balanced, H atoms are not)

   In neutral or acidic solutions, balance H atoms by adding H^+ ions:

1. c. Oxidation:$Fe^{2+}(aq) \rightarrow Fe^{3+}(aq)$

Reduction:$8\ H^+(aq) + MnO_4^-\ (aq) \rightarrow Mn^{2+}(aq) + 4\ H_2O(\ell)$

(all atoms balanced)

3. Balance charges by adding electrons.

Oxidation:$Fe^{2+}(aq) \rightarrow Fe^{3+}(aq) + 1\ e^-$

Reduction:$5\ e^- + 8\ H^+(aq) + MnO_4^-\ (aq) \rightarrow Mn^{2+}(aq) + 4\ H_2O(\ell)$

Note that the number of electrons added to the reduction half-reaction also accounts for the oxidation state of Mn changing from $+7$ to $+2$.

4. Balance numbers of electrons lost in the oxidation half-reaction and gained in the reduction half-reaction.

Oxidation:$5 \times [Fe^{2+}(aq) \rightarrow Fe^{3+}(aq) + 1\ e^-]$

Reduction:$1 \times [5\ e^- + 8\ H^+(aq) + MnO_4^-\ (aq) \rightarrow Mn^{2+}(aq) + 4\ H_2O(\ell)]$

5. Add the two equations and cancel species that appear on both sides of the reaction arrow.

$$\begin{array}{lr} \text{Oxidation:} & 5\ Fe^{2+}(aq) \rightarrow 5\ Fe^{3+}(aq) + \cancel{5\ e^-} \\ \text{Reduction:} & \cancel{5\ e^-} + 8\ H^+(aq) + MnO_4^-(aq) \rightarrow Mn^{2+}(aq) + 4\ H_2O(\ell)] \\ \hline \multicolumn{2}{c}{8\ H^+(aq) + MnO_4^-(aq) + 5\ Fe^{2+}(aq) \rightarrow} \\ \multicolumn{2}{r}{5\ Fe^{3+}(aq) + Mn^{2+}(aq) + 4\ H_2O(\ell)} \end{array}$$

Always check the atom and charge balance of the final net ionic equation. The reactant side contains 8 H, 1 Mn, 4 O, and 5 Fe atoms and the product side contains 8 H, 1 Mn, 4 O, and 5 Fe atoms, so the atoms are balanced. On the reactant side, the charge is $(8+) + (1-) + (10+) = 17+$, and on the product side it is $(15+) + (2+) = 17+$, so the charges are balanced, too.

This method works for writing the net ionic equation for any redox reaction taking place in neutral or acidic aqueous solutions. The oxidation in Figure 4.29, however, was carried out in a basic medium, so how do we write a chemical equation for that reaction? The procedure is almost the same as for acidic solutions: in fact, we carry out the same steps as in the previous exercise, but we add one more in which hydroxide ions are added to neutralize any H^+ ions, forming molecules of H_2O.

SAMPLE EXERCISE 4.21 Balancing Redox Equations That Involve Hydroxide Ions LO9

Wetland soil is blue-gray because it contains $Fe(OH)_2(s)$, whereas well-aerated soils are often orange-red because of the presence of $Fe(OH)_3(s)$ (Figure 4.28). Write the balanced equation for the reaction of $O_2(g)$ with $Fe(OH)_2(s)$ in soil that produces $Fe(OH)_3(s)$ in basic solution.

Collect and Organize We know the reactants and product and can write the unbalanced equation:

$$Fe(OH)_2(s) + O_2(g) \rightarrow Fe(OH)_3(s)$$

Our task is to balance the equation with respect to both mass and charge.

Analyze This reaction takes place with both iron compounds in the solid phase in the presence of hydroxide ions in water. For the oxidation half-reaction, iron(II) hydroxide is oxidized to iron(III) hydroxide. For the reduction half-reaction, O_2 is converted into the additional OH^- ion in the iron(III) hydroxide product.

Solve

1. Separate the equations.

   Oxidation:$Fe(OH)_2(s) \rightarrow Fe(OH)_3(s)$

   Reduction:$O_2(g) \rightarrow OH^-\ (aq)$

2. Balance the atoms.

    1. Balance all atoms except H and O. This step is not needed because Fe is already balanced.
    2. Balance O atoms by adding water as needed.

       Oxidation: $H_2O(\ell) + Fe(OH)_2(s) \rightarrow Fe(OH)_3(s)$

       Reduction: $O_2(g) \rightarrow OH^-(aq) + H_2O(\ell)$

    3. Balance H atoms by adding H^+ ions as needed.

$$H_2O(\ell) + Fe(OH)_2(s) \rightarrow Fe(OH)_3(s) + H^+(aq)$$

$$3\,H^+(aq) + O_2(g) \rightarrow OH^-(aq) + H_2O(\ell)$$

3. Balance the charges.

$$H_2O(\ell) + Fe(OH)_2(s) \rightarrow Fe(OH)_3(s) + H^+(aq) + 1\,e^-$$

$$4\,e^- + 3\,H^+(aq) + O_2(g) \rightarrow OH^-(aq) + H_2O(\ell)$$

4. Balance the numbers of electrons lost and gained.

$$4 \times [H_2O(\ell) + Fe(OH)_2(s) \rightarrow Fe(OH)_3(s) + H^+(aq) + 1\,e^-]$$

$$1 \times [4\,e^- + 3\,H^+(aq) + O_2(g) \rightarrow OH^-(aq) + H_2O(\ell)]$$

5. Add the two equations.

$$3\,\cancel{4}\,H_2O(\ell) + 4\,Fe(OH)_2(s) + \cancel{4\,e^-} + \cancel{3\,H^+(aq)} + O_2(g) \rightarrow$$
$$4\,Fe(OH)_3(s) + \cancel{3}\,4\,H^+(aq) + \cancel{4\,e^-} + OH^-(aq) + \cancel{H_2O(\ell)}$$

This gives us the balanced equation:

$$3\,H_2O(\ell) + 4\,Fe(OH)_2(s) + O_2(g) \rightarrow 4\,Fe(OH)_3(s) + OH^-(aq) + H^+(aq)$$

This equation can be simplified further because $OH^- + H^+$ form $H_2O(\ell)$:

$$3\,H_2O(\ell) + 4\,Fe(OH)_2(s) + O_2(g) \rightarrow 4\,Fe(OH)_3(s) + \underbrace{OH^-(aq) + H^+(aq)}_{H_2O(\ell)}$$

Canceling the molecule of H_2O common to both sides produces a balanced equation:

$$2\ H_2O(\ell) + 4\ Fe(OH)_2(s) + O_2(g) \rightarrow 4\ Fe(OH)_3(s)$$

Think About It A check of the equation reveals that it is balanced in terms of both the number of atoms of each element and electrical charges (there aren't any). Another approach to writing chemical equations for redox reactions balances the changes in oxidation number in the first step instead of balancing the losses and gains of electrons in the last step.

The reaction above involves the oxidation of the Fe^{2+} ions $Fe(OH)_2(s)$ to Fe^{3+} ions in $Fe(OH)_3(s)$. This means the change in oxidation number (ΔO.N.) for each iron ion is $+1$. The oxidation number for each of the 2 O atoms in a molecule of O_2 changes from 0 to -2 as it becomes part of an OH^- ion on the product side. The overall ΔO.N. per molecule of O_2 is $2 \text{ atoms} \times (-2/\text{atom}) = -4$. To balance the $+1$ and -4 changes in oxidation number, we need 4 iron ions for every 1 molecule of O_2 so that $4 \times (+1) - 4 = 0$. A preliminary expression based on the 4:1 mole ratio looks like this

$$4\ Fe(OH)_2(s) + O_2(g) \rightarrow 4\ Fe(OH)_3(s)$$

The Fe atoms are balanced, but the right side has 12 H atoms and 12 O atoms whereas the left side has only 8 H atoms and 10 O atoms. To correct this imbalance, we add 2 molecules of H_2O to the left side, producing a balanced chemical equation:

$$4\ Fe(OH)_2(s) + O_2(g) + 2\ H_2O(\ell) \rightarrow 4\ Fe(OH)_3(s)$$

Practice Exercise Hydroperoxide ions, $HO_2^-\ (aq)$, react with permanganate ions, $MnO_4^-\ (aq)$, producing $MnO_2(s)$ and oxygen gas. Balance the equation for the oxidation of hydroperoxide ion to $O_2(g)$ by a permanganate ion in a basic solution.

(Answers to Practice Exercises are in the back of the book.)

Reactions in aqueous solutions are an integral part of our daily lives. On a large scale, in oceans, rivers, and rain, they shape our physical world. Many reactions that produce the substances that are part of modern life—from paint pigments to drugs—are run in water, and many analytical procedures rely on reactions in water to determine the content of aqueous solutions that we drink, swim in, and use in countless consumer products such as car batteries and shampoos. On a small scale, reactions in the water within the cells of our bodies and in all living organisms make the chemical processes that are essential to life possible. On Earth, there may be water without life, but there is no life without water.

SAMPLE EXERCISE 4.22 Integrating Concepts: Shelf-Stability of Drugs

Commercial pharmaceutical agents undergo extensive analysis to establish how long they may be stored without degradation and loss of potency. A candidate drug, a diprotic acid, has the following percent composition from combustion analysis: C, 62.50%; H, 4.20%. A standard tablet containing 325 mg of the drug is dissolved in 100.00 mL of water and titrated to the equivalence point with 16.45 mL of 0.2056 *M* NaOH(*aq*). After storage at 50°C under high humidity for one month, a second tablet, when dissolved in 50.00 mL of water, requires 10.10 mL of 0.1755 *M* NaOH(*aq*) to be completely neutralized.

1. What is the empirical formula of the drug?
2. What is its molar mass?
3. What is its molecular formula?
4. What is the percent of active drug substance remaining in the tablet after storage?

Collect and Organize We are given the percent composition of the drug and information from titration experiments. From these data we can find the empirical formula, the molar mass, and the amount of active drug in the stored tablet.

Analyze The percent composition data from the combustion analysis do not add to 100%. We may assume that the amount missing results from oxygen in the molecule. The drug is a diprotic acid, so neutralizing 1 mole of the drug requires 2 moles of NaOH. The titration of the drug requires about 20 mL of 0.2 *M* NaOH, which is about 0.004 mol OH^-. That means the pure sample is about 0.002 mol of the drug; if about 0.3 g contains 0.002 mol, the drug must have a molar mass of about 150 g. If any of the drug decomposes upon storage, we should have less than 325 mg in the second sample.

Solve

1. The percent oxygen in the drug molecule is

   $100.00\% - (62.50\% + 4.20\%) = 33.30\%$

   Calculating the moles of C, H, and O in exactly 100 g of the drug:

   $$\frac{62.50 \text{ g C}}{12.01 \text{ g/mol}} = 5.20 \text{ mol C}$$

   $$\frac{4.20 \text{ g H}}{1.008 \text{ g/mol}} = 4.17 \text{ mol H}$$

   $$\frac{33.30 \text{ g O}}{16.00 \text{ g/mol}} = 2.08 \text{ mol O}$$

   Reducing these quantities to ratios of small whole numbers,

$$\frac{5.20\text{ g C}}{2.08} = 2.50\text{ mol C}$$

$$\frac{4.17\text{ mol H}}{2.08} = 2.00\text{ mol H}$$

$$\frac{2.08\text{ mol O}}{2.08} = 1.00\text{ mol O}$$

requires multiplying by 2, which yields

5 mol C:4 mol H:2 mol O

The empirical formula is $C_5H_4O_2$.

2. To find the molar mass of the drug from the titration data, we first find the number of moles of drug in the sample:

$$0.01645\ \cancel{\text{L NaOH}} \times \frac{0.2056\ \cancel{\text{mol NaOH}}}{1\ \cancel{\text{L NaOH}}} \times \frac{1\text{ mol drug}}{2\ \cancel{\text{mol NaOH}}} = 0.001691\text{ mol drug}$$

If 0.325 g of drug is 0.001691 mol of drug, then the mass of 1 mole is

$$\mathcal{M}_{\text{drug}} = \frac{0.325\text{ g}}{0.001691\text{ mol}} = 192.2\text{ g/mol}$$

3. The mass of 1 mole of empirical formula units ($C_5H_4O_2$) is

$(5 \times 12.01\text{ g/mol}) + (4 \times 1.008\text{ g/mol}) + (2 \times 16.00\text{ g/mol}) = 96.08\text{ g/mol}$

The number of moles of formula units per mole of molecules is

$$\frac{192.16\ \frac{\cancel{g}}{\cancel{mol}}}{96.08\ \frac{\cancel{g}}{\cancel{mol}}} = 2$$

The molecular formula of the drug, then, is

$(C_5H_4O_2)_2 = C_{10}H_8O_4$

4. The stored tablet contains

$$0.01010\ \text{L NaOH} \times \frac{0.1755\ \text{mol NaOH}}{1\ \text{L NaOH}} \times \frac{1\ \text{mol drug}}{2\ \text{mol NaOH}} = 0.0008863\ \text{mol drug} = 8.863 \times 10^{-4}\ \text{mol}$$

Comparing this value with the original amount yields:

$$\frac{8.863 \times 10^{-4}\ \text{mol}}{1.691 \times 10^{-3}\ \text{mol}} \times 100\% = 52.41\%$$

Thus, 52.41% of the active drug is left in the tablet.

Think About It The molar mass we calculated is close to our estimated value, so it seems reasonable. If only half the active agent is present in the tablet after storage under these conditions, the manufacturer may have to reformulate the drug or package it differently to protect it from its surroundings.

Glossary

oxidation number (O.N.) (also called oxidation state)

a positive or negative number based on the number of electrons an atom gains or loses when it forms an ion, or that it shares when it forms a covalent bond with another element; pure elements have an oxidation number of zero.

oxidation number (O.N.) (also called oxidation state)

a positive or negative number based on the number of electrons an atom gains or loses when it forms an ion, or that it shares when it forms a covalent bond with another element; pure elements have an oxidation number of zero.

oxidation

a chemical change in which a species loses electrons; the oxidation number of the species increases.

reduction

a chemical change in which a species gains electrons; the oxidation number of the species decreases.

oxidizing agent

a substance in a redox reaction that contains the element being reduced.

reducing agent

a substance in a redox reaction that contains the element being oxidized.

half-reaction

one of the two halves of an oxidation–reduction reaction; one half-reaction is the oxidation component, and the other is the reduction component.

activity series

a high-to-low ranking of metals based on their strengths as reducing agents.

Learning Objectives

- Determine oxidation numbers and use them to identify redox reactions, oxidizing agents, and reducing agents. Use the activity series to explain redox reactions between metals and metal ions **Return to Sample Exercises 4.16, 4.17, 4.19,**

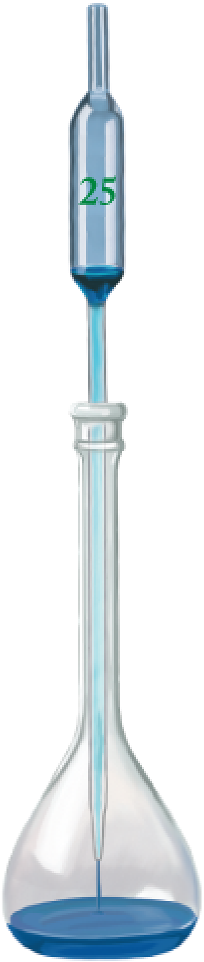
SUMMARY

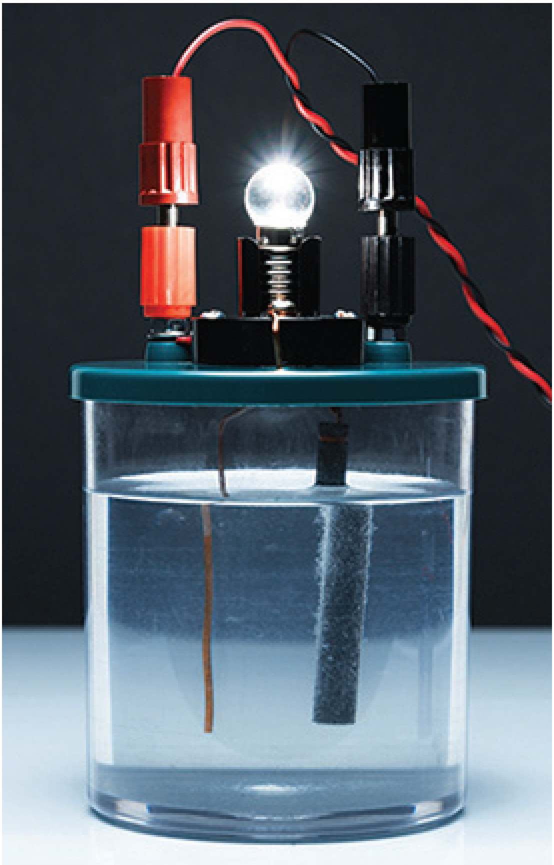
LO1 The concentration of solute in a solution can be expressed many different ways: as mass of solute per mass of solution (such as grams of solute per kilogram of solution), parts per million (1 ppm = 1 μg solute/g solution = 1 mg solute/kg solution), or parts per billion (1 ppb = 1 μg solute/kg solution). Solute concentration can also be expressed as mass of solute per volume of solvent and as moles of solute per liter of solution, or molarity (*M*). One set of units can be converted into another by using dimensional analysis. (Sections 4.1 and 4.2)



- LO2 Two common ways of making solutions of a desired concentration are determining the mass of solute to be dissolved in an appropriate amount of solvent to produce the quantity of solution needed and by dilution of a stock solution. During dilution, the quantity of solute in a sample does not change, but adding solvent increases the volume of the sample and decreases the concentration of the solution. (Sections 4.2 and 4.3)
- LO3 We can determine the concentration of a solution by spectrophotometry and the application of Beer's law, which relates the absorbance of a solution (A) to concentration (c), path length (b), and molar absorptivity(ϵ) by the equation A

$= \varepsilon bc$. (Section 4.3)

- LO4 In molecular equations reactants and products are written as neutral compounds. Overall ionic equations include all species in the reaction mixture, including the ions that exist in solution. Net ionic equations eliminate spectator ions and show only the species that are involved in the reaction. (Sections 4.5, 4.6, 4.7, and 4.8)



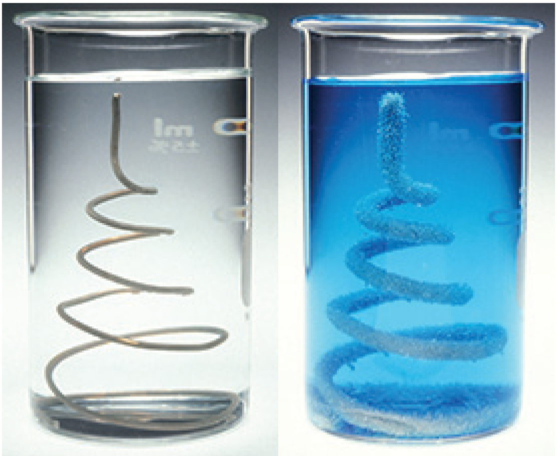
- LO5 Measuring the conductivity of a solution enables us to identify solutes as strong electrolytes, weak electrolytes, or nonelectrolytes. In a neutralization reaction, Brønsted–Lowry acids are proton donors and Brønsted–Lowry bases are proton acceptors; they are also strong or weak electrolytes in aqueous solution. (Sections 4.4 and 4.5)
- LO6 Titrations are volumetric methods of chemical analysis in which the concentrations of solutions are determined by

reacting them with known volumes and concentrations of standard solutions called titrants. When the amount of titrant is enough to completely react the dissolved solute in the sample, the titration has reached the equivalence point. (Section 4.6)

100
APPROX
80

- LO7 Solubility rules define substances that dissolve readily in water and those that have very limited solubility. We can remove ions from solution by precipitation, and we can quantify the amount of precipitate formed and the concentration of ions left in solution after reaction. (Section 4.7)
- LO8 In a redox reaction, substances either gain electrons (and thereby undergo reduction) or lose electrons (undergo oxidation). A reaction is a redox reaction if the oxidation numbers (O.N.), or oxidation states, of the atoms in the

reactants change during the reaction. The activity series allows us to predict whether a particular metal will reduce an ion of a different metal. (Section 4.8)



- LO9 Oxidation and reduction are complementary processes. When balancing equations, the number of electrons lost by the substance being oxidized must match the number of electrons gained by the substance being reduced. (Section 4.8)

PARTICULATE PREVIEW WRAP-UP

The balanced equation when the contents of the two beakers are mixed is

$$NH_4Cl(aq) + AgNO_3(aq) \rightarrow NH_4NO_3(aq) + AgCl(s)$$

Therefore, ammonium nitrate remains as dissociated ions dissolved in water, and silver chloride precipitates as a solid. $AgNO_3(aq)$ is the limiting reagent, and all the nitrate ions remain in solution because they are spectator ions. The starting materials are drawn showing four cations and four anions for each reactant, so they form the products drawn here.

PROBLEM-SOLVING SUMMARY

Type of Problem	Concepts and Equations	Sample Exercises
Comparing the concentrations of aqueous solutions	Use conversion factors to express concentrations in different units.	4.1
Calculating molarity from solute mass and solution volume or from solute mass, solution mass, and density	Convert the mass of solute to moles. Calculate volume of solution by dividing mass of solution by the density of the solvent. Divide moles of solute by liters of solution: $M = \frac{n}{V}$ (4.1)	4.2, 4.3
Calculating the mass of solute or volume of stock solution to prepare a solution	Multiply the known molarity (M) of the target solution by its volume (in L) to obtain the moles of solute needed: $n = V \times M$ (4.2) Then multiply moles of solute by solute molar mass, $\mathscr{M}$, to get mass of solute needed: $m_{\text{solute}} = (V \times M)\mathscr{M}$ (4.3) Given three of the four variables, use $V_{\text{initial}} \times M_{\text{initial}} = V_{\text{diluted}} \times M_{\text{diluted}}$ (4.4) to solve for the fourth.	4.4, 4.5
Applying Beer's law	Solve for the absorbance (A), concentration (c), or molar absorptivity (ε) of a sample using Equation 4.5 and the values of the other variables in the equation. $A = \varepsilon bc$ (4.5)	4.6
Writing molecular, overall ionic, and net ionic equations for neutralization reactions	Write the molecular equation, balancing the number of H^+ ions donated by the acid and accepted by the base. Next, create the overall ionic equation that incorporates the formulas of the ions in strong electrolytes. Finally, create the net ionic equation by eliminating spectator ions from the overall ionic equation.	4.7, 4.11
Comparing electrolytes, acids, and bases	Use the definitions of a strong electrolyte, a weak electrolyte, a nonelectrolyte, an acid, and a base to classify compounds into one or more categories.	4.8
Calculating molarity from titration data	Use the volume and concentration of titrant used to neutralize a sample along with a balanced chemical equation to calculate the number of moles in a sample of known volume and determine its molarity.	4.9, 4.10
Predicting precipitation reactions	Write the ions in the solutions being mixed. If any	4.11, 4.12

cation/anion pair forms a slightly soluble compound, assume that compound will precipitate.

Calculating the mass of a precipitate

4.13, 4.15 Use the balanced equation to calculate moles of precipitate from moles of limiting reactant. Use the molar mass of the precipitate to convert moles of it into grams.

Calculating a solute concentration from a precipitate mass

4.14 Convert precipitate mass into moles by dividing by its molar mass. Convert moles of precipitate into moles of solute. Calculate molarity of the solute in the sample by dividing moles of solute by the volume of sample in liters.

Determining oxidation numbers (O.N.)

4.16 O.N. of a monatomic ion is equal to the ion's charge. O.N. of a pure element is 0. To assign O.N. in a molecule containing more than one type of atom, assign O.N. +1 to H, − 2 to O, and then calculate O.N. for any remaining atoms such that all the O.N. values sum to 0 for compounds or to the charge of a polyatomic ion.

Identifying oxidizing and reducing agents and number of electrons transferred

4.17 The *oxidizing* agent contains an atom whose O.N. *decreases*; the *reducing* agent contains an atom whose O.N. *increases*; the change in O.N. determines the number of electrons transferred.

Balancing redox reactions with half-reactions

4.18 Multiply one or both half-reactions by the appropriate coefficient(s) to balance the loss and gain of electrons. Combine the two half-reactions and simplify.

Using the activity series

4.19, 4.20 Any metal will reduce a cation listed *below* it in the activity series.

Balancing redox reactions that involve acidic or basic conditions

4.21 Follow the steps described in Section 4.8 for balancing redox equations.

VISUAL PROBLEMS

(Answers to boldface end-of-chapter questions and problems are in the back of the book.)

In Figure P4.1, which shows a solution containing three binary acids, one of the three is a weak acid and the other two are strong acids. Which color sphere represents the anion of the dissociated weak acid?

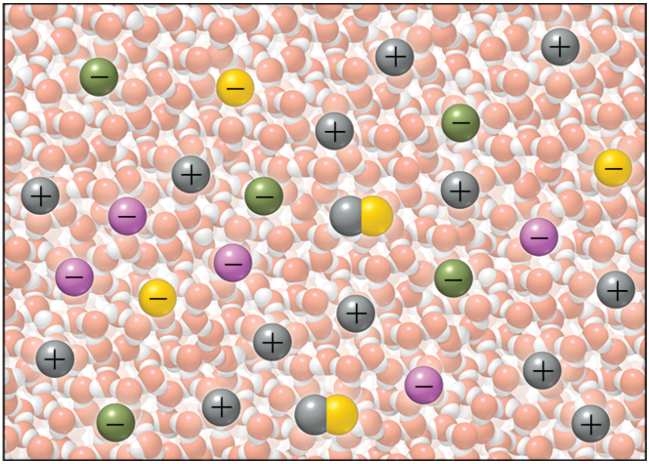


FIGURE P4.1

Solutions of sodium chloride and silver iodide are mixed together and shaken vigorously. Which colored spheres in Figure P4.2 represent the following ions? (a) Na^+; (b) Cl^-; (c) I^-

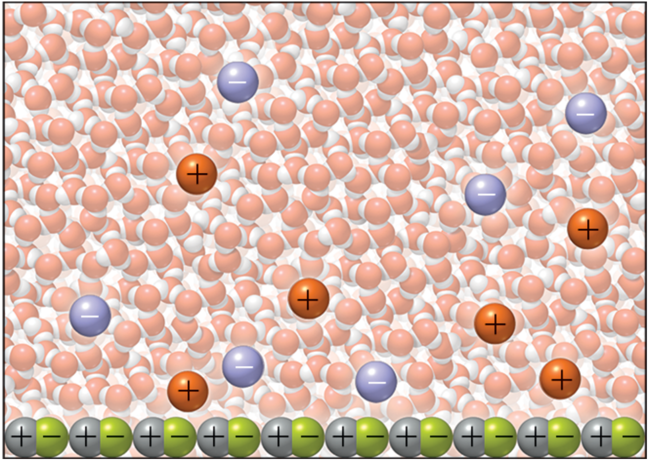

FIGURE P4.2

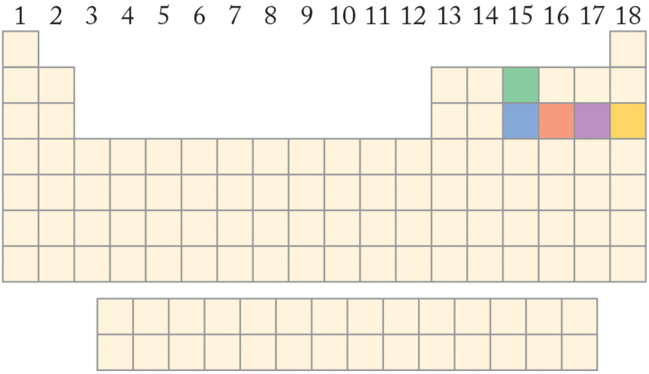
Which of the highlighted elements in Figure P4.3 forms an acid with the following generic formula? (a) HX; (b) H_2XO_4; (c) HXO_3; (d) H_3XO_4



1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 16 17 18

FIGURE P4.3

In which of the highlighted groups of elements in Figure P4.4 will you find an element that forms the following? (a) slightly soluble halides; (b) slightly soluble hydroxides; (c) hydroxides that are soluble; (d) binary compounds with hydrogen that are strong acids

QUESTIONS AND PROBLEMS

Quantifying Particles in Solution

Concept Review

How do you decide which component in a solution is the solvent?

Can a solid ever be a solvent? Explain.

What is the molarity of a solution that contains 1.00 mmol of solute per milliliter of solution?

A beaker contains 100 mL of 1.00 *M* NaCl. If you pour 50 mL of the solution into another beaker, what is the molarity of the solution in each of the two beakers?

Problems

Calculate the molarity of each of the following solutions:

0.56 mol of $BaCl_2$ in 100.0 mL of solution

2. 0.200 mol of Na_2CO_3 in 200.0 mL of solution
3. 0.325 mol of $C_6H_{12}O_6$ in 250.0 mL of solution
4. 1.48 mol of KNO_3 in 250.0 mL of solution

Calculate the molarity of each of the following solutions:

1. 0.150 mol of urea (CH_4N_2O) in 250.0 mL of solution
2. 1.46 mol of $NaC_2H_3O_2$ in 1.000 L of solution
3. 1.94 mol of methanol (CH_3OH) in 5.000 L of solution
4. 0.045 mol of sucrose ($C_{12}H_{22}O_{11}$) in 50.0 mL of solution

Calculate the molarity of each of the following ions:

1. 0.33 g Na^+ in 100.0 mL of solution
2. 0.38 g Cl^- in 100.0 mL of solution
3. 0.46 g SO_4^{2-} in 50.0 mL of solution
4. 0.40 g Ca^{2+} in 50.0 mL of solution

Calculate the molarity of each of the following solutions:

1. 64.7 g LiCl in 250.0 mL of solution
2. 29.3 g $NiSO_4$ in 200.0 mL of solution
3. 50.0 g KCN in 500.0 mL of solution
4. 0.155 g $AgNO_3$ in 100.0 mL of solution

How many grams of solute are needed to prepare each of the following solutions?

1. 1.000 L of 0.200 *M* NaCl
2. 250.0 mL of 0.125 *M* $CuSO_4$
3. 500.0 mL of 0.400 *M* CH_3OH

How many grams of solute are needed to prepare each of the following solutions?

1. 500.0 mL of 0.250 *M* KBr
2. 25.0 mL of 0.200 *M* $NaNO_3$
3. 100.0 mL of 0.375 *M* CH_3OH

River Water The Mackenzie River in northern Canada contains, on average, 0.820 m*M* Ca^{2+}, 0.430 m*M* Mg^{2+}, 0.300 m*M* Na^{+}, 0.0200 m*M* K^{+}, 0.250 m*M* Cl^{-}, 0.380 m*M* SO_4^{2-}, and 1.82 m*M* HCO_3^{-}. What, on average, is the total mass of these ions in 2.75 L of Mackenzie River water?

Toxicity of Metal Ions Zinc, copper, lead, and mercury ions are toxic to Atlantic salmon at concentrations of 6.42×10^{-2} m*M*, 7.16×10^{-3} m*M*, 0.965 m*M*, and 5.00×10^{-2} m*M*, respectively. What are the corresponding concentrations in milligrams per liter?

Calculate the number of moles of solute contained in the following volumes of aqueous solutions of four pesticides:

1. 0.400 L of 0.024 *M* lindane
2. 1.65 L of 0.473 m*M* dieldrin
3. 25.8 L of 3.4 m*M* DDT
4. 154 L of 27.4 m*M* aldrin

Hemoglobin in Blood A typical adult body contains 6.0 L of blood. The hemoglobin content of blood is about 15.5 g/100.0 mL of blood. The approximate molar mass of hemoglobin is 64,500 g/mol. How many moles of hemoglobin are present in a typical adult?

DDT Affects Neurons The pesticide DDT ($C_{14}H_9Cl_5$) kills insects such as malaria-carrying mosquitoes by opening sodium ion channels in neurons. This causes them to fire spontaneously, which leads to spasms and eventual death. However, its toxicity in wildlife and humans led to the banning of its use in the United States in 1972. Analysis of DDT concentrations in groundwater samples between 1969 and 1971 in Pennsylvania yielded the following results:

Sample Site	Sample Size	Mass of DDT
Orchard	250 mL	0.030 mg
Residential	0.750 L	0.036 mg
Residential after a storm	5.0 L	0.057 mg

Express these concentrations in ppm and in millimoles per liter.

Pesticides in the Environment From 1969 to 1975, pesticide concentrations in the Rhine River, which flows between Germany and France, averaged 0.55 mg/L of hexachlorobenzene (C_6Cl_6), 0.06 mg/L of dieldrin ($C_{12}H_8Cl_6O$), and 1.02 mg/L of hexachlorocyclohexane ($C_6H_6Cl_6$). Express these concentrations in ppb and in millimoles per liter.

Nitrogen trifluoride (NF_3) is used in the production of flat panel displays. It is also a potent greenhouse gas. The average concentration of NF_3 in the atmosphere increased from 0.02 parts per trillion (ppt) in 1978 to 0.454 ppt in 2008. What is the concentration of NF_3 in mg per kg of air?

Gases Found in Air Sulfur hexafluoride (SF_6) is used in electrical transformers. Like NF_3, it has a potential impact on climate. Between 1978 and 2012, the concentration of SF_6 increased from 0.51 parts per trillion (ppt) to 7.48 ppt. How many *more* molecules of SF_6 were found in one liter of air in 2012 than in 1978? (1 mole of gas = 22.4 L of gas.)

The concentration of copper(II) sulfate in one brand of soluble plant fertilizer is 0.07% by mass. If a 20 g sample of this fertilizer is dissolved in 2.0 L of solution, what is the molarity of Cu^{2+}?

For which of the following compounds is it possible to make a 1.0 *M* solution at 20°C?

1. $CuSO_4$, solubility = 32.0 g/100 mL
2. $Ba(OH)_2$, solubility = 3.9 g/100 mL
3. $FeCl_2$, solubility = 68.5 g/100 mL
4. $Ca(OH)_2$, solubility = 0.173 g/100 mL

Dilutions

Problems

Calculate the final concentrations of the following aqueous solutions after each has been diluted to a final volume of 25.0 mL:

1. 3.00 mL of 0.175 M K^+
2. 2.50 mL of 10.6 mM LiCl
3. 15.00 mL of 7.24×10^{-2} mM Zn^{2+}

Dilution of Adult-Strength Cough Syrup A standard dose of an over-the-counter cough suppressant for adults is 20.0 mL. A portion this size contains 35 mg of the active pharmaceutical ingredient (API). Your pediatrician says you may give this medication to your 6-year-old child, but the child may take only 10.0 mL at a time and receive a maximum of 4.00 mg of the API. What is the concentration in mg/mL of the adult-strength medication, and how many millimeters of it would you need to dilute to make 100.0 mL of child-strength cough syrup?

The concentration of Na^+ ions in seawater, 0.481 M, is higher than in the cytosol, the fluid inside human cells (12 mM). How much water must be added to 1.50 mL of seawater to make the Na^+ ion concentration equal to that found in the cytosol? Assume the volumes are additive.

The concentration of chloride ion in blood, 116 mM, is less than that in the ocean, 0.559 M. Describe how you would prepare 2.50 mL of a solution of 116 mM chloride ion from seawater.

Water is allowed to evaporate from 100.0 mL of 0.24 M Na_2SO_4 until the solution volume is 60.0 mL. What is the molar concentration of the evaporated solution?

Mixing Fertilizer The label on a bottle of “organic” liquid fertilizer concentrate states that it contains 8 g of phosphate per 100.0 mL and that 15.8 mL should be diluted with water to make 4.0 L of fertilizer to be applied to growing plants. What is the phosphate concentration in grams per liter in the diluted fertilizer?

If the absorbance of a solution of copper ion decreases by 45% upon dilution, how much water was added to 15.0 mL of a 1.00 *M* solution of Cu^{2+}?

By what percentage does the absorbance decrease if 12.25 mL of water is added to a 16.75 mL sample of 0.500 *M* Cr^{3+}?

The reaction of $SnCl_2(aq)$ with $Pt^{4+}(aq)$ in aqueous HCl yields a yellow-orange solution of a 1:1 Pt–Sn compound with a molar absorptivity (ε) of $1.3 \times 10^4 M^{-1}\ cm^{-1}$. What is the absorbance in a cell with a path length of 1.00 cm of a solution prepared by adding 100 mL of an aqueous solution of 5.2 mg $(NH_4)_2PtCl_6$ to 100 mL of an aqueous solution of 2.2 mg $SnCl_2$?

The reaction of $SnCl_2(aq)$ with $RhCl_3(aq)$ in aqueous HCl yields a red solution of a 1:1 Rh–Sn compound. If a solution prepared by adding 150 mL of a 0.272 m*M* aqueous solution of $SnCl_2$ to 50 mL of an aqueous solution of 8.5 mg $RhCl_3$ has an absorbance of 0.85, as measured in a 1.00 cm cell, what is the molar absorptivity of the red compound?

Electrolytes and Nonelectrolytes

Concept Review

A solution of table salt is a good conductor of electricity, but a solution containing an equal molar concentration of table sugar is not. Why?

Corrosion at Sea Metallic fixtures on the bottom of a ship corrode more quickly in seawater than in freshwater. Why?

Explain why liquid methanol (CH_3OH) cannot conduct electricity, whereas molten NaOH can.

Fuel Cells The electrolyte in an electricity-generating device called a *fuel cell* consists of a mixture of Li_2CO_3 and K_2CO_3 heated to 650°C. These two ionic solids melt at this temperature. Explain how this mixture of molten carbonates can conduct electricity.

A beaker containing an aqueous solution of potassium chloride sits uncovered on a lab bench overnight. Half of the solvent evaporates. How does the conductivity of the more concentrated solution compare to the original, more dilute solution?

Two 0.1 *M* aqueous solutions of sucrose are prepared, one using distilled water and one using tap water. The distilled water solution does not conduct electricity, but the tap water solution does. Suggest a reason why these two solutions have different conductivities.

Problems

Rank the following solutions on the basis of their ability to conduct electricity, starting with the most conductive: (a) 1.0 *M* NaCl; (b) 1.2 *M* KCl; (c) 1.0 *M* Na_2SO_4; (d) 0.75 *M* LiCl.

Rank the conductivities of 1 *M* aqueous solutions of each of the following solutes, starting with the most conductive: (a) acetic acid; (b) methanol; (c) sucrose (table sugar); (d) hydrochloric acid.

Calculate the molarity of Na^+ ions in a 0.025 *M* aqueous solution of: (a) NaBr; (b)Na_2SO_4; (c) Na_3PO_4.

Calculate the molarity of each ion in a 0.025 *M* aqueous solution of: (a) KCl; (b)$CuSO_4$; (c) $CaCl_2$.

Which of the following solutions has the greatest number of particles (atoms or ions) of solute per liter? (a) 1 *M* NaCl; (b) 1 *M* $CaCl_2$; (c) 1 *M* ethanol; (d) 1 *M* acetic acid

Which of the following solutions contains the most solute particles per liter? (a) 1 *M* KBr; (b) 1 *M* $Mg(NO_3)_2$; (c) 4 *M* ethanol; (d) 4 *M* acetic acid

Rank these aqueous solutions in order of increasing concentration of potassium ions: (a) 0.1 *M* potassium chloride; (b) 0.2 *M* potassium sulfate; (c) 0.3 *M* potassium acetate.

Rank these aqueous solutions in order of increasing conductivity: (a) 0.1 *M* calcium chloride; (b) 0.2 *M* ammonium chloride; (c) 0.3 *M* sodium chloride.

Acid–Base Reactions: Proton Transfer

Concept Review

What name is given to a proton donor?

What is the difference between a strong acid and a weak acid?

Identify each compound as either a weak acid or a strong acid in aqueous solution: (a) HNO_3; (b) HNO_2; (c) $CH_3CH_2CH_2COOH$; (d) H_2SO_4.

An aqueous solution of acetic acid consists of water molecules, molecules of CH_3COOH, acetate ions, and protons. Which species is present in the largest amount? Which substances are present in the smallest amount?

What name is given to a proton acceptor?

What is the difference between a strong base and a weak base?

Identify each compound as either a weak base or a strong base in aqueous solution: (a) $Ca(OH)_2$; (b) NH_3; (c) $CH_3CH_2NH_2$; (d) NaOH.

Write the net ionic equation for the neutralization of a strong acid by a strong base.

Problems

For each of the following acid–base reactions, identify the acid and the base, and then write the overall ionic and net ionic equations.

1. $H_2SO_4(aq) + Ca(OH)_2(aq) \rightarrow CaSO_4(s) + 2\ H_2O(\ell)$
2. $PbCO_3(s) + H_2SO_4(aq) \rightarrow PbSO_4(s) + CO_2(g) + H_2O(\ell)$
3. $Ca(OH)_2(s) + 2\ CH_3COOH(aq) \rightarrow Ca(CH_3COO)_2(aq) + 2\ H_2O(aq)$

Complete and balance each of the following neutralization reactions, name the products, and write the overall ionic and net ionic equations.

1. $HBr(aq) + KOH(aq) \rightarrow$
2. $H_3PO_4(aq) + Ba(OH)_2 + (aq) \rightarrow$
3. $Al(OH)_3(s) + HCl(aq) \rightarrow$
4. $CH_3COOH(aq) + Sr(OH)_2(aq) \rightarrow$

Write a balanced molecular equation and a net ionic equation for the following reactions:

1. Solid magnesium hydroxide reacts with a solution of sulfuric acid.
2. Solid magnesium carbonate reacts with a solution of hydrochloric acid.
3. Ammonia gas reacts with hydrogen chloride gas.
4. Gaseous sulfur trioxide is dissolved in water and reacts with a solution of sodium hydroxide.

Write a balanced molecular equation and a net ionic equation for the following reactions:

1. Solid aluminum hydroxide reacts with a solution of hydrobromic acid.
2. A solution of sulfuric acid reacts with solid sodium carbonate.
3. A solution of calcium hydroxide reacts with a solution of nitric acid.
4. Solid potassium oxide is dissolved in water and reacts with a solution of sulfuric acid.

Toxicity of Lead Pigments The use of lead(II) carbonate and lead(II) hydroxide as white pigments in paint was discontinued because children have been known to eat paint chips. The pigments dissolve in stomach acid, and lead ions enter the nervous system and interfere with neurotransmissions in the brain, causing neurological disorders. Using net ionic equations, show why lead(II) carbonate and lead(II) hydroxide dissolve in acidic solutions.

Lawn Care Many homeowners treat their lawns with $CaCO_3(s)$ to reduce the acidity of the soil. Write a net ionic equation for the reaction of $CaCO_3(s)$ with a strong acid.

Titrations

Problems

How many milliliters of 0.250 *M* NaOH are required to neutralize the following solutions?

1. 60.0 mL of 0.0750 *M* HCl
2. 35.0 mL of 0.226 *M* HNO_3
3. 75.0 mL of 0.190 *M* H_2SO_4

How many milliliters of 0.250 *M* HNO_3 are needed to neutralize the following solutions?

1. 25.0 mL of 0.395 *M* KOH

78.6 m2L. of 0.0100 M $Al(OH)_3$
65.9 m3L. of 0.475 M NaOH

If 22.4 mL of 0.25 M sodium hydroxide are required to neutralize 15.0 mL of a hydroiodic acid solution, how many grams of hydrogen iodide were dissolved in the solution?

If 12.5 mL of 0.10 M hydrobromic acid are required to neutralize 25.0 mL of a calcium hydroxide solution, how many grams of calcium hydroxide were dissolved in the solution?

The solubility of slaked lime, $Ca(OH)_2$, in water at 20°C is 0.185 g/100.0 mL. What volume of 0.00100 M HCl is needed to neutralize 10.0 mL of a saturated $Ca(OH)_2$ solution?

The solubility of magnesium hydroxide, $Mg(OH)_2$, in water is 9.0×10^{-4} g/100.0 mL at 20°C. What volume of 0.00100 M HNO_3 is required to neutralize 1.00 L of saturated $Mg(OH)_2$ solution?

A 10.0 mL dose of the antacid in Figure P4.73 contains 830 mg of magnesium hydroxide. What volume of 0.10 M stomach acid (HCl) could one dose neutralize?

MIL
MAGNE
LAXATIVE/ANTACI
ALWAYS STIMULANT FREE!
EFFECTIVE OVERNIGHT RELIEF
ORIGINAL
12 FL OZ (355 mL)

FIGURE P4.73

Exercise Physiology The ache, or "burn," you feel in your muscles during strenuous exercise is related to the accumulation of lactic acid, which has the structure shown in Figure P4.74. Only the hydrogen atom in the − COOH group is acidic, that is, can be released as an H^+ ion in aqueous solutions. To determine the concentration of a solution of lactic acid, a chemist titrates a 20.00 mL sample of it with 0.1010 *M* NaOH and finds that 12.77 mL of titrant is required to reach the equivalence point. What is the concentration of the lactic acid solution in moles per liter?

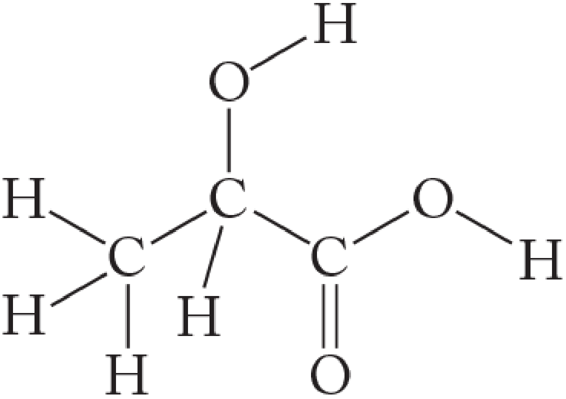

FIGURE P4.74

Precipitation Reactions

Concept Review

What is the difference between a saturated solution and a supersaturated solution?

When two aqueous solutions of ionic compounds are mixed but no precipitate forms, what does this suggest about the overall ionic equation?

An aqueous solution containing Ca^{2+}, Cl^-, CO_3^{2-}, and NO_3^- is allowed to evaporate. Which compound will precipitate first?

A precipitate may appear when two completely clear aqueous solutions are mixed. What circumstances are responsible for this event?

Is a saturated solution always a concentrated solution? Explain.

Behavior of Honey Honey is a concentrated solution of sugar molecules in water. Clear, viscous honey becomes cloudy after being stored for long periods. Explain how this transition illustrates supersaturation.

Problems

According to the solubility rules in Table 4.4 and Table 4.5, which of the following compounds have limited solubility in water? (a) barium sulfate; (b) barium hydroxide; (c) lanthanum nitrate; (d) sodium acetate; (e) lead hydroxide; (f) calcium phosphate

Ocean Vents The black "smoke" that flows out of deep ocean hydrothermal vents (Figure P4.82) consists of metal sulfides suspended in seawater. Of the following cations that are present in the water flowing up through these vents, which ones could contribute to the formation of the black smoke? Na^+, Li^+, Mn^{2+}, Fe^{2+}, Ca^{2+}, Mg^{2+}, Zn^{2+}, Pb^{2+}, Cu^{2+}

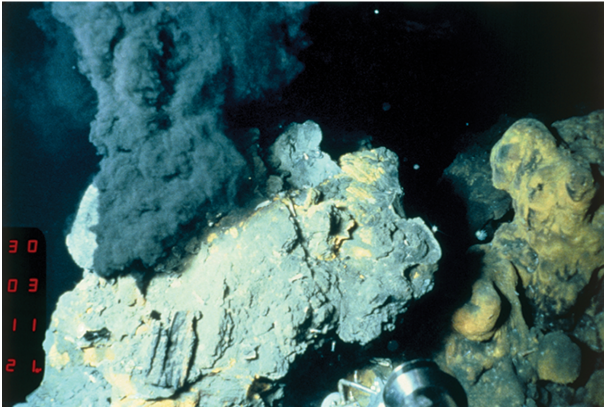

FIGURE P4.82

Complete and balance the molecular equations for the precipitation reactions, if any, between the following pairs of reactants, and write the overall and net ionic equations.

1. $Pb(NO_3)_2(aq) + Na_2SO_4(aq) \rightarrow$
2. $NiCl_2(aq) + NH_4NO_3(aq) \rightarrow$
3. $FeCl_2(aq) + Na_2S(aq) \rightarrow$
4. $MgSO_4(aq) + BaCl_2(aq) \rightarrow$

Complete and balance the molecular equations for the precipitation reactions, if any, between aqueous solutions of the following pairs of reactants, and write the overall and net ionic equations.

1. ammonium acetate and potassium sulfide
2. strontium hydroxide and lithium phosphate
3. silver nitrate and hydrochloric acid
4. lithium fluoride and potassium chloride

Calculate the mass of $MgCO_3$ precipitated by mixing 10.0 mL of a 0.200 *M* Na_2CO_3 solution with 5.00 mL of 0.0500 *M* $Mg(NO_3)_2$ solution.

Toxic chromate can be precipitated from an aqueous solution by bubbling SO_2 through the solution. How many grams of SO_2 are required to treat 3.0×10^8 L of 0.050 m*M* CrO_4^-?

$$2\ CrO_4^{2-}(aq) + 3\ SO_2(g) + 4\ H^+(aq) \rightarrow Cr_2(SO_4)_3(s) + 2\ H_2O(\ell)$$

Iron(II) can be precipitated from a slightly basic aqueous solution by bubbling oxygen through the solution, which converts soluble $Fe(OH)^+$ to practically insoluble $Fe(OH)_3$. How many grams of O_2 are consumed to precipitate all of the iron in 75 mL of 0.090 *M* iron(II)?

$$4\ Fe(OH)^+(aq) + 4\ OH^-(aq) + O_2(g) + 2\ H_2O(\ell) \rightarrow 4\ Fe(OH)_3(s)$$

Given the following equation, how many grams of $PbCO_3$ will dissolve when 1.00 L of 1.00 *M* H^+ is added to 5.00 g of $PbCO_3$?

$$PbCO_3(s) + 2\ H^+(aq) \rightarrow Pb^{2+}(aq) + H_2O(\ell) + CO_2(g)$$

Treating Drinking Water Phosphate can be removed from drinking-water supplies by treating the water with $Ca(OH)_2$. How much $Ca(OH)_2$ is required to remove 90% of the PO_4^{3-} from 4.5×10^6 L of drinking water containing 25 mg/L of PO_4^{3-}?

$$5\ Ca(OH)_2(aq) + 3\ PO_4^{3-}(aq) \rightarrow Ca_5OH(PO_4)_3(s) + 9\ OH^-(aq)$$

Toxic cyanide ions can be removed from wastewater by adding hypochlorite.

$$2\ CN^-(aq) + 5\ OCl^-(aq) + H_2O(\ell) \rightarrow N_2(g) + 2\ HCO_3^-(aq) + 5\ Cl^-(aq)$$

1. If 1.50×10^3 L of 0.125 *M* OCl^- is required to remove the CN^- in 3.4×10^6 L of wastewater, what is the CN^- concentration in the water in mg/L?
2. How many milliliters of 0.575 *M* $AgNO_3$ would you need to add to a 50.00 mL aliquot of the final solution (consider the volumes simply additive) to precipitate the chloride ions formed in the reaction?

For each of the following aqueous mixtures, determine which ionic concentrations decrease and which remain the same.

1. Sodium chloride and silver nitrate are dissolved in 100 mL of water.
2. Equimolar amounts of sodium hydroxide and hydrochloric acid react.
3. Ammonium sulfate and potassium bromide are dissolved in 100 mL of water.

For each of the following aqueous mixtures, determine which ionic concentrations decrease and which remain the same.

1. Sodium chloride and iron(II) chloride are dissolved in 100 mL of water.

2. Equimolar amounts of sodium carbonate and sulfuric acid react.
3. Potassium sulfate and barium nitrate are dissolved in 100 mL of water.

Oxidation–Reduction Reactions: Electron Transfer

Concept Review

How are the gains or losses of electrons related to changes in oxidation numbers?

What is the sum of the oxidation numbers of the atoms in a molecule?

What is the sum of the oxidation numbers of all the atoms in each of the following polyatomic ions? (a) OH^-; (b) $NH_4{}^+$; (c) $SO_4{}^{2-}$; (d) $PO_4{}^{3-}$

Gold does not dissolve in concentrated H_2SO_4 but readily dissolves in H_2SeO_4 (selenic acid). Which acid is the stronger oxidizing agent?

Silver dissolves in sulfuric acid to form silver sulfate and H_2, but gold does not dissolve in sulfuric acid to form gold sulfate. Which of the two metals is the better reducing agent?

What is meant by a half-reaction?

When an electric current is passed through molten NaCl, the salt decomposes in much the way that water decomposes when current is passed through it (see Figure 1.6). Decomposition occurs via two half-reactions: reduction takes place at the negative electrode and oxidation takes place at the positive electrode. Write the two-half reactions that describe the decomposition of NaCl.

Electron gain is associated with ____ half-reactions, whereas electron loss is associated with ____ half-reactions.

Problems

Give the oxidation number of boron in each of the following: (a) HBO_2 (metaboric acid); (b) H_3BO_3 (boric acid); (c) $Na_2B_4O_7$ (sodium borate).

Give the oxidation number of nitrogen in each of the following: (a) elemental nitrogen (N_2); (b) hydrazine (N_2H_4); (c) ammonium ion (NH_4^+).

Balance the following half-reactions by adding the appropriate number of electrons. Identify the oxidation half-reactions and the reduction half-reactions.

1. $Br_2(\ell) \rightarrow 2\ Br^-(aq)$
2. $Pb(s) + 2\ Cl^-(aq) \rightarrow PbCl_2(s)$
3. $O_3(g) + 2\ H^+(aq) \rightarrow O_2(g) + H_2O(\ell)$
4. $2\ H_2SO_3(aq) + H^+(aq) \rightarrow HS_2O_4^-(aq) + 2\ H_2O(\ell)$

Balance the following half-reactions by adding the appropriate number of electrons. Which are oxidation half-reactions, and which are reduction half-reactions?

1. $Fe^{2+}(aq) \rightarrow Fe^{3+}(aq)$
2. $AgI(s) \rightarrow Ag(s) + I^-(aq)$
3. $VO_2^+(aq) + 2\ H^+(aq) \rightarrow VO^{2+}(aq) + H_2O(\ell)$
4. $I_2(s) + 6\ H_2O(\ell) \rightarrow 2\ IO_3^-(aq) + 12\ H^+(aq)$

Balance the following net ionic reactions. Identify the oxidizing agent and the reducing agent. Identify which elements are oxidized and which are reduced:

1. $MnO_2(s) + HCl(aq) \rightarrow Mn^{2+}(aq) + Cl_2(g)$
2. $I_2(s) + S_2O_3^{2-}(aq) \rightarrow S_4O_6^{2-}(aq) + I^-(aq)$
3. $MnO_4^-(aq) + Fe^{2+}(aq) \rightarrow Mn^{2+}(aq) + Fe^{3+}(aq)$

Balance the following net ionic reactions. Identify the oxidizing agent and the reducing agent. Identify which elements are oxidized and which are reduced:

1. $MnO_4^-(aq) + S^{2-}(aq) \rightarrow MnO_2(s) + S(s)$
2. $IO_3^-(aq) + I^-(aq) \rightarrow I_2(s)$
3. $Mn^{2+}(aq) + BiO_3^-(aq) \rightarrow MnO_4^-(aq) + Bi^{3+}(aq)$

Earth's Crust The following chemical reactions have helped to shape Earth's crust. Determine the oxidation numbers of all the elements in the reactants and products, and identify which elements are oxidized and which are reduced.

1. $3\ SiO_2(s) + 2\ Fe_3O_4(s) \rightarrow 3\ Fe_2SiO_4(s) + O_2(g)$
2. $SiO_2(s) + 2\ Fe(s) + O_2(g) \rightarrow Fe_2SiO_4(s)$
3. $4\ FeO(s) + O_2(g) + 6\ H_2O(\ell) \rightarrow 4\ Fe(OH)_3(s)$

Determine the oxidation numbers of each of the elements in the following reactions, and identify which of them are oxidized or reduced, if any.

1. $SiO_2(s) + 2\ H_2O(\ell) \rightarrow H_4SiO_4(aq)$
2. $2\ MnCO_3(s) + O_2(g) \rightarrow 2\ MnO_2(s) + 2\ CO_2(g)$
3. $3\ NO_2(g) + H_2O(\ell) \rightarrow 2\ NO_3^-(aq) + NO(g) + 2\ H^+(aq)$

Combine the half-reaction for the reduction of O_2

$O_2(aq) + 4\ H^+(aq) + 4\ e^- \rightarrow 2\ H_2O(\ell)$

with the following oxidation half-reactions (which are based on common iron minerals) to develop complete redox reactions:

1. $2\ FeCO_3(s) + H_2O(\ell) \rightarrow Fe_2O_3(s) + 2\ CO_2(g) + 2\ H^+(aq) + 2\ e^-$
2. $3\ FeCO_3(s) + H_2O(\ell) \rightarrow Fe_3O_4(s) + 3\ CO_2(g) + 2\ H^+(aq) + 2\ e^-$
3. $2\ Fe_3O_4(s) + H_2O(\ell) \rightarrow 3\ Fe_2O_3(s) + 2\ H^+(aq) + 2\ e^-$

Uranium is found in Earth's crust as UO_2 and an assortment of compounds containing $UO_2{}^{n+}$ cations. Add the following pairs of reduction and oxidation equations to develop overall equations for converting soluble uranium polyatomic ions into practically insoluble UO_2.

1. $6\ H^+(aq) + UO_2(CO_3)_3{}^{4-}(aq) + 2\ e^- \rightarrow UO_2(s) + 3\ CO_2(g) + 3\ H_2O(\ell)$

   $Fe^{2+}(aq) + 3\ H_2O(\ell) \rightarrow Fe(OH)_3(s) + 3\ H^+(aq) + e^-$

2. $6\ H^+(aq) + UO_2(CO_3)_3{}^{4-}(aq) + 2\ e^- \rightarrow UO_2(s) + 3\ CO_2(g) + 3\ H_2O(\ell)$

   $HS^-(aq) + 4\ H_2O(\ell) \rightarrow SO_4{}^{2-}(aq) + 9\ H^+(aq) + 8\ e^-$

3. $2\ e^- + UO_2(HPO_4)_2{}^{2-}(aq) \rightarrow UO_2(s) + 2\ HPO_4{}^{2-}(aq)$

   $3\ OH^-(aq) \rightarrow H_2O(\ell) + HO_2{}^-(aq) + 2\ e^-$

Nitrogen in the hydrosphere is found primarily as ammonium ions and nitrate ions. Complete and balance the following chemical equation describing the oxidation of ammonium ions to nitrate ions in acid solution:

$NH_4{}^+(aq) + O_2(g) \rightarrow NO_3{}^-(aq)$

When Soil Smells Bad In sediments and waterlogged soil, dissolved O_2 concentrations are so low that the microorganisms living there must rely on other sources of oxygen for respiration. Some bacteria can extract the oxygen from sulfate ions, reducing the sulfur in them to hydrogen sulfide gas and giving the sediments or soil a distinctive rotten-egg odor.

1. What is the change in oxidation state of sulfur as a result of this reaction?
2. Write the balanced net ionic equation for the reaction, under acidic conditions, that releases O_2 from sulfate and

forms hydrogen sulfide gas.

Chromium is more toxic and more soluble in natural waters as $HCrO_4^-$ than as chromium(III) ion. In the presence of H_2S, the following reaction takes place in neutral solution:

$HCrO_4^-(aq) + H_2S(aq) \rightarrow Cr_2O_3(s) + SO_4^{2-}(aq)$

1. Assign oxidation numbers to the reactants and products.
2. Balance the equation.
3. How many electrons are transferred for each atom of chromium that reacts?

The water-soluble uranyl cation (UO_2^+) can be removed by reaction with methane gas:

$UO_2^+(aq) + CH_4(g) \rightarrow UO_2(s) + HCO_3^-(aq)$

1. Assign oxidation numbers to the reactants and products.
2. Balance the equation in acidic solution.
3. How many electrons are transferred for each atom of uranium that reacts?

The solubilities of Fe and Mn in freshwater streams are affected by changes in their oxidation states. Complete and balance the following redox equation in which soluble Mn^{2+} becomes solid MnO_2:

$Fe(OH)_2^+(aq) + Mn^{2+}(aq) \rightarrow MnO_2(s) + Fe^{2+}(aq)$

Bactericide and Virucide The water-soluble gas ClO_2 is known as an oxidative biocide. It destroys bacteria by oxidizing their cell walls and destroys viruses by attacking their viral envelopes. ClO_2 may be prepared for use as a decontaminating agent from several different starting materials in slightly acidic solutions. Complete and balance the following chemical equations for the synthesis of ClO_2.

1. $ClO_3^-(aq) + SO_2(g) \rightarrow ClO_2(g) + SO_4^{2-}(aq)$
2. $ClO_3^-(aq) + Cl^-(aq) \rightarrow ClO_2(g) + Cl_2(g)$
3. $ClO_3^-(aq) + Cl_2(g) \rightarrow ClO_2(g) + O_2(g)$

Refer to Table 4.6 to determine which of the following metals will reduce aqueous Fe^{2+} to iron metal: lead, copper, zinc, or aluminum.

Which ions will oxidize aluminum? Li^+; Ca^{2+}; Ag^+; Sn^{2+}

Through appropriate experiments, we could expand the activity series in Table 4.6 to include additional metals. If aluminum is oxidized by V^{3+} but aluminum does not reduce Sc^{3+}, where would you place vanadium and scandium in the activity series? Which metal would you test to firmly establish scandium's position?

If iron is oxidized by Cd^{2+} but iron does not reduce Ga^{3+}, where would you place cadmium and gallium in the activity series? Which metal would you test to firmly establish gallium's position?

Dichromate ion oxidizes Fe^{2+} ion in aqueous, acidic solution, producing Fe^{3+} and Cr^{3+} by the unbalanced chemical equation:

$$Cr_2O_7^{2-}(aq) + Fe^{2+}(aq) \rightarrow Fe^{3+} + 2\ Cr^{3+}(aq)$$

1. Balance the equation.
2. If 15.2 mL of 0.135 *M* $Cr_2O_7^{2-}$ is required to completely react with 100.0 mL of Fe^{2+}, what is the concentration of the Fe^{2+} solution?

Ozone (O_3) reacts with iodide ion (I^-) in basic solution to form O_2 and I_2 by the following unbalanced chemical equation:

$O_3(aq) + I^-(aq) \rightarrow O_2(g) + I_2(aq)$

1. Balance the equation.
2. A saturated solution of ozone in 125 mL of water at 0°C is treated with 10 mL of 2.0 *M* KI. After the reaction is complete, the solution is titrated with 0.100 *M* H^+. If 54.7 mL of acid is needed, what is the concentration of O_3 in a saturated solution?

Additional Problems

A puddle of coastal seawater, caught in a depression formed by some coastal rocks at high tide, begins to evaporate on a hot summer day as the tide goes out. If the volume of the puddle decreases to 23% of its initial volume, what is the concentration of Na^+ after evaporation if initially it was 0.449 *M*?

Antifreeze Ethylene glycol is the common name for the liquid used to keep the coolant in automobile cooling systems from freezing. It is 38.7% carbon, 9.7% hydrogen, and 51.6% oxygen by mass. Its molar mass is 62.07 g/mol, and its density is 1.106 g/mL at 20°C.

1. What is the empirical formula of ethylene glycol?
2. What is the molecular formula of ethylene glycol?
3. In a solution prepared by mixing equal volumes of water and ethylene glycol, which ingredient is the solute, and which is the solvent?

According to the label on a bottle of concentrated hydrochloric acid, the contents are 36.0% HCl by mass and have a density of 1.18 g/mL.

1. What is the molarity of concentrated HCl?
2. What volume of it would you need to prepare 0.250 L of 2.00 *M* HCl?
3. What mass of sodium hydrogen carbonate would be needed to neutralize the spill if a bottle containing 1.75 L of concentrated HCl dropped on a lab floor and

broke open?

4. What is the molarity of concentrated HCl?
5. What volume of it would you need to prepare 0.250 L of 2.00 *M* HCl?
6. What mass of sodium hydrogen carbonate would be needed to neutralize the spill if a bottle containing 1.75 L of concentrated HCl dropped on a lab floor and broke open?

Why is $HSO_4^-(aq)$ a weaker acid than $H_2SO_4(aq)$?

Synthesis and Toxicity of Chlorine Chlorine was first prepared in 1774 by heating a mixture of NaCl and MnO_2 in sulfuric acid:

$$NaCl(aq) + H_2SO_4(aq) + MnO_2(s) \rightarrow Na_2SO_4(aq) + MnCl_2(aq) + H_2O(l) + Cl_2(g)$$

1. Assign oxidation numbers to the elements in each compound and balance the redox reaction in acid solution.
2. Write a net ionic equation describing the reaction for the formation of chlorine.
3. If chlorine gas is inhaled, it causes pulmonary edema (fluid in the lungs) because it reacts with water in the alveolar sacs of the lungs to produce the strong acid HCl and the weaker acid HOCl. Balance the equation for the conversion of Cl_2 to HCl and HOCl.

When a solution of dithionate ions ($S_2O_4^{2-}$) is added to a solution of chromate ions (CrO_4^{2-}), the products of the reaction under basic conditions include soluble sulfite ions and solid chromium(III) hydroxide. This reaction is used to remove chromium(VI) from wastewater generated by factories that make chrome-plated metals.

1. Write the net ionic equation for this redox reaction.
2. Which element is oxidized and which is reduced?
3. Identify the oxidizing and reducing agents in this reaction.

4. How many grams of sodium dithionate would be needed to remove the chromium(VI) in 100.0 L of wastewater that contains 0.00148 *M* chromate ion?

An Iron Battery A prototype battery based on iron compounds with large, positive oxidation numbers was developed in 1999. In the following reactions, assign oxidation numbers to the elements in each compound and balance the redox reactions in basic solution.

1. $FeO_4^{2-}(aq) + H_2O(\ell) \rightarrow FeO(OH)(s) + O_2(g) + OH^-(aq)$
2. $FeO_4^{2-}(aq) + H_2O(\ell) \rightarrow Fe_2O_3(s) + O_2(g) + OH^-(aq)$

Polishing Silver Silver tarnish is the result of silver metal reacting with sulfur compounds, such as H_2S, in the air. The tarnish on silverware (Ag_2S) can be removed by soaking in a solution of $NaHCO_3$ (baking soda) in a basin lined with aluminum foil.

1. Write a balanced equation for the tarnishing of Ag to Ag_2S and assign oxidation numbers to the reactants and products. How many electrons are transferred per mole of silver?
2. Write a balanced equation for the reaction of Ag_2S with Al metal, $NaHCO_3$, and water to produce $Al(OH)_3$, H_2S, H_2, and Ag metal.

Many nonmetal oxides react with water to form acidic solutions. Give the formula and name for the acids produced from the following reactions:

1. $P_4O_{10}(s) + 6\ H_2O(\ell) \rightarrow$
2. $SeO_2(s) + H_2O(\ell) \rightarrow$
3. $B_2O_3(s) + 3\ H_2O(\ell) \rightarrow$

Write overall and net ionic equations for the reactions that occur when

1. a sample of acetic acid is titrated with a solution of KOH.

2. a solution of sodium carbonate is mixed with a solution of calcium chloride.
3. calcium oxide dissolves in water.

Write both the molecular equation and the net ionic equation for each of the following reactions.

1. a neutralization reaction that results in the formation of sodium fluoride
2. a precipitation reaction that results in the formation of strontium sulfate
3. a redox reaction that results in the formation of potassium chloride

Wastewater Treatment Show with appropriate net ionic equations how Cr^{3+} and Cd^{2+} can be removed from wastewater by treatment with solutions of sodium hydroxide.

Fluoride Ion in Drinking Water Sodium fluoride is added to drinking water in many municipalities to protect teeth against cavities. The target of the fluoridation is hydroxyapatite, $Ca_{10}(PO_4)_6(OH)_2$, a compound in tooth enamel. There is concern, however, that fluoride ions in water may contribute to skeletal fluorosis, an arthritis-like disease.

1. Write a net ionic equation for the reaction between hydroxyapatite and sodium fluoride that produces fluorapatite, $Ca_{10}(PO_4)_6F_2$.
2. The EPA currently restricts the concentration of F^- in drinking water to 4 mg/L. Express this concentration of F^- in molarity.
3. One study of skeletal fluorosis suggests that drinking water with a fluoride concentration of 4 mg/L for 20 years raises the fluoride content in bone to 6 mg/g, a level at which a patient may experience stiff joints and other symptoms. How much fluoride (in milligrams) is present in a 100 mg sample of bone with this fluoride concentration?

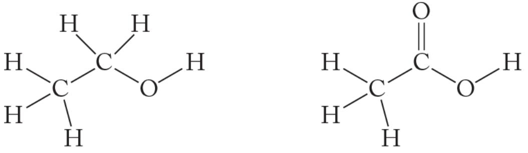
Rocket Fuel in Drinking Water Near Las Vegas, NV, improper disposal of perchlorates used to manufacture rocket fuel has contaminated a stream that flows into Lake Mead, the largest artificial lake in the United States and a major supply of drinking and irrigation water for the American Southwest. The EPA has proposed an advisory range for perchlorate concentrations in drinking water of 4 to 18 μg/L. The perchlorate concentration in the stream averages 700.0 μg/L, and the stream flows at an average rate of 609 million liters per day.

1. What are the formulas of sodium perchlorate and ammonium perchlorate?
2. How many kilograms of perchlorate flow from the Las Vegas stream into Lake Mead each day?
3. What volume of perchlorate-free lake water would have to mix with the stream water each day to dilute the stream's perchlorate concentration from 700.0 to 4 μg/L?
4. Since 2008, Maryland (MD), Massachusetts (MA), and New Mexico (NM) have limited perchlorate concentrations in drinking water to 0.1 μg/L. Five replicate samples were analyzed for perchlorates by laboratories in each state, and the following data (μg/L) were collected:

MD	MA	NM
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]

Which of the labs produced the most precise analytical results?

Making Apple Cider Vinegar Some people who prefer natural foods make their own apple cider vinegar. They start with freshly squeezed apple juice that contains about 6% natural sugars. These sugars, which all have nearly the same empirical formula, CH_2O, are fermented with yeast in a chemical reaction that produces equal numbers of moles of ethanol (Figure P4.137a) and carbon dioxide. The product of this fermentation, called hard cider, undergoes an acid fermentation step in which ethanol and dissolved oxygen gas react to form acetic acid (Figure P4.137b) and water. This acetic acid is the principal solute in vinegar.



Ethanol $CH_3—CH_2—OH$ (a)

Acetic acid $CH_3—COOH$ (b)

FIGURE P4.137

---

1. Write a balanced chemical equation describing the fermentation of natural sugars to ethanol and carbon dioxide. You may use the empirical formula, CH_2O.
2. Write a balanced chemical equation describing the acid fermentation of ethanol to acetic acid.
3. What are the oxidation states of carbon in the reactants and products of the two fermentation reactions?
4. If a sample of apple juice contains 1.00×10^2 g of natural sugar, what is the maximum quantity of acetic acid that could be produced by the two fermentation reactions?

Acidic Mine Drainage Water draining from abandoned mines on Iron Mountain in California is extremely acidic and leaches iron, zinc, and other metals from the underlying rock (Figure P4.138). One liter of drainage contains as much as 80.0 g of dissolved iron and 6 g of zinc.

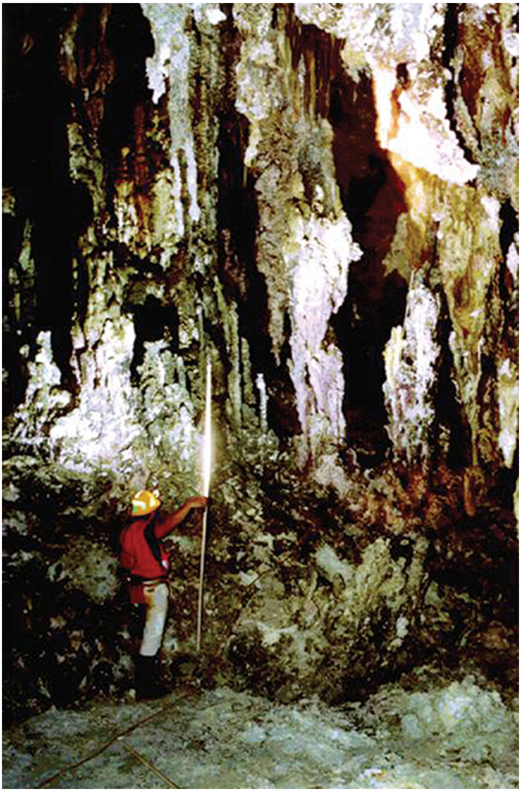


FIGURE P4.138

1. Calculate the molarity of iron and of zinc in the drainage.
2. One source of the dissolved iron is the reaction between water containing H_2SO_4 and solid $Fe(OH)_3$. Complete the following chemical equation and write a net ionic equation for the process.

$$2\ Fe(OH)_3(s) + 3\ H_2SO_4(aq) \rightarrow$$

3. Sources of zinc include the mineral smithsonite, $ZnCO_3$. Write a balanced net ionic equation for the reaction between smithsonite and H_2SO_4 that produces $Zn^{2+}(aq)$.
4. One member of a class of minerals called ferrites is found to contain a mixture of zinc(II), iron(II), and iron(III) oxides. The generic formula for the mineral is $Zn_xFe_12_xO \cdot Fe_2O_3$. If acidic mine

waste flowing through a deposit of this mineral contains 80 g of Fe and 6 g of Zn as a result of dissolution of the mineral, what is the value of x in the formula of the mineral in the deposit?

A food chemist determines the concentration of acetic acid in a sample of apple cider vinegar (see Problem 4.137) by acid–base titration. The density of the sample is 1.01 g/mL. The titrant is 1.002 *M* NaOH. The average volume of titrant required to titrate 25.00 mL aliquots of the vinegar is 20.78 mL. What is the concentration of acetic acid in the vinegar? Express your answer the way a food chemist probably would: as percent by mass.

One way to follow the progress of a titration and detect its equivalence point is by monitoring the conductivity of the titration reaction mixture. For example, consider the way the conductivity of a sample of sulfuric acid changes as it is titrated with a standard solution of barium hydroxide before and then after the equivalence point.

1. Write the overall ionic equation for the titration reaction.
2. Which of the four graphs in Figure P4.140 comes closest to representing the changes in conductivity during the titration? (The zero point on the y-axis of these graphs represents the conductivity of pure water; the break points on the x-axis represent the equivalence point.)

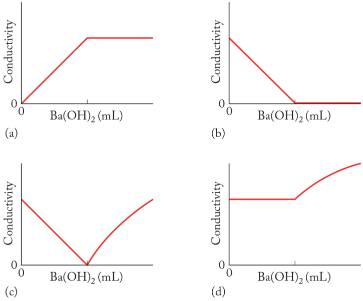

FIGURE P4.140

Which of the graphs in Figure P4.141 best represents the changes in conductivity that occur before and after the equivalence point in each of the following titrations:

sample =1$AgNO_3(aq)$; titrant = $KCl(aq)$
sample =2$HCl(aq)$; titrant = $LiOH(aq)$
sample =3$CH_3COOH(aq)$; titrant = $NaOH(aq)$

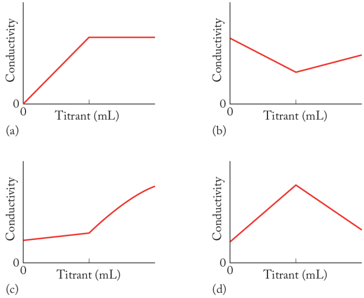

FIGURE P4.141

When electrodes connected to a light bulb are inserted into an aqueous solution of acetic acid, the bulb glows dimly. Will the bulb become brighter, remain the same, or turn off after one equivalent of aqueous NaOH is added to the solution? Write a balanced net ionic equation that supports your answer.

When electrodes connected to a light bulb are inserted into a beaker containing silver carbonate and water, will the bulb not glow, glow dimly, or glow brightly? What do you think will happen after addition of one equivalent of aqueous HCl? Write a balanced net ionic equation that supports your answer.

Superoxide Dismutases Oxygen in the form of superoxide ions (O_2^-) is quite hazardous to human health. Superoxide dismutases are enzymes that convert superoxide ions to hydrogen peroxide and oxygen by the unbalanced chemical equation:

$$O_2^-(aq) + H^+(aq) \rightarrow H_2O_2(aq) + O_2(aq)$$

Identify 1the oxidation and reduction half-reactions.

2. Balance the equation.

Nitrogen-Fixing Bacteria Bacteria found among the roots of legumes perform an important biological function, converting nitrogen to ammonia in a process known as nitrogen fixation. The electrons required for this redox reaction are supplied by enzymes called nitrogenases that contain transition metals. The unbalanced chemical equation for this process is

$$N_2(g) + H^+(aq) + M^{2+}(aq) \rightarrow NH_3(aq) + H_2(g) + M^{3+}(aq)$$

where M represents a transition metal such as iron. Nitrification is a multistep process in which the nitrogen in organic and inorganic compounds is biochemically oxidized. Bacteria and fungi are responsible for a part of the *nitrification process* described by the reaction:

$$NH_4{}^+(aq) + M^{3+}(aq) \rightarrow NO_2{}^-(aq) + M^{2+}(aq)$$

1. What are the oxidation numbers of nitrogen in the reactants and products of each reaction?
2. Which compounds or ions are being reduced in each reaction?
3. Balance the equations in acidic solution.

Formations in Caves The stalactites and stalagmites in most caves are made of limestone (calcium carbonate; see Figure 4.14). In the Lower Kane Cave in Wyoming, however, they are made of gypsum (calcium sulfate). The presence of $CaSO_4$ is explained by the following sequence of reactions:

$$H_2S(aq) + 2\ O_2(g) \rightarrow H_2SO_4(aq)$$

$$H_2SO_4(aq) + CaCO_3(s) \rightarrow CaSO_4(s) + H_2O(\ell) + CO_2(g)$$

1. Which (if either) of these reactions is a redox reaction? How many electrons are transferred?

2. Write a net ionic equation for the reaction of H_2SO_4 with $CaCO_3$.
3. How would the net ionic equation differ if the reaction were written as follows?

$H_2SO_4(aq) + CaCO_3(s) \rightarrow CaSO_4(s) + H_2CO_3(aq)$

Balance this net ionic reaction and answer the questions that follow:

$BrO_3^-(aq) + Br^-(aq) \rightarrow Br_2(aq)$

1. Is $BrO_3^-(aq)$ reduced?
2. What is the product of $BrO_3^-(aq)$ reduction in this reaction?
3. Is $Br^-(aq)$ oxidized?
4. What is the product of $Br^-(aq)$ oxidation in this reaction?

Which of the following reactions of calcium compounds is/are redox reactions?

1. $CaCO_3(s) \rightarrow CaO(s) + CO_2(g)$
2. $CaO(s) + SO_2(g) \rightarrow CaSO_3(s)$
3. $CaCl_2(s) \rightarrow Ca(s) + Cl_2(g)$
4. $3\ Ca(s) + N_2(g) \rightarrow Ca_3N_2(s)$

Preparation of Fluorine Gas HF is prepared by reacting CaF_2 with H_2SO_4:

$CaF_2(s) + H_2SO_4(\ell) \rightarrow 2\ HF(g) + CaSO_4(s)$

HF can in turn be electrolyzed when dissolved in molten KF to produce fluorine gas:

$2\ HF(\ell) \rightarrow F_2(g) + H_2(g)$

Fluorine is extremely reactive, so it is typically sold as a 5% mixture by volume in an inert gas such as helium. How much CaF_2 is required to produce 500.0 L of 5% F_2 in helium? Assume the density of F_2 gas is 1.70 g/L.

Glossary

concentration

the amount of a solute in a given mass or volume of solvent or solution.

solute

any component in a solution other than the solvent; a solution may contain one or more solutes.

solvent

the component of a solution that is present in the largest number of moles.

molarity (M)

the concentration of a solution expressed in moles of solute per liter of solution ($M = n/V$).

dilution

the process of lowering the concentration of a solution by adding more solvent.

stock solution

a concentrated solution of a substance used to prepare solutions of lower concentration.

Beer’s law

the relation of the absorbance of a solution (A) to concentration (c), the light’s path length (b), and the solute’s molar absorptivity (ε) by the equation $A = \varepsilon bc$.

molecular equation

an equation describing a reaction in solution in which the reactants and products are written as neutral compounds.

overall ionic equation

an equation describing a reaction in solution that shows all the species, both ionic and molecular, present in the reaction mixture.

net ionic equation

an equation describing a reaction in solution that contains only the species changed by the reaction; it is obtained by eliminating the spectator ions from the overall ionic equation.

spectator ion

an ion present in a reaction mixture in solution that is unchanged by the reaction; spectator ions appear in overall ionic equations but not in net ionic equations.

strong electrolyte

a substance that dissociates completely into ions when it dissolves in water.

weak electrolyte

a substance that dissolves in water with most molecules staying intact, but with a small fraction dissociating into ions.

nonelectrolyte

a substance that does *not* dissociate into ions and therefore does *not* result in conductivity when dissolved in water.

neutralization reaction

a reaction that takes place when an acid reacts with a base and produces a solution of a salt in water.

acid (Brønsted–Lowry acid)

a proton donor.

base (Brønsted–Lowry base)

a proton acceptor.

titration

an analytical method for determining the concentration of a solute in a sample by reacting the solute with a standard solution of known concentration.

titrant

the standard solution added to the sample in a titration.

equivalence point

the point in a titration at which just enough titrant has been added to completely react the substance being analyzed.

solubility

the maximum amount of a substance that dissolves in a given volume of solution at a given temperature.

precipitation reaction

a reaction that produces a slightly soluble product upon mixing two solutions.

reduction

a chemical change in which a species gains electrons; the oxidation number of the species decreases.

oxidation

a chemical change in which a species loses electrons; the oxidation number of the species increases.

activity series

a high-to-low ranking of metals based on their strengths as reducing agents.

oxidation number (O.N.) (also called oxidation state)

a positive or negative number based on the number of electrons an atom gains or loses when it forms an ion, or that it shares when it forms a covalent bond with another element; pure elements have an oxidation number of zero.

oxidation number (O.N.) (also called oxidation state)

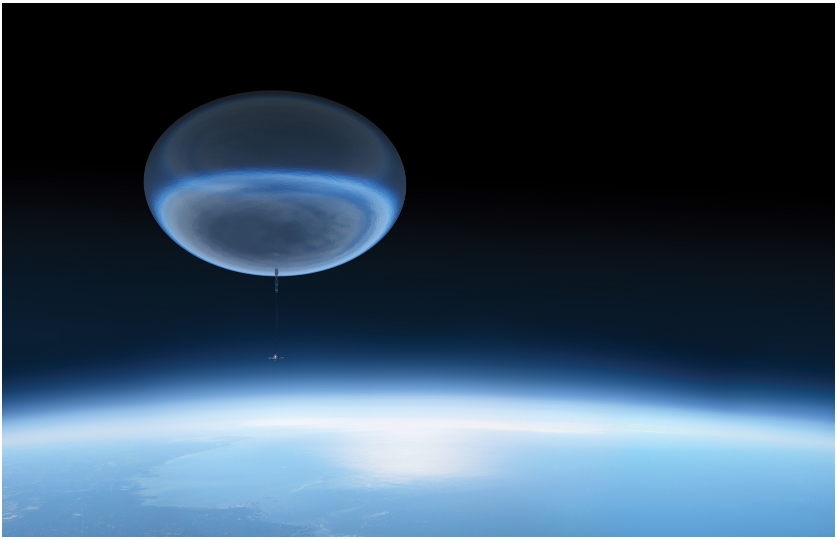
a positive or negative number based on the number of electrons an atom gains or loses when it forms an ion, or that it shares when it forms a covalent bond with another element; pure elements have an oxidation number of zero.

absorbance (A)

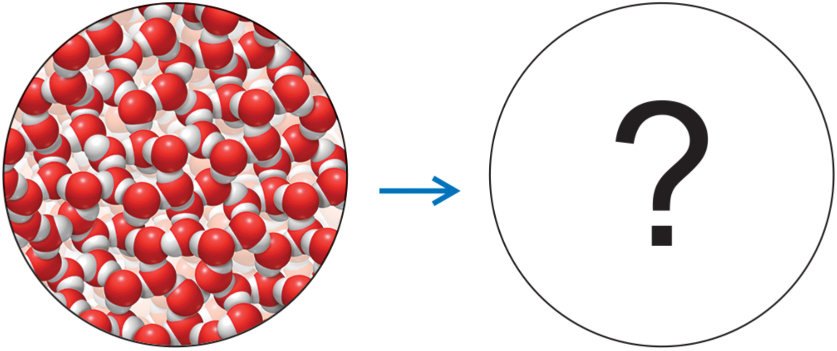
a measure of the quantity of light absorbed by a sample.

molar absorptivity (ϵ)

a measure of how well a compound or ion absorbs light.



THE AIR WE BREATHE An enormous balloon like the one in this photograph is scheduled to lift NASA’s Galactic/Extragalactic Spectroscopic Terahertz Observatory into the sky above Antarctica in December 2021. Its mission is to study the composition of trace gases and dust that are found between stars.



5

Properties of Gases
The Air We Breathe

PARTICULATE REVIEW

Particles in the Gas Phase

In Chapter 5 we focus on the properties of gases, including those that serve as fuels in combustion reactions, as described in Chapter 3, and in other forms of energy production. One such fuel is hydrogen gas, which can be produced by passing an electric current through water, causing molecules of liquid H_2O to decompose into molecules of H_2 and O_2 gas.

- Write a balanced chemical equation describing this decomposition reaction.
- In the circle on the right, draw the products that would be produced by decomposition of six of the water molecules on the left.
- Classify the products as elements, compounds, or a mixture. Choose all that apply.

(Review Sections 1.1, 1.2, and 3.3 if you need help.)

(Answers to Particulate Review questions are in the back of the book.)

PARTICULATE PREVIEW

Pressure, Volume, and Temperature

As you read Chapter 5, look for ideas that will help you answer these questions.

- Draw particulate images of the helium in the tank and in the balloon. How do these drawings differ?
- Suppose the tank and several helium-filled balloons are placed in the trunk of a car on a hot summer day.

- ○ How would your particulate image for the helium in the balloon change?
- ○ How would your particulate image for the helium in the tank change?

Learning Outcomes

- LO1 Describe how gas pressure is measured and convert between the different units used to express gas pressure

  Sample Exercises 5.1, 5.2

- LO2 Use the individual, combined, and ideal gas laws to relate changes in the volume, temperature, pressure, and number of moles of a gas and express these changes quantitatively

  Sample Exercises 5.3, 5.4, 5.5, 5.6, 5.7

- LO3 Relate the volumes of gas phase reactants and products to the quantities of other reactants and products by using the stoichiometry of a reaction and the ideal gas law

  Sample Exercises 5.8, 5.9

- LO4 Relate the density of a gas to its molar mass, temperature, and pressure

  Sample Exercises 5.10, 5.11

- LO5 Determine the mole fraction and partial pressure of a gas in a mixture of gases

  Sample Exercises 5.12, 5.13, 5.14

- LO6 Use kinetic molecular theory to explain the physical properties of gases
- LO7 Relate the root-mean-square speed of a gas and its rate of effusion and diffusion to its temperature and molar mass

Sample Exercises 5.15, 5.16

- LO8 Explain the molecular origins of nonideal behavior of real gases at high temperatures and low pressures and relate such behavior to the terms in the van der Waals equation

  Sample Exercise 5.17

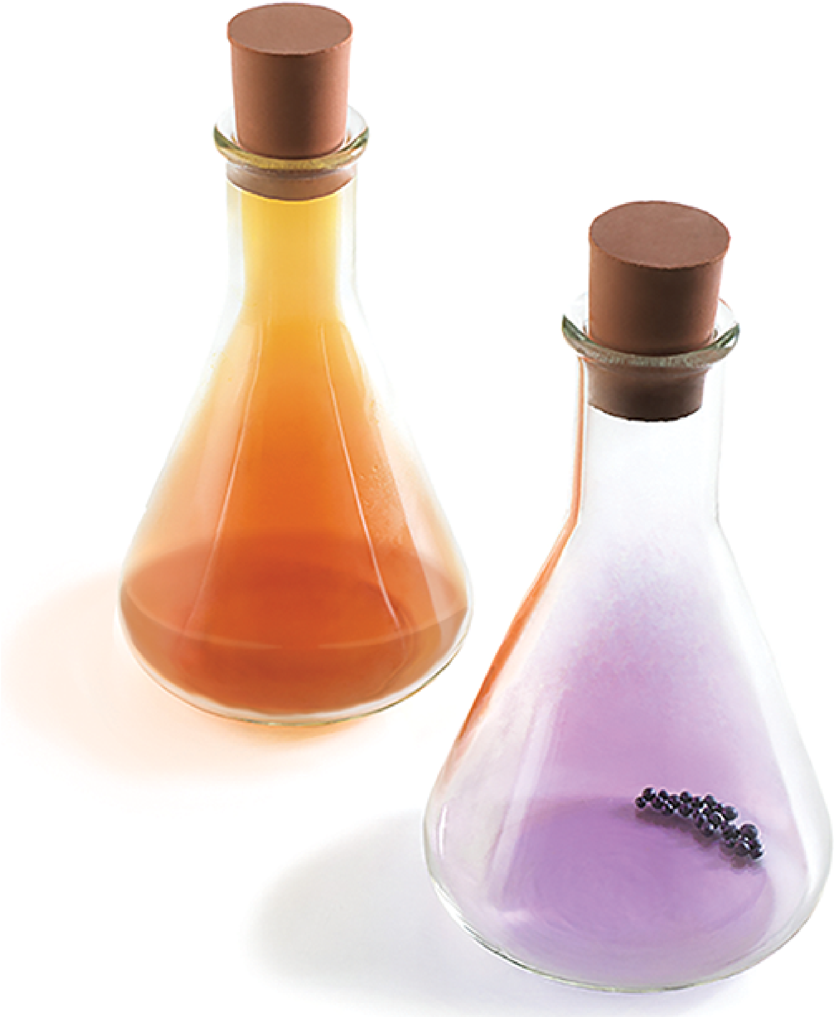


FIGURE 5.1 The space above crystals of solid iodine fill with purple iodine vapor, and the space above a puddle of liquid bromine fills with orange-brown bromine vapor. The solid and liquid phases of these elements are hundreds of times denser than the vapors above them.

5.1 Air: An Invisible Necessity

How often do you think about air? You probably remember how important air is when you don't have enough of it, such as when you dive into a pool of water or hike to the top of a tall mountain. Otherwise you probably don't give much thought to breathing or to the mixture of gases that make up the air you breathe. You may not think much about the oxygen needed to stay alive because it is colorless, tasteless, odorless—and free. But the exchange of gases between your lungs and the surrounding atmosphere is crucial to life. Air is an invisible necessity.

Having the right mixture of gases in our bodies is critical during surgery, which is why anesthesiologists in a hospital operating room constantly monitor levels of oxygen and carbon dioxide in the blood. The management of the delicate balance of gases entering and leaving a patient can mean the difference between a normal recovery and an irreversible coma.

TABLE 5.1 Composition of Dry Air[a]

Component	% (by volume)
Nitrogen	78.08
Oxygen	20.95
Argon	0.934
Carbon dioxide	0.0409[b]
Neon	0.0018
Helium	0.00052
Methane	0.00018
Hydrogen	0.00011

We have seen how dissolved compounds react in aqueous solution. Chemical reactions also take place in the gas phase, and gases are intimately involved in chemical reactions in living systems and the material world. Most life in our biosphere requires oxygen. Insects, birds, mammals, plants, and even underwater organisms need O_2 to metabolize nutrients.

How do gases differ from solids and liquids? Gases have neither definite volumes nor definite shapes; they expand to occupy the entire volume of their container and assume the container's shape. Under everyday conditions, other properties also distinguish gases from liquids and solids:

1. Unlike the volume occupied by a liquid or solid, the volume occupied by a gas changes significantly with pressure. If we carry an inflated balloon from sea level (0 m) to the top of a 1600-m mountain, the balloon volume increases by about 20%. The volume of a liquid or solid is unchanged under these conditions.
2. The volume of a gas changes with temperature. For example, the volume of a balloon filled with room-temperature air (~20°C) decreases about 7% when the balloon is taken outside on a cold winter's day (~0°C), whereas the volume of a liquid or solid remains practically unchanged by this modest temperature change.
3. Gases are miscible, which means they can be mixed in any proportion (unless they chemically react with one another). A hospital patient experiencing respiratory difficulties may be given a mixture of nitrogen and oxygen in which the proportion of oxygen is much higher than its proportion in air. Alternatively, a scuba diver may leave the ocean surface with a tank of air containing a homogeneous mixture of 17% oxygen, 34% nitrogen, and 49% helium. In contrast, many liquids are immiscible, such as oil and water.
4. Gases are typically much less dense than liquids or solids (**Figure 5.1**). One indicator of this large difference is that gas densities are expressed in grams per *liter*, whereas liquid densities are expressed in grams per *milliliter*. The density of dry air at 20°C and typical atmospheric pressure is 1.20 g/L, for example, whereas the density of liquid water under the same conditions is 1.00 g/mL—more than 800 times greater than the density of dry air.

These four observations about gases are consistent with the idea that the particles of a gas (be they molecules or atoms) are farther apart than the particles in solids and liquids. The larger spaces between the molecules in air, for example, make it possible to compress air into scuba tanks. Greater distances between molecules also account for both the lower densities and the miscibility of gases.

Glossary

miscible

capable of being mixed in any proportion.

Endnotes

Decomposition of $CaCO_3$ during sample roasting produces CO_2, the partial pressure of which is detected by the manometer.

5.2 Atmospheric Pressure and Collisions

Earth is surrounded by a layer of gases 50 km thick. We call this mixture of gases either *air* or *the atmosphere*. By volume it is composed primarily of nitrogen (78%) and oxygen (21%), with lesser amounts of other gases (**Table 5.1**). To put the thickness of the atmosphere in perspective: if Earth were the size of an apple, the atmosphere would be about as thick as the apple's skin.

Earth's atmosphere is pulled toward Earth by gravity and exerts a force that is spread across the entire surface of the planet (**Figure 5.2**). The molecules of N_2 and O_2 (along with the other elements and compounds in Table 5.1) are in constant motion in the atmosphere. As these molecules collide with one another and with the surface of Earth, the force of each collision creates pressure (P). Pressure is defined as the ratio of force (F) to surface area (A):

The force exerted by the atmosphere of colliding atoms and molecules on Earth's surface is called atmospheric pressure (P_{atm}).

Atmospheric pressure is measured with an instrument called a barometer. A simple but effective barometer design consists of a tube nearly 1 m long, filled with mercury, and closed at one end (**Figure 5.3**). The tube is inverted with its open end immersed in a pool of mercury that is open to the atmosphere (which means that molecules of N_2 and O_2 collide against the surface of the liquid mercury). Gravity pulls the mercury in the tube downward, creating a vacuum at the top of the tube, while atmospheric pressure pushes the mercury in the pool up into the tube (from the force of the collisions). The net effect of these opposing forces is indicated by the height of the mercury in the tube, which provides a measure of atmospheric pressure.

Atmospheric pressure varies from place to place and with changing weather conditions. Several units are used to express pressure. An atmosphere (atm) of pressure, or 1 atm, is the pressure capable of supporting a column of mercury 760 mm high in a barometer. This column height is the average height of mercury in a barometer at sea level and is the physical basis for another unit of pressure: *millimeters of mercury (mmHg)*. Pressure is also expressed in a unit called the torr in honor of Evangelista Torricelli (1608–1647), the Italian mathematician and physicist who invented the barometer. There are exactly 760 torr in 1 atm, which leads to these unit equivalents:

1 atm = 760 torr = 760 mmHg

The SI unit of pressure is the *pascal* (Pa), named in honor of the French mathematician and physicist Blaise Pascal (1623–1662), who was the first to propose that atmospheric pressure decreases with increasing altitude. The atmospheric pressure at any given location on Earth's surface is related to the mass of the column of air *above* that location (**Figure 5.4**). As altitude increases, the mass of air in the column decreases, which means the mass of the gases in the column decreases. Less mass means fewer collisions among molecules in the atmosphere and therefore a smaller force exerted by the air. According to Equation 5.1, a smaller force means less pressure.

The pascal is a derived SI unit; it is defined using the SI base units kilogram, meter, and second:

To understand the logic of this combination of units, consider the relationship in physics that states that pushing an object of mass m with a force F causes the object to accelerate at the rate a:

Combining Equations 5.1 and 5.2, we have

If m is in kilograms, a is in meters per second-squared (m/s^2), and A is in square meters (m^2), the units for P are

The relationship between atmospheres and pascals is

1 atm = 101,325 Pa

Thus, 1 Pa is a tiny quantity of pressure. In many applications it is more convenient to express pressure in kilopascals.

For many years, meteorologists have expressed atmospheric pressure in *millibars* (mbar). Weather maps show changes in atmospheric pressure by constant-pressure contour lines, called *isobars*, spaced 4 mbar apart (**Figure 5.5**). There are exactly 10 mbar in 1 kPa; thus,

TABLE 5.2 Units for Expressing Pressure

Unit	Value
Atmosphere (atm)	1 atm
Millimeter of mercury (mmHg)	1 atm = 760 mmHg
Torr	1 atm = 760 torr
Pascal (Pa)	1 atm = 1.01325×10^5 Pa
Kilopascal (kPa)	1 atm = 101.325 kPa
Bar	1 atm = 1.01325 bar
Millibar (mbar)	1 atm = 1013.25 mbar
Pounds per square inch (psi)	1 atm = 14.7 psi
Inches of mercury	1 atm = 29.92 inches of Hg

SAMPLE EXERCISE 5.1 Calculating Atmospheric Pressure LO1

The atmosphere on Titan (**Figure 5.6**), one of Saturn's moons, is composed almost entirely of nitrogen (98%). Its oceans contain substances thought to be important in the evolution of life, however, making Titan interesting for planetary scientists. The mass of Titan's atmosphere is estimated to be 9.0×10^{18} kg. The surface area of Titan is 8.3×10^{13} m^2. The acceleration due to gravity on Titan's atmosphere is 1.35 m/s^2. From these values, calculate an average atmospheric pressure in kilopascals.

Collect, Organize, and Analyze Equation 5.3 allows us to use the mass of Titan's atmosphere, its surface area, and acceleration due to its gravity to calculate its atmospheric pressure.

Solve Substituting the given values into Equation 5.3:

Think About It The atmospheric pressure on Titan is similar to Earth's (1.01×10^2 kPa). The greater mass of Titan's atmosphere and its smaller surface area compensate for its weaker acceleration due to gravity.

Practice Exercise Calculate the pressure in pascals exerted on a tabletop by a sugar cube that is 1.00 cm on each side and has a mass of 4.15 g. The acceleration due to gravity on Earth is 9.8 m/s^2.

(Answers to Practice Exercises are in the back of the book.)

Scientists conducting experiments with gases may monitor the pressures exerted by the gases by using a manometer. One type of manometer is illustrated in **Figure 5.7**. It consists of a U-shaped tube filled with mercury (or another dense liquid) that is connected to a container holding the gas sample whose pressure is being measured. The other end of the manometer is open to the atmosphere. When the valve is opened, the gas exerts pressure on the mercury.

The difference in heights of the mercury column represents the difference between the pressure in the flask and atmospheric pressure. When the pressure in the flask is *greater* than atmospheric pressure (Figure 5.7b), the level in the arm open to the atmosphere is higher than the level in the arm attached to the flask; when the pressure in the flask is *lower* than atmospheric pressure (Figure 5.7c), the level in the arm attached to the flask is higher than the level in the arm open to the atmosphere.

Manometers have been largely displaced by pressure sensors based on flexible metallic or ceramic diaphragms. As the pressure on one side of the diaphragm increases, it distorts away from that side. This is the mechanism used to sense changes in atmospheric pressure in barometers, including the recording barometer, or *barograph*, shown in **Figure 5.8**.

Though manometers are not as widely used as they once were, many other devices are used, which, like the manometer in Figure 5.7, measure the pressure of a gas relative to atmospheric pressure. These devices are said to measure gauge pressure. Familiar examples include the gauges used to measure the pressure in automobile or bicycle tires. The values these devices display represent how much air pressure there is inside a tire *above atmospheric pressure.* Thus, a gauge pressure of 2.0 atm represents a total gas pressure of 2.0 + 1.0 = 3.0 atm.

SAMPLE EXERCISE 5.2 Measuring Gas Pressure with a Manometer LO1

Oyster shells are composed of calcium carbonate ($CaCO_3$). When the shells are roasted, they produce solid calcium oxide (CaO) and CO_2. A chemist roasts some oyster shells in an evacuated flask that is attached to a manometer (**Figure 5.9a**). When the roasting is complete, and the system has cooled to room temperature, the difference in levels of mercury (Δh) in the arms of the manometer is 144 mm (**Figure 5.9b**). Calculate the pressure created by the $CO_2(g)$ in (a) torr, (b) atmospheres, and (c) kilopascals on a day when the atmospheric pressure is 758 torr.

Collect, Organize, and Analyze The difference in the heights of the mercury levels in the arms of the manometer is equal to $P_{\text{sample}} - P_{\text{atmosphere}}$ (see Figure 5.7b) in mmHg. The conversion factors from Table 5.2 that we need are 760 mmHg = 760 torr = 1 atm = 101.325 kPa. The pressures expressed in mmHg and torr should be the same, and they should be about 800 times greater than the pressure expressed in atmospheres and about 8 times greater than the pressure in kPa.

Solve

1. Calculating the partial pressure of CO_2 (P_{sample}) in mmHg and torr:

$$\Delta h = P_{\text{sample}} - P_{\text{atmosphere}}$$

or

$$P_{\text{sample}} = P_{\text{atmosphere}} + \Delta h$$

$$= 758 + 144 = 902.3\ \text{mmHg} = 902\ \text{torr}$$

2. Converting torr to atmospheres:

$$902\ \cancel{\text{torr}} \times \frac{1\ \text{atm}}{760\ \cancel{\text{torr}}} = 1.187\ \text{atm} = 1.19\ \text{atm}$$

3. Converting atmospheres to kilopascals:

$$1.19\ \cancel{\text{atm}} \times \frac{101.325\ \text{kPa}}{1\ \cancel{\text{atm}}} = 120\ \text{kPa}$$

Think About It The calculated pressure values make sense given our estimates and the relative heights of the mercury levels in the barometer, which indicate that $P_{\text{sample}} > P_{\text{atmosphere}}$. Therefore, the P_{sample} values should be greater than 760 torr, 1 atm, and 101.35 kPa.

Practice Exercise What if exactly half the quantity of oyster shells were roasted and P_{CO_2} was determined as described in this sample exercise. What would be the value of Δh in millimeters? On which side of the manometer, sample or atmosphere, would the mercury level be higher?

(Answers to Practice Exercises are in the back of the book.)

Glossary

pressure (P)

the ratio of a force to the surface area over which the force is applied.

atmospheric pressure (P_{atm})

the force exerted by the gases surrounding Earth on Earth’s surface and on all surfaces of all objects.

barometer

an instrument that measures atmospheric pressure.

atmosphere (atm)

a unit of pressure equal to Earth’s mean atmospheric pressure at sea level.

torr

a unit of pressure. There are exactly 760 torr in 1 atm of pressure.

manometer

an instrument for measuring the pressure exerted by a gas.

gauge pressure

the pressure of a gas that is above atmospheric pressure.

Learning Objectives

- Describe how gas pressure is measured and convert between the different units used to express gas pressure **Return to Sample Exercises 5.1, 5.2**
- Describe how gas pressure is measured and convert between the different units used to express gas pressure **Return to Sample Exercises 5.1, 5.2**

FIGURE 5.11 Boyle used a J-shaped tube for his experiments on the relationship between *P* and *V*. The volume of air trapped in the closed end of the tube decreases as the difference in height of mercury in the tube increases. The total pressure on the gas is equal to the pressure exerted by the added mercury (Δh) plus atmospheric pressure.

$$P \propto \frac{1}{V} \qquad (T \text{ and } n \text{ constant}) \qquad (5.4)$$

$$P = (\text{constant})\frac{1}{V}$$

$$PV = \text{constant} \tag{5.5}$$

$$P_1V_1 = P_2V_2 \tag{5.6}$$

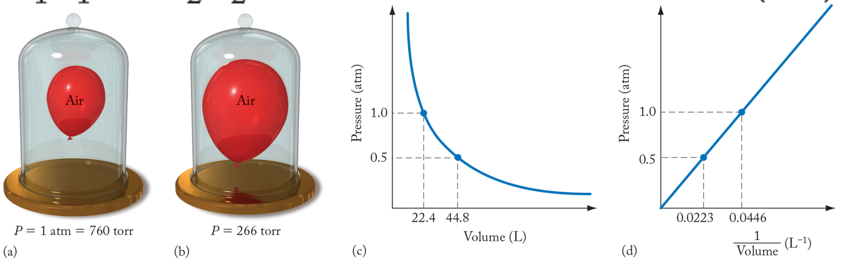

FIGURE 5.12 The sizes of the balloon in these images demonstrates the inverse relationship between pressure and volume. (a) The balloon inside the bell jar is surrounded by a pressure of 760 torr (1 atm). (b) After some of the air is pumped out of the bell jar, the pressure of the air inside it is only 266 torr. The decrease in pressure allows the balloon to expand until the pressure inside and outside the balloon is equal. (c) At constant temperature, the pressure of a given quantity of gas is inversely proportional to the volume it occupies; the graph of an inverse proportion is a hyperbola. (d) The inverse proportion between P and V means that a plot of P versus $1/V$ is a straight line.

$$P_1V_1 = P_2V_2$$

$$P_2 = \frac{P_1V_1}{V_2} = \frac{(0.500\ \text{atm})(44.8\ \cancel{\text{L}})}{22.4\ \cancel{\text{L}}}$$

$$= 1.00\ \text{atm}$$

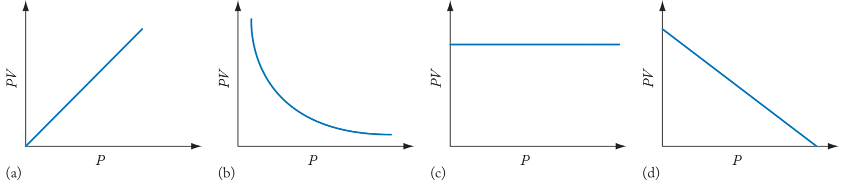

FIGURE 5.13

$$V \propto T \qquad (P \text{ and } n \text{ constant}) \tag{5.7}$$

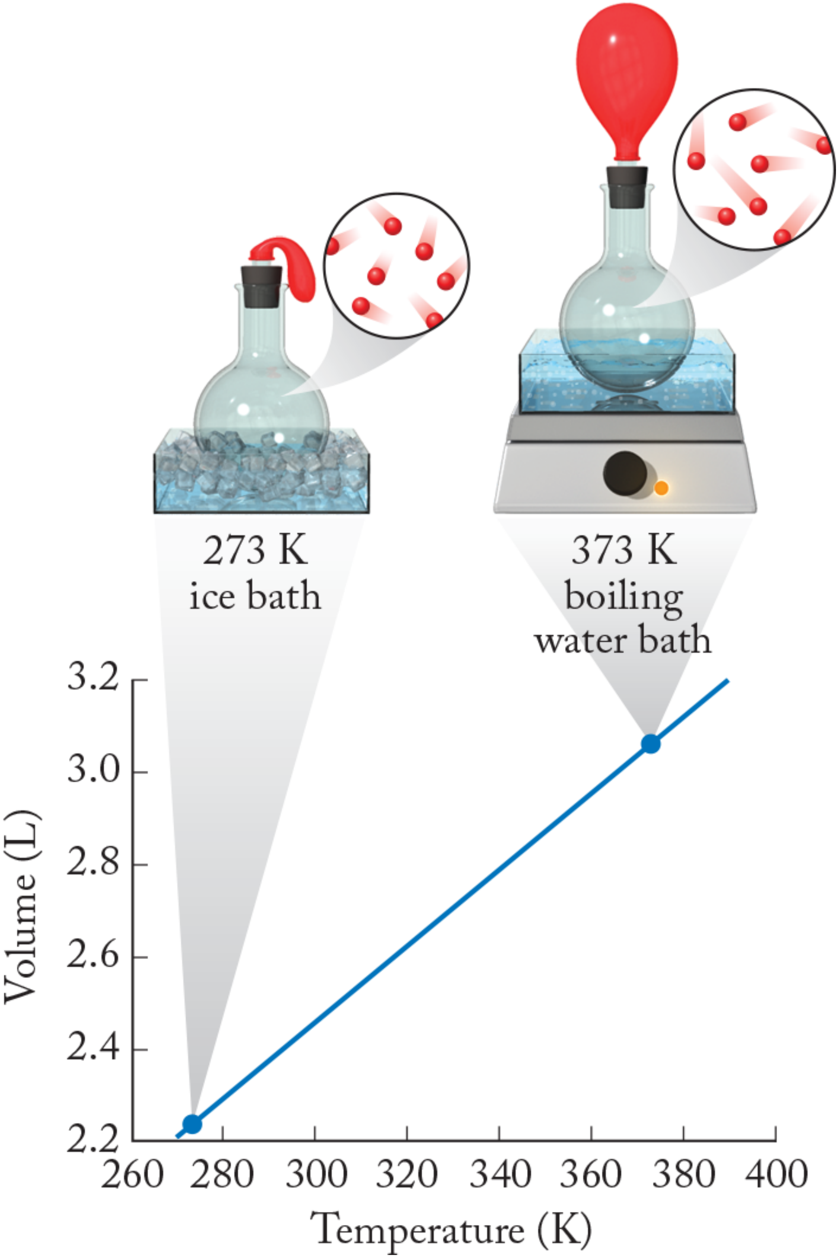

FIGURE 5.14 A balloon attached to a flask inflates as the temperature of the gas inside the flask increases from 273 K to 373 K at constant atmospheric pressure. This behavior is described by Charles's law.

$$V = (\text{constant})T$$

$$\frac{V}{T} = \text{constant} \tag{5.8}$$

$$\frac{V_1}{T_1} = \frac{V_2}{T_2} \tag{5.9}$$

$$V_2 = \frac{V_1 T_2}{T_1}$$

$$V_2 = \frac{2.00\ \text{L} \times 273\ \cancel{\text{K}}}{293\ \cancel{\text{K}}} = 1.86\ \text{L}$$

$$\%\ \text{decrease} = \frac{V_1 - V_2}{V_1} \times 100\% = \frac{2.00\ \cancel{\text{L}} - 1.86\ \cancel{\text{L}}}{2.00\ \cancel{\text{L}}} \times 100\% = 7.0\%$$

$$T_2 = \frac{V_2 T_1}{V_1}$$

$$T_2 = \frac{V_2 T_1}{V_1} = \frac{(3.00\ \cancel{\text{L}})(273 + 15\ \text{K})}{2.00\ \cancel{\text{L}}} = 432\ \text{K}$$

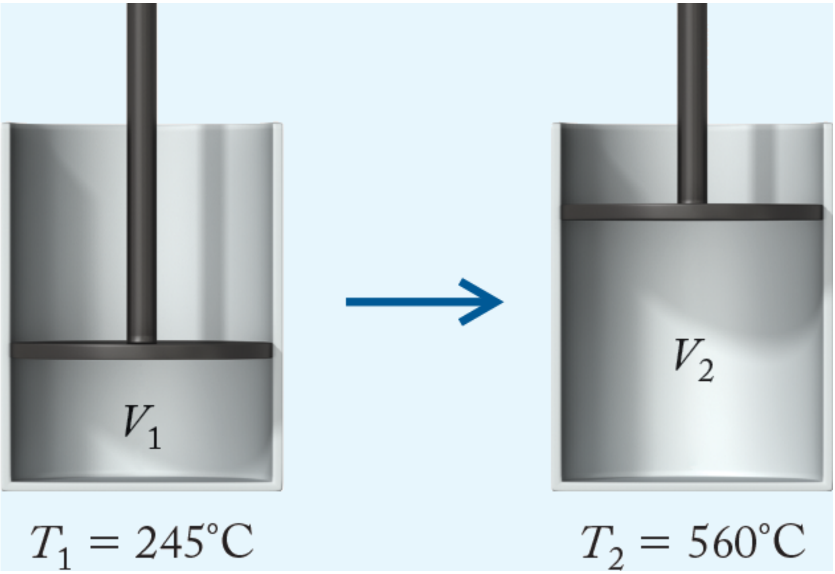

FIGURE 5.15 The volume of a gas in a cylinder changes as the temperature of the gas increases from 245°C to 560°C.

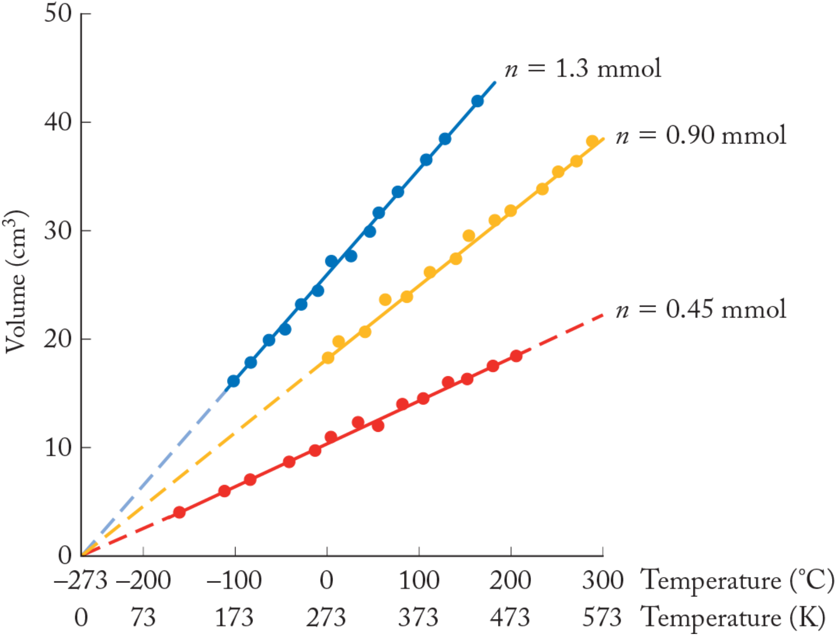

FIGURE 5.16 The volumes of three quantities of gas at the same pressure plotted against temperature on both the Celsius and Kelvin scales. As predicted by Charles's law, volume decreases as the temperature decreases; the relationship is linear on both scales. The

dashed lines show an extrapolation from the experimental data to a point corresponding to zero volume. This temperature is known as absolute zero: $-273.15°C$ on the Celsius scale and 0 K on the Kelvin scale.

$$V \propto n \quad \text{or} \quad \frac{V}{n} = \text{constant} \qquad (P \text{ and } T \text{ constant}) \qquad (5.10)$$

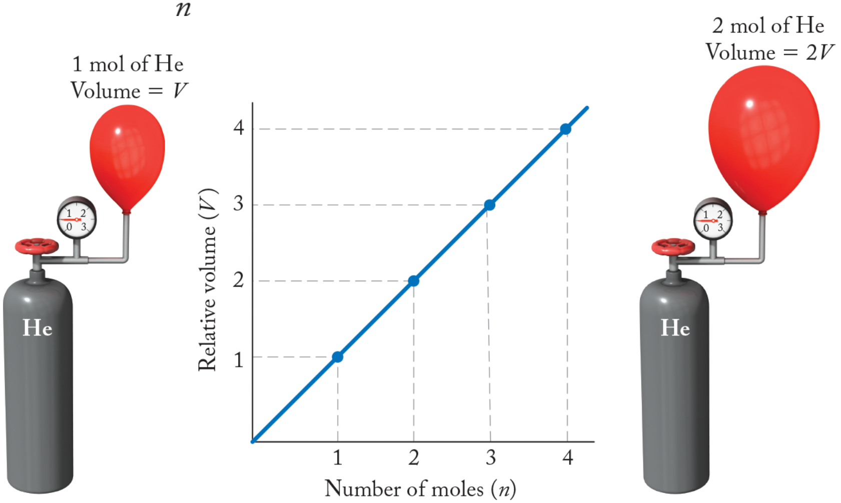

FIGURE 5.17 The balloon on the right has twice the volume of the balloon on the left because it is filled with twice the quantity of helium. This direct relationship between volume and number of moles of a gas at constant temperature and pressure demonstrates Avogadro's law.

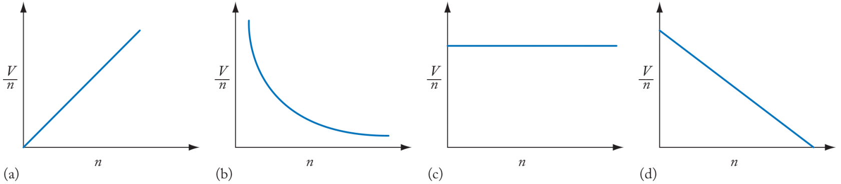

FIGURE 5.18

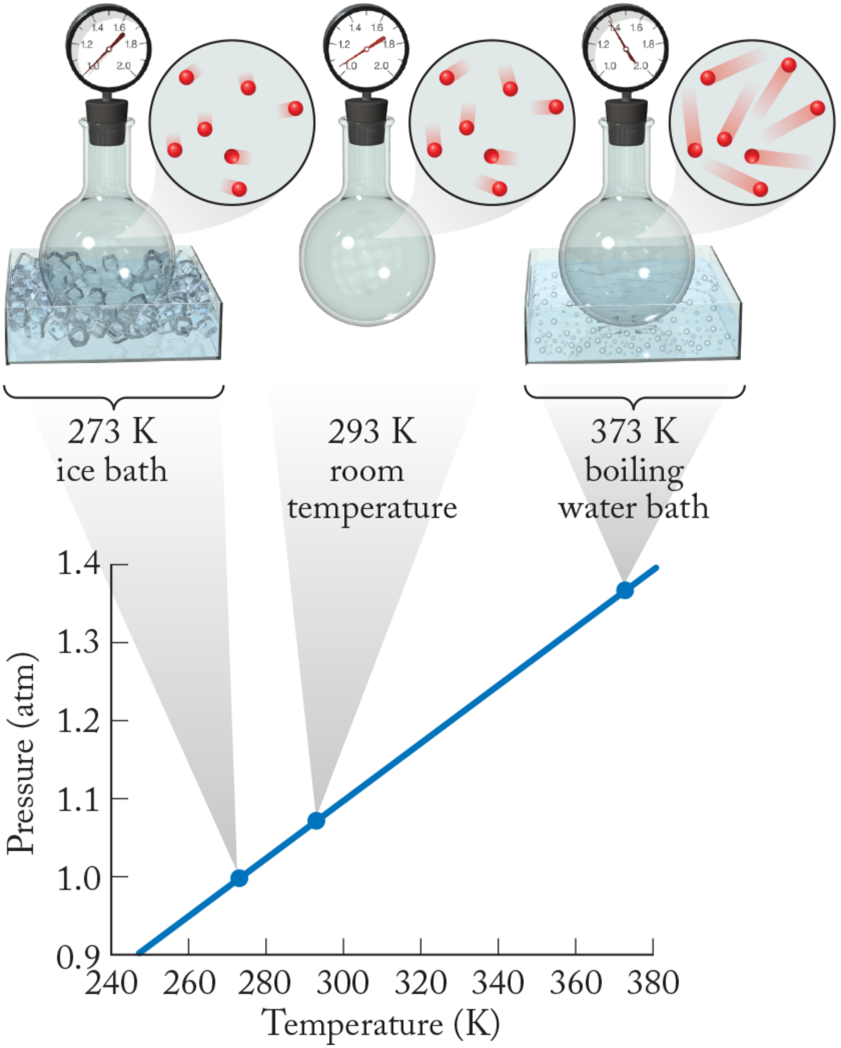

FIGURE 5.19 The pressure of a given quantity of gas is directly proportional to its absolute temperature at constant volume. The average speeds of gas molecules increase with increasing temperature, causing more frequent and more forceful collisions with the walls of the flasks and higher pressures.

$$\frac{P_1}{T_1} = \frac{P_2}{T_2} \tag{5.12}$$

$$P_2 = \frac{P_1 T_2}{T_1} = \frac{(6.8\ \text{atm})(273\ \cancel{\text{K}})}{298\ \cancel{\text{K}}} = 6.2\ \text{atm}$$

$$T_2 = \frac{T_1 P_2}{P_1}$$

$$T_2 = \frac{(25\ +\ 273)\ \text{K} \times 3.00\ \cancel{\text{atm}}}{2.20\ \cancel{\text{atm}}} = 406\ \text{K}$$

5.3 The Gas Laws

In Section 5.1 we summarized some of the properties of gases and described the effect of pressure and temperature on volume, mostly in qualitative terms. Our knowledge of the quantitative relationships among *P, T,* and *V* goes back more than three centuries, to a time before the field of chemistry as we now know it even existed. Some of the experiments that led to our understanding of how gases behave were driven by human interest in hot-air balloons, and today balloons are still used to study weather and atmospheric phenomena (**Figure 5.10**). Their successful and safe use requires an understanding of gas properties that was first gained in the 17th and 18th centuries.

Boyle’s Law: Relating Pressure and Volume

When a diver exhales underwater, the bubbles increase in size as they rise toward the surface. As the bubbles rise, the pressure exerted on them decreases—and as the pressure exerted on a gas decreases, its volume increases. The inverse is also true: as the pressure on a gas increases, its volume decreases. In other words, gases are compressible, a property that allows us to store gases (which would typically occupy large volumes under atmospheric pressure) in relatively small metal cylinders at high pressure.

The relationship between the pressure and volume of a fixed quantity of gas (constant value of n, where n is the number of moles) at constant temperature was investigated by the British chemist Robert Boyle (1627–1691), who conducted experiments with a J-shaped tube open at one end and closed at the other end (**Figure 5.11**). When a small amount of mercury was poured into the tube, a column of air became trapped at the closed end. The pressure on the trapped air was changed by varying the amount of mercury poured into the open arm. The more mercury added, the greater the force exerted by the mercury ($F = ma$), and hence the greater the force per unit area ($P = F/A$) on the column of trapped air in the closed arm. The pressure exerted on this trapped air depended on the difference in the height of the mercury in the two sides of the tube and the atmospheric pressure.

As Boyle added mercury to the open arm, the *amount* (number of moles) of trapped air remained constant, but the volume it occupied decreased. At the time Boyle discovered the relationship between P and V, scientists lacked a clear understanding of atoms or molecules. We now know that because the molecules in the trapped gas were in constant random motion within a smaller, confined space, the number of collisions with one another and with the surface of the mercury *increased*. The more frequent the collisions, the greater the force exerted by the molecules against the surface of the mercury and thus the greater the pressure of the gas. The mathematical relationship describing the inverse relationship between volume and pressure (under conditions of constant moles and constant temperature) is known as Boyle's law (**Figure 5.12**):

where the symbol ∝ means "is proportional to."

Mathematically, we can replace the proportionality symbol with an equals sign and a constant:

The value of the constant depends on the quantity of trapped air and its temperature.

Because the value of the product PV in Equation 5.5 does not change for a given quantity of trapped air at constant temperature, any two combinations of pressure and volume for a given sample of gas at constant temperature are related as follows:

This relationship, which applies to all gases, is illustrated by the dashed lines in Figure 5.12c, d. For example, when 44.8 L (V_1) of gas has a pressure of 0.500 atm (P_1),

$$P_1V_1 = (0.500 \text{ atm})(44.8 \text{ L}) = 22.4 \text{ L} \cdot \text{atm}$$

If this quantity of the gas is compressed into a container half the size, then V_2 is 22.4 L, and P_2, according to Equation 5.6, is

Thus, when the volume is cut in half, Boyle's law shows that the pressure doubles.

CONCEPT TEST

Which of the graphs in **Figure 5.13** correctly depicts the relationship between the product of pressure and volume (PV) as a function of pressure (P) for a given quantity of gas at constant temperature?

(Answers to Concept Tests are in the back of the book.)

SAMPLE EXERCISE 5.3 Using Boyle's Law LO2

A balloon is partially inflated with 5.00 L of helium at sea level where the atmospheric pressure is 1.00 atm. The balloon ascends to an altitude of 1600 m where the pressure is 0.83 atm. (a) What is the volume of the balloon at the higher altitude if the temperature of the helium does not change during the ascent? (b) What is the percent increase in volume?

Collect and Organize We are given the volume ($V_1 = 5.00$ L) of a gas and its pressure ($P_1 = 1.00$ atm), and we are asked to find the volume (V_2) of the gas when the pressure changes ($P_2 = 0.83$ atm). The temperature of the gas does not change.

Analyze The balloon contains a fixed amount of gas and its temperature is constant, so pressure and volume are related by Boyle's law (Equation 5.6). The volume should increase because the pressure decreases.

Solve

1. Rearrange Equation 5.6 to solve for V_2 and insert the given values of P_1, P_2, and V_1:

$$V_2 = \frac{P_1 V_1}{P_2}$$

$$V_2 = \frac{(1.00\ \cancel{\text{atm}})(5.00\ \text{L})}{0.83\ \cancel{\text{atm}}} = 6.0\ \text{L}$$

2. To calculate the percent increase in the volume, we must determine the difference between V_1 and V_2 and compare the result with V_1:

$$\%\ \text{increase in volume} = \frac{V_2 - V_1}{V_1} \times 100\%$$

$$= \frac{6.0\ \cancel{\text{L}} - 5.0\ \cancel{\text{L}}}{5.0\ \cancel{\text{L}}} \times 100\% = 20\%$$

Think About It The volume did, in fact, increase when the pressure decreased. The lower atmospheric pressure means fewer collisions by molecules in the atmosphere on the outside of the helium balloon. The helium balloon will rise until it reaches an altitude where the pressure inside the balloon (i.e., the number of collisions by the helium atoms) equals the atmospheric pressure. Equation 5.6 can thus be used to calculate the change in pressure that takes place at constant temperature when the volume of a quantity of gas changes.

Practice Exercise A scuba diver exhales 3.50 L of air while swimming at a depth of 20.0 m, where the sum of atmospheric pressure and water pressure is 3.00 atm. By the time the exhaled air rises to the surface, where the pressure is 1.00 atm, what is its volume?

(Answers to Practice Exercises are in the back of the book.)

Charles's Law: Relating Volume and Temperature

Nearly a century after Boyle's discovery of the inverse relationship between the pressure exerted by a gas and its volume, the French scientist Jacques Charles (1746–1823) documented the linear relationship between the volume and temperature of a fixed quantity of gas at constant pressure. Now known as Charles's law, this relationship states that, when the pressure exerted by a gas is held constant, the volume of a fixed quantity of gas is directly proportional to the absolute temperature (the temperature on the Kelvin scale) of the gas:

Because the lowest temperature on the absolute temperature scale is 0 K, temperatures expressed in kelvin are always positive numbers.

The effects of Charles's law can be seen in **Figure 5.14**, in which a balloon has been attached to a flask, trapping a fixed amount of gas in the apparatus. Heating the flask causes the gas to expand, inflating the balloon. The higher the temperature, the larger the volume occupied by the gas and the bigger the balloon.

As with Boyle's law, we can replace the proportionality symbol in Equation 5.7 with an equals sign if we include a proportionality constant:

The value of the constant depends on the number of moles of gas in the sample (n) and on the pressure of the gas (P). When those two parameters are held constant, the ratio V/T does not change, and any two combinations of volume and temperature are related as follows:

What happens when a balloon containing 2.00 L of air at 20°C is taken outside on a day when the temperature is 0°C? The amount of gas in the balloon is fixed, and the atmospheric pressure is constant, so Charles's law applies. Experience tells us that the volume of the balloon decreases. We can calculate the final volume with Equation 5.9, provided that we express T_1 and T_2 in kelvin, not degrees Celsius. Solving Equation 5.9 for V_2:

and substituting the known volume and temperature values:

As predicted, the volume of the gas decreases when the temperature of the gas decreases. The percent change in the volume of the balloon is

CONNECTION We learned in Chapter 1 that Kelvin and Celsius temperatures are related by the equation K = °C + 273.15.

CONCEPT TEST

Suppose you have two graphs: graph 1 plots volume (V) as a function of temperature (T) for 1 mole of a gas at a pressure of 1.00 atm, and graph 2 plots volume (V) as a function of T for 1 mole of a gas at 2.00 atm pressure. How do the slopes of the two graphs differ?

(Answers to Concept Tests are in the back of the book.)

SAMPLE EXERCISE 5.4 Using Charles's Law LO2

Charles was drawn to the study of gases because of his interest in hot-air balloons. What temperature (in °C) is required to increase the volume of a sealed balloon from 2.00 L to 3.00 L if the initial temperature is 15°C and the atmospheric pressure is constant?

Collect and Organize We are given the volume ($V_1 = 2.00$ L) of a gas at an initial Celsius temperature ($T_1 = 15°\text{C}$), and we are asked to calculate the Celsius temperature needed to increase the volume of the gas ($V_2 = 3.00$ L). The container (a balloon) is sealed, so n is constant, as is atmospheric pressure.

Analyze The relationship between volume and temperature is given by Charles's law (Equation 5.9). According to Charles's law, the temperature increases when the volume increases. If the volume increases by 50% (i.e., from 2 L to 3 L), then the absolute temperature must also increase by 50%.

Solve First, we rearrange Equation 5.9 to solve for T_2:

We then substitute for V_1, V_2, and T_1, remembering to convert temperature to kelvins:

The final step is to convert T_2 to degrees Celsius:

$T_2 = 432 \text{ K} - 273 = 159°\text{C}$

Think About It To increase the volume by 1.5 times [(1.5)(2.00 L) = 3.00 L], *absolute* temperature must increase 1.5 times [(1.5)(288 K) = 432 K].

Practice Exercise Hot expanding gases can be used to perform useful work in a cylinder fitted with a movable piston, as in **Figure 5.15**. If the temperature of a gas confined to such a cylinder is increased from 245°C to 560°C, what is the ratio of the initial volume to the final volume if the pressure exerted on the gas remains constant?

(Answers to Practice Exercises are in the back of the book.)

Charles's law also made it possible to determine that absolute zero (0 K) is equal to − 273.15°C. Suppose the volume of a fixed quantity of gas at constant pressure is plotted as a function of temperature. Some typical results for three gases are graphed in **Figure 5.16**, showing that the decrease in volume is linear as temperature decreases. There is a limit to how much the temperature of a gas can decrease because at some temperature the gas liquefies, at which point the gas laws no longer apply. However, we can *extrapolate* from our measured data to the point where the volume of a gas would reach zero if condensation did not occur. The dashed lines in Figure 5.16 cross the temperature axis at − 273.15°C, the temperature defined as 0 K, or absolute zero.

Avogadro's Law: Relating Volume and Quantity of Gas

Boyle's and Charles's experiments involved constant quantities of gas. What happens when the amount of gas is *not* held constant, such as when a balloon is inflated (**Figure 5.17**)? As you probably know from personal experience, adding more gas to a balloon causes its volume to increase. If some of this gas escapes, balloon volume decreases. From these observations we may conclude that the volume of a sample of gas is proportional to the quantity (number of moles) of gas in the sample. This relationship between V and n is known as Avogadro's law to honor Amedeo Avogadro (1776–1856), who articulated that the volume of a gas at a given temperature and pressure is directly proportional to the quantity of the gas in moles:

CONNECTION In Chapter 3 the number of particles in a mole was defined as the Avogadro constant, in honor of Amedeo Avogadro's early work with gases that led to determining atomic masses.

CONCEPT TEST

Which graph in **Figure 5.18** correctly describes the relationship between the value of V/n as n is increased at constant P and T?

(Answers to Concept Tests are in the back of the book.)

The following observations illustrate the relationship between pressure (P) and the quantity (n) of a gas. Suppose a bicycle tire is inflated enough to hold its shape, but it is too soft to ride on. If more air is pumped into the tire, its semirigid structure limits any increase in volume, and adding more air increases the pressure inside the tire. As another example, consider a carnival vendor who rapidly fills balloons from a helium tank such as the one in Figure 5.17. If balloon sales are brisk, the pressure reading on the tank gauge will decrease as more and more balloons are filled and the quantity of helium inside the cylinder decreases.

Amontons's Law: Relating Pressure and Temperature

Boyle's law ($PV =$ constant) and Charles's law ($V/T =$ constant) describe what happens to the volume of a gas when its pressure or temperature changes, but what is the relationship between pressure and temperature when the volume of a gas does not change? Experiments show that pressure is directly proportional to temperature when n and V are constant:

The relationship in Equation 5.11 means that as the absolute temperature of a fixed amount of gas held at a constant volume increases, the pressure of the gas increases (**Figure 5.19**). This statement is referred to as Amontons's law in honor of the French physicist Guillaume Amontons (1663–1705), a contemporary of Robert Boyle, who constructed a thermometer based on the observation that the pressure of a gas is directly proportional to its temperature.

Where do we see evidence of Amontons’s law? Suppose a bicycle tire is inflated to a recommended gauge pressure of 85 psi (5.8 atm) on an afternoon in late autumn when the temperature is 25°C. The next morning, after the temperature dropped to 0°C, the pressure in the tire dropped to 76 psi (5.2 atm). Did the tire leak? Perhaps, but the decrease in pressure could also be explained by Amontons’s law.

We can confirm that the decrease in tire pressure was consistent with the decrease in temperature by relating the initial and final *total* pressures in the tire to the initial (T_1) and final (T_2) absolute temperatures.

The pressure measured by a tire gauge reflects how much additional pressure above atmospheric pressure is in the tire. To calculate the total pressure initially in the tire, we add 1.0 atm to the gauge pressure so that $P_1 = 5.8 + 1.0 = 6.8$ atm. The predicted P_2 caused by the temperature drop is

This total pressure is equivalent to a gauge pressure of $6.2 - 1.0 = 5.2$ atm, which is the value that was measured at 273 K. Therefore, the decrease in tire pressure resulted from a decrease in temperature, not a leak.

Why is pressure proportional to absolute temperature? Like pressure, temperature is directly related to molecular motion. The average speed at which a population of molecules moves increases with increasing temperature (see Figure 5.19). For a given number of gas molecules, increasing the temperature increases the average speed and therefore increases both the frequency and force with which the molecules collide with the walls of their container. Because pressure is related to the frequency and force of the collisions, it follows that higher temperatures produce higher pressures if other factors such as volume and quantity of gas are held constant.

SAMPLE EXERCISE 5.5 Using Amontons's Law LO2

Labels on aerosol cans caution against incineration because the cans may explode when their internal pressure exceeds 3.00 atm. At what temperature (in °C) will an aerosol can burst if the initial pressure inside the can is 2.20 atm at 25°C?

Collect and Organize We are given the temperature ($T_1 = 25°\text{C}$) and pressure ($P_1 = 2.20$ atm) of a gas, and we are asked to determine the temperature (T_2) at which the pressure ($P_2 = 3.00$ atm) will cause the can to explode.

Analyze Because the gas is enclosed in an aerosol can, the volume and quantity of gas are constant. We can use Amontons's law (Equation 5.12) because it describes what happens to pressure as the temperature of a gas is changed. To estimate the answer, notice that the pressure in the can must increase by about 50% in order for the pressure to exceed 3 atm. Pressure is directly proportional to temperature, so the *absolute* temperature must also increase by about 50%. The initial temperature is given in degrees Celsius. Because Equation 5.12 works only with absolute temperatures, we must convert T_1 to kelvins. After solving for T_2, we need to convert it back to degrees Celsius to report our answer.

Solve Rearrange Equation 5.12 to solve for T_2:

After converting T_1 from degrees Celsius to kelvins, we have

Convert T_2 to degrees Celsius:

$T_2 = 406\text{ K} - 273 = 133°\text{C}$

Think About It This temperature is certainly higher than the original temperature. In fact, 406 K is about 1.5 times (or 50% higher than) the initial temperature, 298 K, so the answer makes sense.

Practice Exercise The air pressure in the tires of an automobile is adjusted to 2.3 atm at a gas station in San Diego, where the air temperature is 20°C (68°F) and atmospheric pressure is 0.987 atm. After a 3-hour drive along Interstate 8 (I-8), the car and driver are in Yuma, Arizona, where the temperature is 43°C (110°F). What is the pressure in the tires, if we assume that atmospheric pressure is still 0.987 atm? *Note*: The measured tire pressures are *gauge* pressures, meaning that they indicate the pressures in the tires *above atmospheric pressure*.

(Answers to Practice Exercises are in the back of the book.)

Gases that behave according to the relationships discovered by Boyle, Charles, Avogadro, and Amontons are called ideal gases. In an ideal gas, the atoms or molecules are assumed *not* to interact with one another; rather, they move independently with speeds that are related to their masses and to the temperature of the gas. Most gases exhibit ideal behavior at the pressures and temperatures typically encountered in the atmosphere. Under these conditions, the volumes occupied by gas molecules or atoms are insignificant compared with the overall volume occupied by the gas.

Glossary

Boyle’s law

the principle that the volume of a given amount of gas at constant temperature is inversely proportional to its pressure.

Charles’s law

the principle that the volume of a fixed quantity of gas at constant pressure is directly proportional to its absolute temperature.

absolute temperature

temperature expressed in kelvins on the absolute (Kelvin) temperature scale, on which 0 K is the lowest possible temperature.

Avogadro’s law

the principle that the volume of a gas at a given temperature and pressure is proportional to the quantity of the gas.

Amontons’s law

the principle that the pressure of a quantity of gas at constant volume is directly proportional to its absolute temperature.

ideal gas

a gas whose behavior is predicted by the linear relationships defined by Boyle’s, Charles’s, Avogadro’s, and Amontons’s laws.

Learning Objectives

- Use the individual, combined, and ideal gas laws to relate changes in the volume, temperature, pressure, and number of moles of a gas and express these changes quantitatively **Return to Sample Exercises 5.3, 5.4, 5.5, 5.6, 5.7**

$$PV = nRT \tag{5.15}$$

$$V = \frac{(1\ \cancel{\text{mol}})\left(0.08206\ \frac{\text{L} \cdot \cancel{\text{atm}}}{\cancel{\text{mol}} \cdot \cancel{\text{K}}}\right)(273\ \cancel{\text{K}})}{1\ \cancel{\text{atm}}} = 22.4\ \text{L}$$

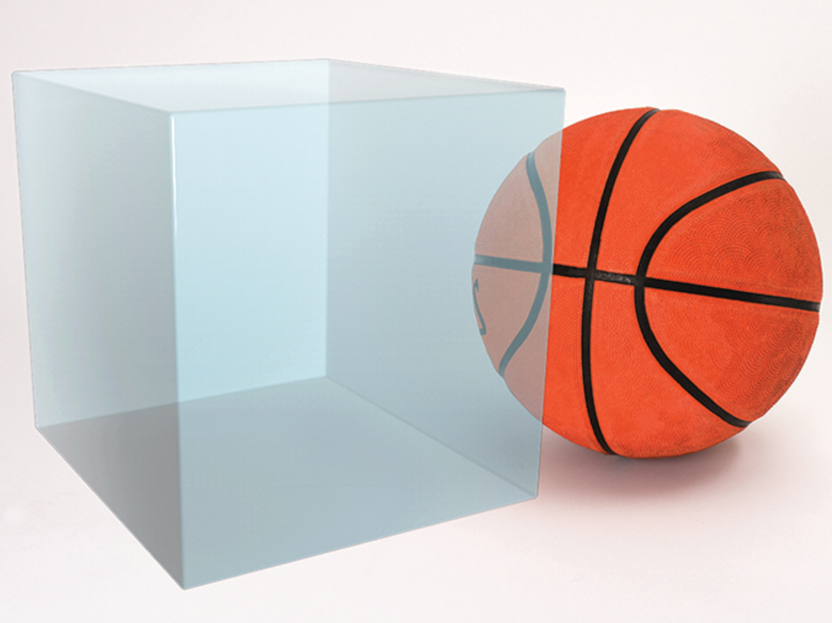

FIGURE 5.20 The box contains 1 mole of gas; the molar volume of an ideal gas is 22.4 L at 0°C and 1 atm of pressure. A basketball fits loosely into a box having this volume.

$$P_1V_1 = n_1RT_1 \qquad \text{so} \qquad \frac{P_1V_1}{n_1T_1} = R$$

and

$$P_2V_2 = n_2RT_2 \qquad \text{so} \qquad \frac{P_2V_2}{n_2T_2} = R \tag{5.16}$$

$$\frac{P_1V_1}{n_1T_1} = \frac{P_2V_2}{n_2T_2} \tag{5.17}$$

$$\frac{P_1V_1}{T_1} = \frac{P_2V_2}{T_2} \tag{5.18}$$

a. $\frac{n_2T_2}{P_2} = \frac{n_1T_1}{P_1}$ at constant V

b. $\frac{n_2V_2}{P_2} = \frac{n_1V_1}{P_1}$ at constant T

c. $\frac{n_2T_2}{V_2} = \frac{n_1T_1}{V_1}$ at constant P

d. $\frac{T_1}{n_1V_1} = \frac{T_2}{n_2V_2}$ at constant P

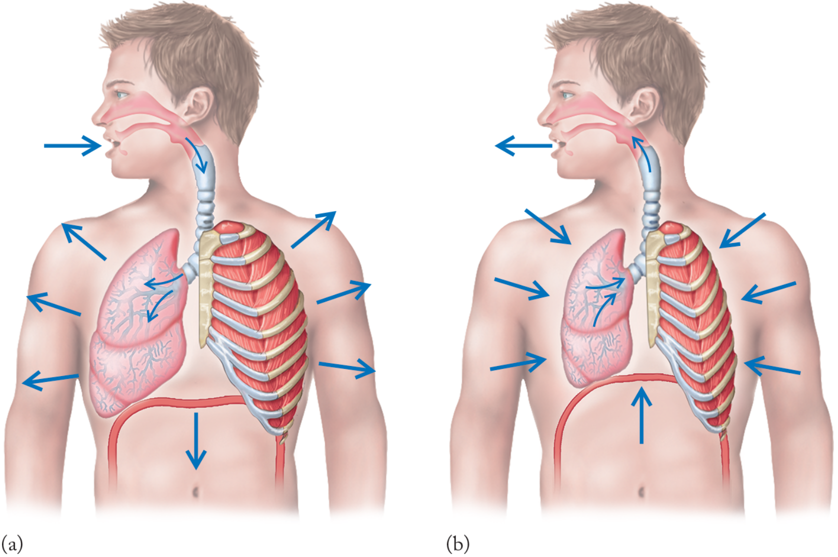

FIGURE 5.21 Breathing illustrates the relationship between *P*, *V*, and *n*. (a) When you inhale, your rib cage expands, and your diaphragm moves down, increasing the volume of your lungs. Increased volume decreases the pressure inside your lungs, which allows more air to flow into them. (b) As you exhale, increased pressure decreases lung volume, forcing air out.

$$T_1 = 20°\text{C} + 273 = 293 \text{ K}$$

$$T_2 = -52°\text{C} + 273 = 221 \text{ K}$$

$$\frac{P_1V_1}{T_1} = \frac{P_2V_2}{T_2}$$

$$V_2 = V_1 \times \frac{P_1}{P_2} \times \frac{T_2}{T_1}$$

$$V_2 = (100.0\ \mathrm{L}) \times \frac{755\ \cancel{\mathrm{torr}}}{195\ \cancel{\mathrm{torr}}} \times \frac{221\ \cancel{\mathrm{K}}}{293\ \cancel{\mathrm{K}}} = 292\ \mathrm{L}$$

5.4 The Ideal Gas Law

What would happen to the volume of a weather balloon if it is launched from the surface of Earth and allowed to drift to an elevation of 10,000 m? The volume of the balloon would expand as the atmospheric pressure decreased, but the air temperature would simultaneously decrease as the balloon ascended, tending to make the volume smaller. How do we determine the final volume of the balloon when both pressure and temperature change at the same time for a given quantity of gas? Taken individually, none of the four gas laws and their accompanying mathematical relations apply. Nevertheless, we can derive a relationship that describes this situation.

Boyle's law (Equation 5.5) states that volume and pressure are inversely proportional, whereas Charles's law (Equation 5.8) states that volume is directly proportional to temperature. Putting these two laws together and combining their constants gives Equation 5.13, which relates *P, V*, and *T*:

Avogadro's law (Equation 5.10), which states that volume is directly proportional to the number of moles of gas when *T* and *P* are constant, can also be included in Equation 5.13. After combining the constant in Equation 5.10 with the combined constant in Equation 5.13,

Equation 5.14 can be turned into the ideal gas equation or ideal gas law (Equation 5.15) by inserting an appropriate constant, R, which is called the universal gas constant:

As **Table 5.3** shows, R has different values depending on the units used. When $R = 0.08206\ \text{L} \cdot \text{atm/(mol} \cdot \text{K)}$, for example, the quantity of gas should be expressed in moles, the volume in liters, the pressure in atmospheres, and the temperature in kelvins.

TABLE 5.3 Values for the Universal Gas Constant (R)

Value of R	Units
0.08206	$\text{L} \cdot \text{atm/(mol} \cdot \text{K)}$
8.314	$\text{kg} \cdot \text{m}^2/(\text{s}^2 \cdot \text{mol} \cdot \text{K})$
8.314	$\text{J/(mol} \cdot \text{K)}$
8.314	$\text{m}^3 \cdot \text{Pa/(mol} \cdot \text{K)}$
62.37	$\text{L} \cdot \text{torr/(mol} \cdot \text{K)}$

A useful reference point when studying the properties of gases is standard temperature and pressure (STP), defined by the International Union of Pure and Applied Chemistry (IUPAC) as 0°C and 1 bar. The pressure unit of 1 atm is very close to 1 bar, so we consider STP to be 0°C and 1 atm in calculations in this textbook. The volume of 1 mole of an ideal gas at STP is known as the molar volume (**Figure 5.20**). We can calculate the molar volume from the ideal gas equation by solving the equation for V and inserting the values of n, P, and T at STP:

Many chemical and biochemical processes take place at pressures near 1 atm and at temperatures between 0°C and 40°C. Within this range, the volume that 1 mole of gaseous reactant or product occupies is no more than about 15% greater than the molar volume. Therefore, volumes can be estimated easily if molar amounts are known. An important feature of molar volume is that it applies to any ideal gas, independent of its chemical composition. In other words, at STP, 1 mole of helium occupies the same volume—22.4 L—as 1 mole of methane (CH_4) or carbon dioxide (CO_2).

We can derive another relationship that is useful when a system starts in an initial state (P_1, V_1, T_1, n_1) and moves to a final state (P_2, V_2, T_2, n_2):

Because both the initial-state and final-state expressions are equal to *R*, they are also equal to each other:

Some processes, such as breathing (**Figure 5.21**), illustrate the relationship between *P, V,* and *n* in Equation 5.17. In closed systems, such as weather balloons, the amount of gas is constant ($n_1 = n_2$), but pressure, temperature, and volume vary, which simplifies Equation 5.17 to

Equation 5.18 is known as the combined gas law, or the general gas equation. Sample Exercise 5.6 shows how to use this equation for determining the effect of changes in *P* and *T* on the volume (*V*) of a weather balloon. Other simplified versions of Equation 5.17 are certainly possible when variables in addition to *n* are fixed, but only Equation 5.18 is known as the combined gas law.

CONCEPT TEST

Which are correct variations of Equation 5.17?

(Answers to Concept Tests are in the back of the book.)

SAMPLE EXERCISE 5.6 Calculations Involving Changes in *P*, *V*, and *T*LO2

A weather balloon filled with 100.0 L of He is launched from ground level ($T = 20^\circ\text{C}$, $P = 755$ torr). No gas is added or removed from the balloon during its flight. Calculate its volume at an altitude of 10 km, where the temperature and pressure in the balloon are -52°C and 195 torr, respectively.

Collect, Organize, and Analyze We are given the initial temperature, pressure, and volume of a gas, and we are asked to determine the final volume after the pressure and temperature have changed. The decrease in temperature leads to a *decrease* in volume, but the decrease in pressure leads to an *increase* in volume. We need to express the temperatures in kelvins and estimate which variable dominates the change. Because the quantity of gas does not change (n is constant), we can solve for V_2 in the combined gas law (Equation 5.18).

Solve First, convert the given Celsius temperatures to kelvins:

Then, use the general gas equation (Equation 5.18) to solve for V_2:

Think About It The volume increases nearly threefold as the balloon ascends to 10 km. This result makes sense because atmospheric pressure decreases to about one-quarter of its ground-level value during the ascent. The volume would have increased more if not for the counteracting effect of the lower temperature at 10 km.

Practice Exercise The balloon in Sample Exercise 5.6 is designed to continue its ascent to an altitude of 30 km, where it bursts, releasing a package of meteorological instruments that parachute back to Earth. If the atmospheric pressure at 30 km is 28.0 torr and the temperature is $-45°\text{C}$, what is the volume of the balloon when it bursts?

(Answers to Practice Exercises are in the back of the book.)

The ideal gas law describes the relations among number of moles, pressure, volume, and temperature for any gas, provided it behaves ideally. Because many gases behave ideally at typical atmospheric pressures, we can apply the ideal gas equation to many situations outside the laboratory. In Sample Exercise 5.7, we calculate the mass of oxygen in an alpine climber's compressed-oxygen cylinder.

SAMPLE EXERCISE 5.7 Applying the Ideal Gas Law LO2

Bottles of compressed O_2 carried by climbers ascending Mt. Everest have an internal volume of 5.90 L. Assume that one such bottle has been filled with O_2 to a pressure of 2025 psi at 25°C. Also assume that O_2 behaves as an ideal gas. (a) How many moles of O_2 are in the bottle? (b) What is the mass in grams of O_2 in the bottle?

Collect, Organize, and Analyze The ideal gas equation enables us to use the given values for *P*, *V*, and *T* to calculate *n*, the number of moles of O_2. Then we can use its molar mass (32.00 g/mol) to calculate the mass of O_2 in the bottle. We can estimate the answer by remembering that 1 mole of gas at STP occupies 22.4 L. Our oxygen bottle has a volume of about 6 L, which is about one-quarter of the molar volume at STP, but the pressure (2025 psi) is more than 100 times greater than 1 atm (see Table 5.2). Thus, we predict that the bottle contains more than 25 moles of O_2.

Solve

1. First, rearrange the ideal gas equation to solve for *n*:

$$PV = nRT$$

$$n = \frac{PV}{RT}$$

Before using this expression for *n*, we need to convert pressure into atmospheres and temperature into kelvins:

$$P = (2025\ \cancel{\text{psi}})\left(\frac{1\ \text{atm}}{14.7\ \cancel{\text{psi}}}\right) = 138\ \text{atm} \qquad T = 25^\circ\text{C} + 273 = 298\ \text{K}$$

$$n = \frac{(138\ \cancel{\text{atm}})(5.90\ \cancel{\text{L}})}{\left(0.08206\ \frac{\cancel{\text{L}} \cdot \cancel{\text{atm}}}{\text{mol} \cdot \cancel{\text{K}}}\right)(298\ \cancel{\text{K}})} = 33.3\ \text{mol}$$

---

2. To convert moles into grams, multiply moles by the molar mass:
$$(33.3\ \cancel{\text{mol}})\ \frac{(32.00\ \text{g})}{1\ \cancel{\text{mol}}} = 1.07 \times 10^{3}\ \text{g}$$

Think About It Our answer in part (a) is certainly reasonable based on our estimate. Most climbers require several bottles to climb Mt. Everest and return.

Practice Exercise Starting with the moles of O_2 calculated in Sample Exercise 5.7, calculate the volume of O_2 the bottle could deliver to a climber at an altitude where the temperature is -38°C and the atmospheric pressure is 0.35 atm.

(Answers to Practice Exercises are in the back of the book.)

Glossary

ideal gas equation (also called ideal gas law)

the principle relating the pressure, volume, number of moles, and temperature of an ideal gas; expressed as $PV = nRT$, where R is the universal gas constant.

universal gas constant

the constant R in the ideal gas equation; its value and units depend on the units used for the variables in the equation.

standard temperature and pressure (STP)

0°C and 1 bar as defined by IUPAC; 0°C and 1 atm are commonly used in the United States and in this textbook.

molar volume

the volume occupied by 1 mole of an ideal gas at STP; 22.4 L.

combined gas law (also called general gas equation)

the principle relating the pressure, volume, and temperature of a quantity of an ideal gas:

$$\frac{P_1V_1}{T_1} = \frac{P_2V_2}{T_2}$$

combined gas law (also called general gas equation)

the principle relating the pressure, volume, and temperature of a quantity of an ideal gas:

$$\frac{P_1V_1}{T_1} = \frac{P_2V_2}{T_2}$$

ideal gas equation (also called ideal gas law)

the principle relating the pressure, volume, number of moles, and temperature of an ideal gas; expressed as $PV = nRT$, where R is the universal gas constant.

5.5 Gases in Chemical Reactions

Gases are reactants or products in many important reactions. For example, if a commercial airliner flying at a high altitude loses cabin pressure, oxygen masks are deployed automatically for the passengers to breathe until the aircraft can descend or the cabin can be pressurized again. The oxygen gas that flows in the masks is produced by the decomposition of solid sodium chlorate, $NaClO_3$. Similarly, when an air bag deploys during an automobile accident, the nitrogen gas that rapidly inflates the protective air bag is the product of the decomposition of solid sodium azide, NaN_3. Gases are also reactants, as in the combustion of charcoal in a backyard grill. Solid carbon reacts with oxygen gas in the air to produce carbon dioxide and the heat used to cook our food:

In any chemical reaction that involves a gas as either a reactant or a product, the volume of the gas indirectly defines the amount of it in the reaction. If *T* and *P* are known, we can use the ideal gas equation to relate volume to the number of moles of gas in the system. Once we know that, we can use stoichiometric calculations to relate quantities of gas to quantities of other reactants and products, including heat. For example, what volume of oxygen is needed to completely burn 1.00 kg (about 2 lb) of charcoal at 1.00 atm of pressure on an average summer day (25°C)? Before starting the calculation, we must first write a balanced chemical equation for the reaction. Equation 5.19 is already balanced, so 1 mole of C reacting with 1 mole of O_2 should yield 1 mole of CO_2. If we start with 1.00 kg of C, we have

---

According to the stoichiometry of the reaction, we need 83.3 moles of O_2 to completely react with the given amount of C. The volume of O_2 that corresponds to 83.3 moles of O_2 is calculated using the ideal gas equation by first rearranging the equation to solve for *V* and then substituting the values of *n, R, T* (in kelvins), and *P*:

SAMPLE EXERCISE 5.8 Combining Stoichiometry and the Ideal Gas Law LO3

Oxygen generators in some airplanes (**Figure 5.22**) are based on the chemical reaction between solid sodium chlorate ($\mathscr{M}$ = 106.44 g/mol) and iron:

$NaClO_3(s) + Fe(s) \rightarrow O_2(g) + NaCl(s) + FeO(s)$

The resultant O_2 is blended with cabin air to provide 10–15 minutes of breathable air for passengers. How many grams of $NaClO_3$ are needed in a typical generator to produce 125 L of O_2 gas at 1.00

atm and 20.0°C?

Collect and Organize We are given the volume of O_2 to be generated at a particular pressure and temperature. Using this information, we can determine the mass of $NaClO_3$ needed based on the stoichiometric relations in the balanced chemical equation.

Analyze The solution requires two calculations. (1) According to the balanced chemical equation, 1 mole of $NaClO_3$ is needed to produce 1 mole of O_2. If we can determine how many moles of O_2 occupy a volume of 125 L at 1.00 atm pressure and 20.0°C, we can determine the number of moles of $NaClO_3$ we need. To determine the moles of O_2 (n_{O_2}), we can use the ideal gas law (Equation 5.15). (2) Then we use our calculated value of n_{O_2} and the balanced chemical equation to determine the number of moles and number of grams of $NaClO_3(s)$ required.

To estimate the answer, notice that the volume of gas we wish to make (125 L) is about five times the molar volume of an ideal gas at STP (22.4 L). The difference between the temperature at STP (0°C = 273 K) and the temperature in this problem (20°C = 293 K) is relatively small, so we need about 5 moles of O_2, which requires about 5 moles or about 500 g $NaClO_3$.

Solve Use the rearranged ideal gas equation to solve for moles of O_2:

To convert moles of O_2 into an equivalent mass of $NaClO_3$, we use the stoichiometry of the reaction to calculate the equivalent number of moles of $NaClO_3$, and we use molar mass to determine the number of grams of $NaClO_3$ required:

Think About It We predicted that about 500 g $NaClO_3$ would be needed, which is within about 10% of the calculated value.

Practice Exercise Automobile air bags (**Figure 5.23**) inflate during a crash or sudden stop as a result of a series of rapid chemical reactions that include the generation of nitrogen gas from solid sodium azide:

$2\ NaN_3(s) \rightarrow 2\ Na(s) + 3\ N_2(g)$

How many grams of sodium azide are needed to produce 50.0 L of N_2 at a pressure of 1.20 atm at 15°C?

(Answers to Practice Exercises are in the back of the book.)

SAMPLE EXERCISE 5.9 Reactant Volumes and the Ideal Gas Law LO3

Scientists exploring nonbiological reactions that lead to amino acid formation are interested in reactions between methane and ammonia. One such reaction produces cyanamide, H_2NCN:

$CH_4(g) + 2\ NH_3(g) \rightarrow H_2NCN(g) + 4\ H_2(g)$

If a reaction mixture contains 1.25 L of methane and 3.00 L of ammonia, what volume of hydrogen could theoretically be produced at constant temperature and pressure?

Collect and Organize We are given the chemical equation and the volumes of the two reactant gases, and we are asked to calculate the volume of product gas. Temperature and pressure are constant, but their values are not specified. According to Avogadro’s law (Equation 5.10), the volume of a gas is proportional to the number of moles of gas in it at constant temperature and pressure.

Analyze When the quantities of two reactants are given, one is likely to be the limiting reactant, so solving this exercise will involve identifying that reactant. The stoichiometric ratio is 4 moles of H_2 produced for every 1 mole of CH_4 and 2 moles of NH_3 consumed, and it is equivalent to the same ratio of volumes at constant T and P. For example, 4 L H_2 : 1 L CH_4 : 2 L NH_3.

Solve Identifying the limiting reactant by calculating the volume of H_2 it could produce:

Methane is the limiting reactant, and the theoretical yield is 5.00 L H_2.

Think About It Had we known the temperature and pressure of the reaction system, we could have used the ideal gas equation to calculate the moles of the two reactants and then calculate the moles of H_2 each could theoretically produce. We then could convert the lesser of those two values into a volume of H_2. This approach would have entailed a lot more arithmetic and yielded the same result: 5.00 L H_2.

Practice Exercise Dinitrogen monoxide, N_2O, commonly known as nitrous oxide, is used as an anesthetic or "laughing gas" in many dental procedures (**Figure 5.24**). If 316 mL of nitrogen is combined with 178 mL of oxygen, what volume of N_2O is produced at constant temperature and pressure if the reaction proceeds to 82% yield?

$2\ N_2(g) + O_2(g) \rightarrow 2\ N_2O(g)$

(Answers to Practice Exercises are in the back of the book.)

Learning Objectives

- Relate the volumes of gas phase reactants and products to the quantities of other reactants and products by using the stoichiometry of a reaction and the ideal gas law **Return to Sample Exercises 5.8, 5.9**

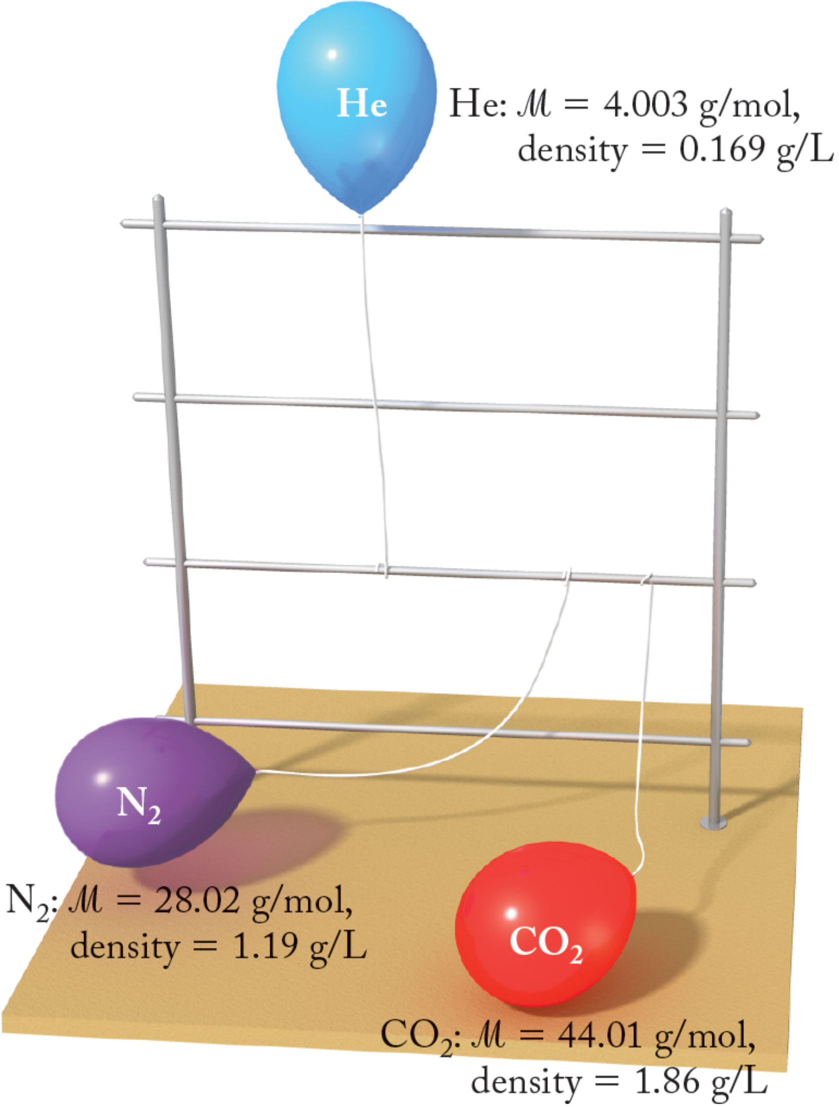
FIGURE 5.25 The release of CO_2 from volcanic centers on Indonesia's Dieng Plateau in 1979 killed many people and animals as the dense gas flowed over the valley floor, effectively displacing the air (i.e., oxygen) that the inhabitants and their livestock needed to survive.

$$\frac{44.01\ \text{g}/\cancel{\text{mol}}}{22.4\ \text{L}/\cancel{\text{mol}}} = 1.96\ \text{g/L}$$

$$\frac{P}{RT} = \frac{n}{V} \tag{5.20}$$

$$\frac{P\mathcal{M}}{RT} = \frac{n\mathcal{M}}{V} = \frac{m}{V}$$

$$d = \frac{P\mathcal{M}}{RT} \tag{5.21}$$



He
He: $\mathcal{M}$ = 4.003 g/mol, density = 0.169 g/L
N_2
N_2: $\mathcal{M}$ = 28.02 g/mol, density = 1.19 g/L
CO_2
CO_2: $\mathcal{M}$ = 44.01 g/mol, density = 1.86 g/L

FIGURE 5.26 At 15°C and 1 atm, the density of the gas inside each balloon determines whether the balloon floats (helium), hovers just slightly above the benchtop (nitrogen), or sinks (carbon dioxide). Note the correlation between molar mass and density: the larger the molar mass of a gas, the greater the density.

FIGURE 5.27 Increasing the temperature of the air in the balloon leads to a decrease in density as the air expands. Hot air in a balloon is less dense than cooler air, making the balloon buoyant.

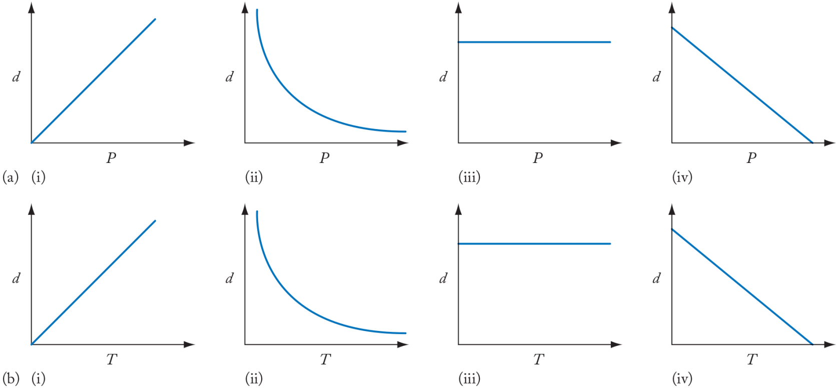


FIGURE 5.28

$$d = \frac{P\mathcal{M}}{RT} = \frac{(1.00\ \cancel{\text{atm}})\left(28.8\ \frac{\text{g}}{\cancel{\text{mol}}}\right)}{[0.08206\ \text{L} \cdot \cancel{\text{atm}}/(\cancel{\text{mol}}) \cdot \cancel{\text{K}}](302\ \cancel{\text{K}})} = 1.16\ \text{g/L}$$

$$\mathcal{M} = \frac{dRT}{P} \tag{5.22}$$

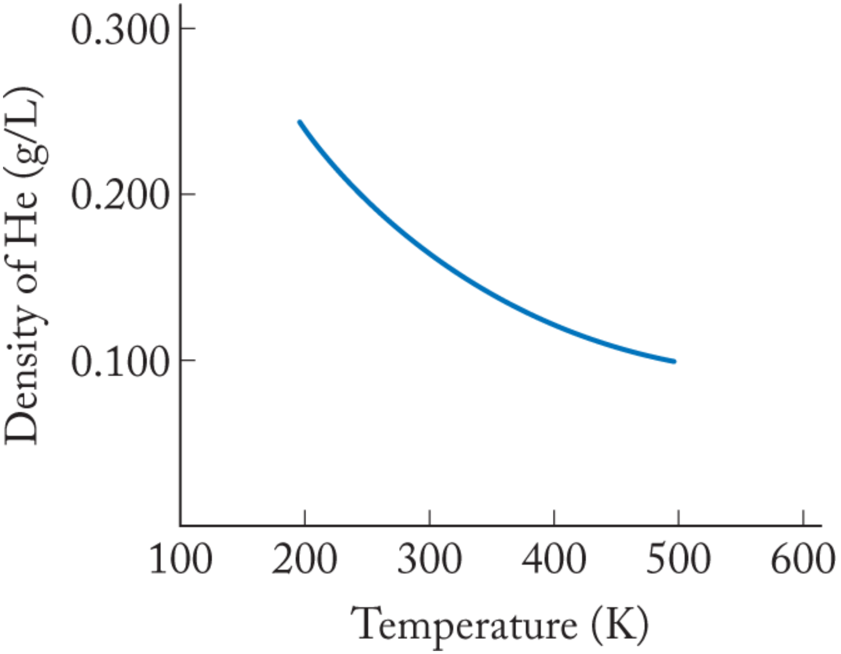

FIGURE 5.29 At $P = 1$ atm, the density of helium decreases with increasing temperature. The density of any ideal gas at constant pressure is inversely proportional to its absolute temperature.

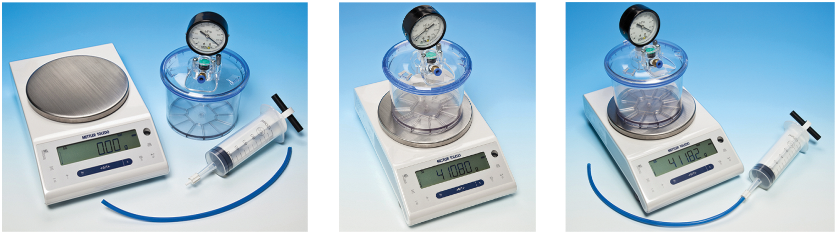

(a) (b) (c)

FIGURE 5.30 (a) A gas collection tube with an internal volume of 235 mL is evacuated by connecting it to a vacuum pump. (b) The mass of the evacuated tube is measured. (c) Then the tube is opened to the atmosphere and refills with air. The difference in mass between the filled and evacuated tubes (0.273 g, or 273 mg) is the mass of the air inside it. The density of the air sample is 273 mg/235 mL, or 1.16 mg/mL.

$$T = 273 + 25.0 = 298\ \text{K}$$

$$P = 757\ \cancel{\text{mmHg}} \times \frac{1}{760\ \cancel{\text{mmHg}}} = 0.996\ \text{atm}$$

$$\mathcal{M} = \frac{dRT}{P} = \left(\frac{0.650\ \text{g}}{\cancel{\text{L}}}\right)\left(\frac{0.08206\ \cancel{\text{L}} \cdot \cancel{\text{atm}}}{\text{mol} \cdot \cancel{\text{K}}}\right)\left(\frac{298\ \cancel{\text{K}}}{0.996\ \cancel{\text{atm}}}\right)$$

$$= 16.0\ \text{g/mol}$$

5.6 Gas Density

Releases of large quantities of $CO_2(g)$ from volcanic activity contribute to growing atmospheric concentrations of the gas, but volcanic emissions can be life-threatening, too. On the Dieng Plateau in Indonesia in 1979, 149 people died from asphyxiation in a valley after a sudden, massive release of carbon dioxide from a nearby volcano (**Figure 5.25**). The deaths occurred because the CO_2 settled into the bottom of the valley, displacing the air (and oxygen) there. This happened because CO_2 is denser than air.

The density of a gas at STP can be calculated by dividing its molar mass by its molar volume. Carbon dioxide has a molar mass of 44.01 g/mol, so its density at STP is

The density of air, which is mostly a mixture of N_2 and O_2, is only about 1.3 g/L at STP. The greater density of CO_2 also explains why it so effectively fights fires: it blankets burning fuel, separating it from the O_2 it needs to burn, thus extinguishing the fire.

CONCEPT TEST

Which gas has the highest density at STP: CH_4, Cl_2, Kr, or C_3H_8?

(Answers to Concept Tests are in the back of the book.)

We can calculate the density of an ideal gas at any temperature and pressure by using the ideal gas equation. Because density is the mass of a sample divided by its volume, $d = m/V$, we need to identify the variables in the ideal gas equation that represent the density. Mass can be determined from the number of moles, and the V in the ideal gas equation is the volume. We can rearrange Equation 5.15:

If we multiply both sides of the equation by the molar mass ($\mathscr{M}$) of the gas, then the numerator on the right side of the equation is the product of $\mathscr{M} \times n$, which has units of [(grams/mole) × mole] or grams. In other words, the product is mass (m):

The right-most fraction (mass/volume) is the definition of density (d). Therefore:

Figure 5.26 illustrates the relationship between density and molar mass of three pure gases and air. Note how the balloon containing $CO_2(g)$ does not float at all but sinks to the benchtop because the density of this pure gas is greater than the density of air. In the absence of any wind currents or mixing, carbon dioxide will always sink through air, just as it filled the valley in the Dieng Plateau disaster.

Equation 5.21 can also be used to explain why a balloon inflated with hot air rises (**Figure 5.27**). Like a bicycle tire, the volume of the balloon is essentially constant once inflated. As the temperature of the air inside the balloon increases, the balloon can no longer expand. However, the balloons in Figure 5.27 represent open systems—gas can escape from the bottom of the balloon, so n decreases. This effect can be seen in Equation 5.20, where increasing T at constant P and V means that n must decrease. If n decreases, d will also decrease. Put another way, the density of a given quantity of gas decreases with increasing temperature, giving the balloon buoyancy.

CONCEPT TEST

Which graph in **Figure 5.28** best approximates (a) the relationship between density and pressure (*n* and *T* constant) and (b) the relationship between density and temperature (*n* and *P* constant) for an ideal gas?

(Answers to Concept Tests are in the back of the book.)

SAMPLE EXERCISE 5.10 Calculating the Density of a Gas LO4

Calculate the density of air at 1.00 atm and 302 K and compare your answer with the density of air at STP (1.29 g/L). Assume that air has an average molar mass of 28.8 g/mol. (This average molar mass is the weighted average of the molar masses of the gases in air as listed in Table 5.1.)

Collect, Organize, and Analyze We are provided with the average molar mass, temperature, and atmospheric pressure of air, and we can use Equation 5.21 to calculate its density. The density of a gas is inversely proportional to temperature, and the temperature in this exercise (302 K) is higher than the temperature at STP, so the density of the air should be less than 1.29 g/L.

Solve Inserting the values of *P*, *T*, and $\mathcal{M}$ into Equation 5.21, we have

Think About It The calculated density of air at 302 K is less than the value at 273 K (1.29 g/L) as we expected. The density of air (and most gases) is considerably less than that of liquids. For example, the density of liquid water is 1.00 g/mL or 1.00 kg/L, about 1000 times greater than the density of air.

Practice Exercise Air is a mixture of mostly nitrogen and oxygen. A balloon filled with only oxygen is released in a room full of air. Will it sink to the floor or float to the ceiling?

(Answers to Practice Exercises are in the back of the book.)

Equation 5.21, which shows that density decreases as temperature increases (**Figure 5.29**), can be rearranged so that the molar mass of a gas can be calculated from its density at any temperature and pressure:

Gas density can be determined with a glass tube of known volume attached to a vacuum pump (**Figure 5.30**). The mass of the tube is determined when it has essentially no gas in it and again when it is filled with the test gas. The difference in the masses divided by the volume of the tube is the density of the gas.

SAMPLE EXERCISE 5.11 Calculating Molar Mass from Density LO4

Vent pipes at solid-waste landfills often emit foul-smelling gases that may be either relatively pure substances or mixtures of several gases. A sample of such an emission has a density of 0.650 g/L at 25.0°C and 757 mmHg. What is the molar mass of the gas emitted? (If the sample is a mixture, then the answer will be the weighted average of the molar masses of the individual gases.)

Collect, Organize, and Analyze We are given the density, temperature, and pressure of a gaseous sample. We can use Equation 5.22 to calculate the molar mass. Don’t forget to convert the temperature to kelvins and the pressure to atmospheres before using these values in the equation.

Many gases have relatively low molar masses, so we expect that the molar mass should be similar to that of typical gases we have discussed in this chapter.

Solve

Think About It The density of the landfill gas (0.650 g/L) is a little more than half the density of air (1.16 g/L) at 302 K, which we calculated in Sample Exercise 5.10, so the calculated molar mass of the gas should be a little more than half that of air (28.8 g/mol), which it is. The calculated value is also consistent with that of methane, a principal component in the mixture of gases emitted by decomposing solid waste.

Practice Exercise When $HCl(aq)$ and $NaHCO_3(aq)$ are mixed, a chemical reaction takes place in which a gas is one of the products. A sample of the gas has a density of 1.81 g/L at 1.00 atm and 23.0°C. What is the molar mass of the gas? Write a balanced chemical equation to identify the gas.

(Answers to Practice Exercises are in the back of the book.)

$$n = \frac{PV}{RT} = \frac{(0.963\ \cancel{\text{atm}})(0.0920\ \cancel{\text{L}})}{[0.08206\ \cancel{\text{L}} \cdot \cancel{\text{atm}}/(\text{mol} \cdot \cancel{\text{K}})](298\ \cancel{\text{K}})} = 0.00362\ \text{mol}$$

$$m_{O_2} = 0.00362\ \cancel{\text{mol}} \times \frac{32.00\ \text{g}}{1\ \cancel{\text{mol}}} = 0.116\ \text{g}$$

5.7 Dalton’s Law and Mixtures of Gases

Air is mostly N_2 and O_2 (Table 5.1) with smaller quantities of other gases. Each gas in air, and in any other gas mixture, exerts its own pressure, called a partial pressure. Atmospheric pressure is the sum of the partial pressure of each gas in the air:

$$P_{\text{atm}} = P_{N2} + P_{O2} + P_{Ar} + P_{CO2} + \ldots$$

A similar expression can be written for any mixture of gases:

This is a mathematical expression of Dalton’s law of partial pressures: the total pressure of any mixture of gases equals the sum of the partial pressure of each gas in the mixture.

The most abundant gases in a mixture have the greatest partial pressures and contribute the most to the total pressure of the mixture: their particles have the largest number of collisions simply because there are more of them. The mathematical term used to express the abundance of each component, x, is its mole fraction (X_x),

where n_x is the number of moles of component x and n_{total} is the sum of the number of moles of all the components of the mixture.

The mole fraction as an expression of concentration has three characteristics worth noting: (1) unlike molarity, mole fractions have no units; (2) unlike molarity, mole fractions are based on numbers of moles and can be used for any mixture or solution (solid, liquid, or gas); and (3) the mole fractions of all the components in a mixture must sum to 1.

To see how mole fractions work, consider a sample of the atmosphere (air) that contains 100.0 moles of atmospheric gases. This sample consists of 21.0 moles of O_2 and 78.1 moles of N_2. The mole fraction of O_2 in the air sample is

and the mole fraction of N_2 is

Mole fractions express concentrations based on numbers of moles (and molecules) of substances in mixtures. In a sample of air, for example, the greater mole fraction of N_2 also means there are more moles (and molecules) of nitrogen than there are moles of oxygen:

N_2 78.1 mol $\times$ (6.022×10^{23} molecules/mol) = 4.70×10^{25} molecules

O_2 21.0 mol $\times$ (6.022×10^{23} molecules/mol) = 1.26×10^{25} molecules

CONCEPT TEST

The partial pressure of one component of a gas mixture cannot be measured directly. Why?

(Answers to Concept Tests are in the back of the book.)

The partial pressure of any gas in air can be calculated by multiplying the mole fraction of the gas times the total atmospheric pressure. If the total pressure is 1.00 atm, for instance, as it often is at sea level, the partial pressures of O_2 and N_2 in the example above are

$$P_{O2} = X_{O2}P_{total} = (0.210)(1.00 \text{ atm}) = 0.210 \text{ atm}$$

$$P_{N2} = X_{N2}P_{total} = (0.781)(1.00 \text{ atm}) = 0.781 \text{ atm}$$

These two equations are specific instances of the general equation for the partial pressure of one gas, *x*, in a mixture of gases:

The pressure of a gas is directly proportional to the *quantity* of the gas in a given volume and does *not* depend on the *identity* of the gas or whether the gas is pure or a mixture (**Figure 5.31**). Because P_{total} is a measure of the total number of collisions within a mixture, the partial pressure of one gas is due to some fraction of the total collisions. That fraction is the mole fraction of that gas.

SAMPLE EXERCISE 5.12 Calculating Mole Fractions LO5

Scuba divers who descend more than 45 m below the surface may use a gas mixture called Trimix to support their breathing. Trimix is available in several different concentrations, including 11.7% He, 56.2% N_2, and 32.1% O_2, by mass. This mixture of gases avoids high concentrations of dissolved nitrogen in the blood at great depth, which can lead to *nitrogen narcosis*, a potentially deadly condition for divers. Calculate the mole fraction of each gas in this mixture.

Collect, Organize, and Analyze If we assume a 100.0 g sample of Trimix with a specified composition, then we can calculate the mass of each gas from the mass percentages. Next, we can convert each mass to moles, from which we can determine the total number of moles in the sample and the mole fraction of each gas. Mole fraction is defined in Equation 5.24, and to calculate it we need to calculate both the total number of moles of gas in the mixture and the number of moles of each component.

We can estimate the answer by considering the relative molar masses of the three gases. The molar masses of nitrogen and oxygen are similar and seven to eight times larger, respectively, than the molar mass of helium. Because N_2 constitutes a higher percentage of the mass of the mixture than does O_2, the mole fraction of nitrogen should be larger than that of oxygen. Furthermore, the mole fractions of He, N_2, and O_2 should be quite different from the mass percentages of the three gases because the molar mass of He is much less than the molar masses of N_2 and O_2.

Solve In 100.0 g of this mixture we would have 11.7 g of He, 56.2 g of N_2, and 32.1 g of O_2. Using molar masses to convert these masses into moles yields

Mole fractions are calculated with Equation 5.24. The total number of moles in 100.0 g of Trimix is the sum of the number of moles of the constituent gases: He, N_2, and O_2.

$n_{\text{total}} = 2.92 + 2.01 + 1.00 = 5.93 \text{ mol}$

Thus, X_{He}, X_{N2}, and X_{O2} are

Alternatively, we could use Equation 5.24 for all but one of the gases in the sample and then calculate the mole fraction of the final component by subtracting the sum of the calculated mole fractions from 1.00. For example, we could use the equation to calculate the mole fractions of He and N_2 and then determine the O_2 mole fraction by difference:

$X_{\text{O2}} = 1 - (X_{\text{He}} + X_{\text{N2}}) = 1 - (0.492 + 0.339) = 0.169$

Think About It We can check the answer by summing the mole fractions; they should add up to 1.

$X_{\text{He}} + X_{\text{N2}} + X_{\text{O2}} = 1$

$0.492 + 0.339 + 0.169 = 1.00$

Finally, as we predicted, the mole fractions of the three gases do not reflect their mass percentages. Although nitrogen is present in the greatest amount by mass in Trimix, helium has the largest mole fraction.

Practice Exercise A gas mixture called Heliox that is 52.17% O_2 and 47.83% He by mass is used in scuba tanks for descents more than 65 m below the surface. Calculate the mole fractions of He and O_2 in this mixture.

(Answers to Practice Exercises are in the back of the book.)

CONCEPT TEST

Does each of the gases in an equimolar mixture of four gases have the same mole fraction?

(Answers to Concept Tests are in the back of the book.)

Let's apply Equation 5.25 to the "thin" air at high altitudes. The mole fraction of oxygen in air is 0.210 and does not change significantly with increasing altitude. The total pressure of the atmosphere, however, and therefore the partial pressure of oxygen, decreases with increasing altitude, as illustrated in Sample Exercise 5.13.

SAMPLE EXERCISE 5.13 Calculating Partial Pressure LO5

Calculate the partial pressure of O_2 (in atm) in the air outside an airplane cruising at an altitude of 10 km, where the atmospheric pressure is 190.0 torr. The mole fraction of O_2 in the air is 0.210.

Collect, Organize, and Analyze We are given both the mole fraction of oxygen and atmospheric pressure, and we are asked to calculate the partial pressure of oxygen. Equation 5.25 relates the partial pressure of a gas in a gas mixture to its mole fraction in the mixture and to the total gas pressure.

Solve

Think About It The partial pressure of oxygen in air at sea level is 0.210 atm. At higher altitudes, the atmosphere becomes thinner (less dense). Our answer of 0.0525 atm makes sense because, at an altitude of 10 km, the air is much less dense than at sea level.

Practice Exercise Assume a scuba diver is working at a depth where the total pressure is 5.0 atm (about 50 m below the surface). What mole fraction of oxygen is necessary in the gas mixture the diver breathes for the partial pressure of oxygen to be 0.21 atm?

(Answers to Practice Exercises are in the back of the book.)

Sample Exercises 5.12 and 5.13 illustrate how much humans depend on the atmosphere and the properties of gases that compose it. If we venture very far from Earth’s surface into the mountains or into the oceans, we have to take the right blend of gases with us to sustain life. The scuba diver can’t breathe the same mixture of gases as we do on the surface of Earth because the increased partial pressure of O_2 can be toxic below 30 m. Similarly, a higher partial pressure of N_2 could lead to nitrogen narcosis, a dangerous condition caused by a high concentration of nitrogen in the blood that leads to hallucinations. Alpine climbers on the tallest peaks on Earth must be vigilant against the opposite problem. For them, the lower atmospheric pressure leads to a lower partial pressure of oxygen, making it hard to get enough oxygen into the blood. Most mountaineers in these locations carry bottled oxygen. The lower partial pressure of oxygen at high elevations is also the reason that aircraft cabins are pressurized.

Dalton’s law of partial pressures is also useful in the laboratory when we want to measure the pressure exerted by a gaseous product in a chemical reaction. For example, heating potassium chlorate ($KClO_3$) in the presence of MnO_2 causes it to decompose into $KCl(s)$ and $O_2(g)$. The oxygen gas produced by this reaction can be collected by bubbling the gas into an inverted bottle that is initially filled with water (**Figure 5.32**). As the reaction proceeds, $O_2(g)$ displaces the water in the bottle. When the reaction is complete, the volume of water displaced provides a measure of the volume of O_2 produced. If you know the temperature of the water and the barometric pressure at the time of the reaction, then you can use the ideal gas law to calculate the number of moles of O_2 produced.

TABLE 5.4 Partial Pressure of $H_2O(g)$ at Selected Temperatures

Temperature (°C)	Pressure (torr)
5	6.5
10	9.2
15	12.8
20	17.5
25	23.8
30	31.8
35	42.2
40	55.3
45	71.9
50	92.5

This procedure works for any gas that neither reacts with nor dissolves appreciably in water. However, one additional step is needed to calculate the number of moles of gas produced from the ideal gas law. At room temperature (nominally 20°C), any enclosed space above a pool of liquid water contains some $H_2O(g)$, meaning some water vapor is in the collection flask in addition to the gas produced by the reaction. In the $KClO_3$ reaction in Figure 5.32, therefore, the gas collected is a mixture of both $O_2(g)$ and $H_2O(g)$. A mixture of a gas and water vapor is said to be *wet*, in contrast to a gas that contains no water vapor, which is said to be *dry*. The amount of water vapor increases as temperature increases (**Table 5.4**). Dalton's law of partial pressures gives us the total pressure of the mixture at the point where the water level inside the collection vessel matches the water level outside the vessel:

To calculate the quantity of oxygen produced using the ideal gas law, we must know P_{O2}, which we get by subtracting P_{H2O} at 20°C (see Table 5.4) from P_{atm}. If we know the values of T and V, we can calculate the number of moles (or subsequently, the number of grams) of oxygen produced.

SAMPLE EXERCISE 5.14 Determining the Quantity of a Gas Collected over Water LO5

During the decomposition of $KClO_3$, 92.0 mL of gas was collected by the displacement of water at 25.0°C. If atmospheric pressure is 756 torr, what mass of O_2 was collected?

Collect and Organize We are given the atmospheric pressure, the volume of oxygen, and the temperature, and we are asked to calculate the mass of oxygen collected by water displacement. According to Table 5.4, the vapor pressure of water at 25°C is 23.8 torr.

Analyze Because O_2 is collected by water displacement, the total pressure inside the collection vessel, which is 756 torr, is the sum of the partial pressure of O_2 and the vapor pressure of water (23.8 torr). At 25°C the molar volume of an ideal gas should be about 10% more than 22.4 L, or about 25 L. The volume of gas collected is about $0.1\text{ L}/25\text{ L} = 0.004$ molar volumes. The gas is mostly O_2, so multiplying $0.004 \times 32.00\text{ g }O_2/\text{mol}$ gives an estimate of 0.12 g O_2 collected.

Solve Calculating P_{O2} in the collected gas

$$P_{O2} = P_{\text{total}} - P_{H2O} = 756\text{ torr} - 23.8\text{ torr} = 732\text{ torr}$$

Using the ideal gas equation to calculate the moles of O_2 requires first converting P_{O2} to atmospheres, V to liters, and T to kelvins:

The mass of O_2 collected is

Think About It The calculated mass of O_2 matches the preliminary estimate even though we ignored the presence of water vapor in developing the estimate. However, the estimate is based on calculations that often use values expressed with only one significant figure. The contribution of water vapor to total pressure becomes significant when the goal is a quantity expressed with two or more significant figures.

Practice Exercise Electrical energy can be used to separate water into $O_2(g)$ and $H_2(g)$—a process called electrolysis. The gases are collected separately. In one demonstration of this reaction, 27 mL of H_2 was collected over water at 25°C. If the atmospheric pressure was 761 torr, how many milligrams of H_2 were collected?

(Answers to Practice Exercises are in the back of the book.)

Glossary

partial pressure	the contribution to the total pressure made by one gas in a mixture of gases.
Dalton’s law of partial pressures	the principle that the total pressure of any mixture of gases equals the sum of the partial pressure of each gas in the mixture.
mole fraction (X_x)	the ratio of the number of moles of a component in a mixture to the total number of moles in the mixture.

5.8 The Kinetic Molecular Theory of Gases

The fundamental discoveries of Boyle, Charles, and Amontons all took place before scientists recognized the existence of molecules. Only Avogadro, because he lived after Dalton, had the advantage of knowing Dalton's proposal that matter was composed of tiny particles called atoms. Thus, Avogadro recognized that the volume of a gas was directly proportional to the number of particles (moles) of gas. Still, Avogadro's law, V/n = constant (Equation 5.10), does not explain why 1 mole of relatively small He(g) atoms at STP has the same volume as 1 mole of much larger SF_6(g) molecules. Dalton's law of partial pressures (Equation 5.23) does not explain *why* each gas in a mixture contributes a partial pressure based on its mole fraction. Similarly, Boyle's, Charles's, and Amontons's laws demand explanations for why pressure and volume are inversely proportional to each other, but both are directly proportional to temperature.

In this section we examine the kinetic molecular theory of gases, a unifying theory developed in the late 19th century that explains the relationships described by the ideal gas law and its predecessors, the laws of Boyle, Charles, Dalton, Amontons, and Avogadro.

The main assumptions of the kinetic molecular theory are:

1. Gas molecules have tiny volumes compared with the collective volume they occupy. Their individual volumes are so small as to be considered negligible, allowing particles in a

gas to be treated as *point masses*—masses with essentially no volume. Gas molecules are separated by large distances; hence, a gas is mostly empty space.
2. Gas molecules move constantly and randomly throughout the volume they collectively occupy.
3. The motion of these molecules is associated with an average kinetic energy that is proportional to the absolute temperature of the gas. All populations of gas molecules at the same temperature have the same average kinetic energy.
4. Gas molecules continually collide with one another and with their container walls. These collisions are *elastic*; that is, they result in no net transfer of energy to the walls. Therefore, the average kinetic energy of gas molecules is not affected by these collisions and remains constant as long as there is no change in temperature.
5. Each gas molecule acts independently of all other molecules in a sample. We assume there are no forces of attraction or repulsion between the molecules.

Explaining Boyle’s, Dalton’s, and Avogadro’s Laws

Every collision between a gas molecule and a wall of its container generates a force. The more frequent the collisions, the greater the force and thus the greater the pressure. Compressing molecules into a smaller space by reducing the volume of the container means more collisions take place per unit time, and the pressure increases (Boyle’s law: $P \propto 1/V$). Because $P \propto n$, we can also increase the number of collisions by increasing the number of gas molecules (number of moles, n) in a container of fixed volume (**Figure 5.33a and b**). We can increase n either by adding more of the same gas to a container of fixed volume or by adding some quantity of a different gas to the container. If we add two gases, such as N_2 and O_2, to a container in a 4:1 mole ratio, then the number of collisions involving nitrogen molecules and a container wall will be greater than the number involving oxygen molecules. Therefore, the pressure due to nitrogen (P_{N2}) will be greater than that due to oxygen (P_{O2}), and the total pressure will be $P_{\text{total}} = P_{O2} + P_{N2}$. This statement is precisely what Dalton proposed in his law of partial pressures.

Kinetic molecular theory explains Avogadro's law ($V \propto n$), too. Avogadro observed that the volume of a gas *at constant pressure* is directly proportional to the number of moles of the gas. Because additional gas molecules in a given volume lead to increased numbers of collisions and an increase in pressure, one way to reduce the pressure is to allow the gas to expand (**Figure 5.33c**).

CONCEPT TEST

If the collisions between molecules and the walls of the container were *not* elastic and energy was lost to the walls, would the pressure of the gas be higher or lower than that predicted by the ideal gas law?

(Answers to Concept Tests are in the back of the book.)

Explaining Amontons's and Charles's Laws

Amontons's law ($P \propto T$) and Charles's law ($V \propto T$) both depend on temperature, and both can be explained in terms of kinetic molecular theory. Why is pressure directly proportional to temperature? Like pressure, temperature is directly related to molecular motion. The average speed at which a population of molecules moves increases with increasing temperature. For a given number of gas molecules, increasing the temperature increases the velocity of the molecules and therefore increases the frequency and average kinetic energy with which the molecules collide with one another and with the walls of their container. Because pressure is related to the frequency and force of these collisions, it follows that higher temperatures produce higher pressures, as long as volume and quantity of gas are constant. **Figure 5.34a** illustrates Amontons's law on a molecular level.

How do increased frequency of collisions and higher average kinetic energy explain Charles's law, which states that the volume of a quantity of an ideal gas is proportional to its absolute temperature at constant pressure? As temperature increases, the system must expand—increase its volume—to maintain a constant pressure (**Figure 5.34b**).

Molecular Speeds and Kinetic Energy

Kinetic molecular theory tells us that all populations of gas particles at a given temperature have the same *average* kinetic energy. The kinetic energy of a single molecule or atom of a gas is given by the following equation

where m is the mass of a molecule of the gas and u is its speed. At any given moment, however, not all gas molecules in a population are traveling at the same speed. Even elastic collisions between two molecules may result in one of them moving with a greater speed than the other after the collision. One molecule might even stop moving. Thus, collisions between gas molecules cause the molecules in any sample to have a range of speeds.

Figure 5.35 shows a typical distribution of speeds in a population of gas molecules. The peak in the curve represents the *most probable speed* (u_{m}) of molecules in the population. It is the speed of the largest number of molecules in the sample. The value of u_{m} depends on gas temperature because higher temperatures mean higher kinetic energies and higher molecular speeds.

Because the distribution of speeds is not symmetrical, the *average speed* (u_{avg}), which is the simple arithmetic mean of all the speeds of all the molecules in the population, is a little higher than the most probable speed. The root-mean-square speed (u_{rms}) is the speed of a molecule that has the average kinetic energy of a population of gas molecules. Average kinetic energy and u_{rms} are related by an equation with a familiar appearance:

The value of the u_{rms} of a gas can be calculated from its molar mass and temperature:

Equation 5.28 conveys the message that the velocities of gas particles are proportional to the square root of their absolute temperature and inversely proportional to the square root of their masses: the smaller the particles, the faster they move. **Figure 5.36** shows how the most probable molecular speed (u_m, dashed lines) of a gas increases with increasing temperature and how the distribution of these speeds broadens with increasing temperature. **Figure 5.37** shows the different distributions of speeds for several gases with a range of molar masses from 2 to 32 g/mol at the same temperature.

CONCEPT TEST

Rank these gases in order of increasing root-mean-square speed at 20°C, lowest speed first: H_2, CO_2, Ar, SF_6, UF_6, Kr.

(Answers to Concept Tests are in the back of the book.)

To calculate u_{rms} using Equation 5.28 we need an R value with velocity units in it. Table 5.3 contains such an R value:

Using this value for R requires that we express molar mass in kilograms per mole instead of grams per mole, as illustrated in the following sample exercise.

SAMPLE EXERCISE 5.15 Calculating Root-Mean-Square Speeds LO7

Calculate the root-mean-square speed of nitrogen molecules at 300.0 K in meters per second.

Collect, Organize, and Analyze We are asked to calculate the value of u_{rms} of N_2 molecules at 300.0 K. The molar mass of N_2 is 28.01 g/mol. Equation 5.28 relates T, $\mathscr{M}$, and R, but first the value of $\mathcal{M}$ must be converted into kg/mol.

Solve Convert $\mathcal{M}_{N2}$ to kg/mol

Think About It The calculated root-mean-square speed of an N_2 molecule is very high but makes sense because the value of $3RT$ is about 8000 and the value of $\mathcal{M}_{N2}$ in kg/mol is about 0.03, making the value of the fraction about $(250,000)^{1/2}$ or 500.

Practice Exercise Calculate the root-mean-square speed of helium at 300.0 K in meters per second and compare your result with the root-mean-square speed of nitrogen calculated in Sample Exercise 5.15.

(Answers to Practice Exercises are in the back of the book.)

Why are the pressures exerted by two different gases the same at a given temperature when their root-mean-square speeds are quite different? The answer lies in the assumption in the kinetic molecular theory that all populations of gas molecules have the same average kinetic energy at a given temperature, independent of their molar mass. To better understand this, let's calculate the average kinetic energy of 1 mole of N_2 and 1 mole of He at 300 K. According to the solution to Sample Exercise 5.15, the u_{rms} of N_2 molecules at 300 K is 517 m/s. The root-mean-square speed of He atoms is 1367 m/s (the result for the practice exercise of Sample Exercise 5.15). Using these values of speed and the mass of 1 mole of each gas ($m = \mathcal{M}$) in Equation 5.27 gives

---

This calculation demonstrates that the same quantities of two *different* gases have the same average kinetic energy at the same temperature, which means they should exert the same pressure. The slower N_2 molecules collide with the container walls less often, but because they are more massive than He atoms, the N_2 molecules exert a greater force during each collision.

Equation 5.28 enables us to compare the relative root-mean-square speeds of two gases at the same temperature. Consider an equimolar mixture of $N_2(g)$ and $He(g)$. We have just demonstrated that at any given temperature their average kinetic energies are the same:

Rearranging this equation to express the ratio of the root-mean-square speeds in terms of the ratio of the molar masses and then taking the square root of each side, we get

The root-mean-square speed of helium atoms should be 2.645 times higher than that of nitrogen molecules. We can test this by using the values for u_{rms} used above to calculate KE_{N2} and KE_{He}:

The relationship between root-mean-square speeds and molar masses applies to any pair of gases x and y:

This equation leads to the conclusion that the root-mean-square speed of more massive particles is *lower* than the root-mean-square speed of lighter particles.

CONCEPT TEST

Because root-mean-square speed depends on temperature, why doesn't the ratio of the u_{rms} of two gases change with temperature?

(Answers to Concept Tests are in the back of the book.)

Graham's Law: Effusion and Diffusion

Figure 5.38 shows two balloons—one filled with nitrogen and the other with helium. The volume, temperature, and pressure of the gases are identical in the two balloons, and the pressure inside each balloon is greater than atmospheric pressure. Over time, the volume of the helium balloon decreases significantly, but the volume of the nitrogen balloon does not. Why?

The skin of any balloon is slightly permeable; that is, it has microscopic holes that allow gas to escape, reducing the pressure inside the balloon. Why does the helium leak more quickly than the nitrogen? We now know the relationship between root-mean-square speeds and molar masses of two gases, and we have calculated that helium atoms move about 2.65 times faster than nitrogen atoms at the same temperature. The gas with the greater root-mean-square speed (He) leaks out of the balloon at a higher rate. The process of moving through a small opening from a higher-pressure region to a lower-pressure region is called effusion.

In the 19th century, Scottish chemist Thomas Graham (1805–1869) recognized that the effusion rate of a gas is related to its molar mass. Today this relation is known as Graham's law of effusion, and it states that the effusion rate of any gas is inversely proportional to the square root of its molar mass. We can derive a mathematical representation of Graham's law starting from Equation 5.28 for two gases x and y:

We take the ratio of the root-mean-square speeds, which we designate as the effusion rates r_x and r_y:

Equation 5.30 simplifies to Equation 5.31, the usual form of Graham's law:

Using Equation 5.31 for the helium and nitrogen balloons, we see that the effusion rate of helium compared to nitrogen is:

This expression has the same form—and hence the ratio has the same value—as the ratio of the root-mean-square speeds of the N_2 and He molecules.

Two things about Equation 5.31 are worth noting: (1) Like the root-mean-square speed in Equation 5.29, Graham's law involves a square root. (2) With labels x and y for two gases in a mixture, the left side of Equation 5.31 has the x term in the numerator and the y term in the denominator, whereas the right side of the equation has the opposite: the y term is in the numerator and x term in the denominator. Keeping the labels straight is the key to solving problems involving Graham's law.

How does the kinetic molecular theory explain Graham's law of effusion? The escape of a gas molecule from a balloon requires that the molecules encounter one of the microscopic holes in the balloon. The faster a gas molecule moves, the more likely it is to find one of these holes.

Effusion of gas molecules is related to diffusion, which is the spread of one substance through another. If we focus our attention on gases, then diffusion contributes to the passage of odors such as a perfume throughout a room and the smell of baking bread throughout a house. **Figure 5.39** illustrates the diffusion of orange-brown bromine vapor through an apparatus. The rates of diffusion of gases depend on the average speeds of the gas molecules, which depend on their molar masses. Like effusion, the diffusion of gases is described by Graham's law.

SAMPLE EXERCISE 5.16 Applying Graham's Law to Rates of Diffusion of Gases LO7

An odorous gas emitted by a hot spring was found to diffuse 2.92 times slower than helium. What is the molar mass of the emitted gas?

Collect and Organize We are asked to determine the molar mass of an unknown gas on the basis of its rate of diffusion relative to the rate for helium.

Analyze Graham's law (Equation 5.31) relates the relative rate of diffusion of two gases to their molar masses. We know that helium ($\mathscr{M}_{\mathrm{He}} = 4.003$ g/mol) diffuses 2.92 times faster than the unidentified gas (y). Because helium diffuses faster than the unknown gas, we predict that the unidentified gas has a larger molar mass. In fact, it should be about nine (or 3^2) times the mass of He according to Graham's law, or about 36 g/mol, because the ratio of the molar masses will equal the square of the ratio of the diffusion rates.

Solve Beginning with Equation 5.31, and rearranging it to obtain an expression for $\mathscr{M}_y$:

Substituting for the ratio of the diffusion rates and the mass of 1 mole of helium gives

Think About It The molar mass of the unidentified gas is 34.1 g/mol, which is consistent with our prediction. One possibility for the identity of this gas is $H_2S(g)$, $\mathscr{M} = 34.08$ g/mol, a foul-smelling and toxic gas frequently emitted from volcanoes that is also responsible for the odor of rotten eggs.

Practice Exercise Helium effuses 3.16 times as fast as which other noble gas?

(Answers to Practice Exercises are in the back of the book.)

Glossary

kinetic molecular theory	a model that describes the behavior of ideal gases; all equations defining relationships between pressure, volume, temperature, and number of moles of gases can be derived from the theory.
root-mean-square speed (u_{rms})	the square root of the average of the squared speeds of all the molecules in a population of gas molecules; a molecule possessing the average kinetic energy moves at this speed.
effusion	

the process by which a gas escapes from its container through a tiny hole into a region of lower pressure.

Graham’s law of effusion

the principle that the rate of effusion of a gas is inversely proportional to the square root of its molar mass.

diffusion

the spread of one substance (usually a gas or liquid) through another.

Learning Objectives

- Relate the root-mean-square speed of a gas and its rate of effusion and diffusion to its temperature and molar mass **Return to Sample Exercises 5.15, 5.16**
- Relate the root-mean-square speed of a gas and its rate of effusion and diffusion to its temperature and molar mass **Return to Sample Exercises 5.15, 5.16**

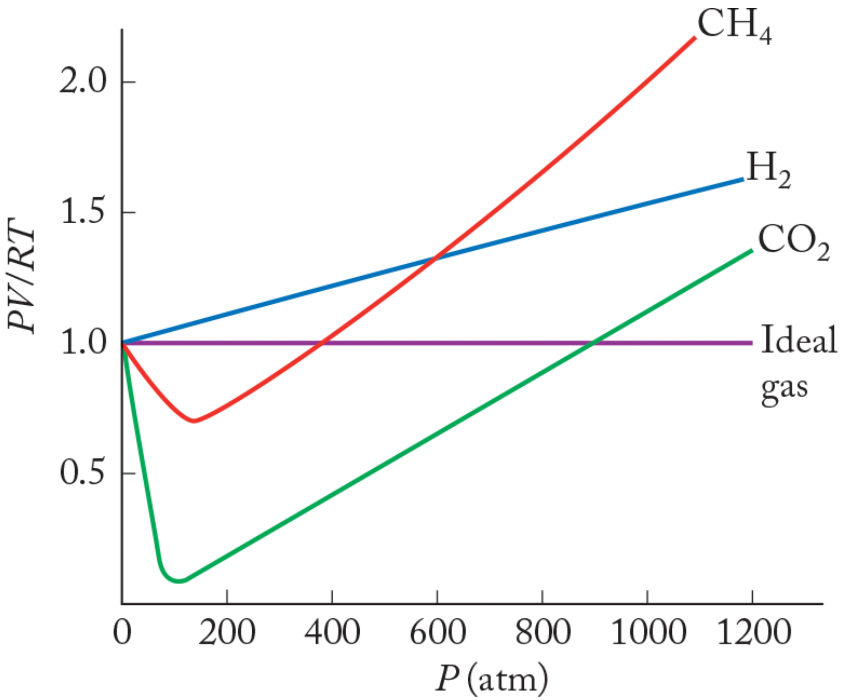

FIGURE 5.40 The effect of very high pressure on the behavior of real and ideal gases. The curves for real gases drop below the horizontal ideal-gas line because of interactions among their molecules. Those curves go above the line as gas molecules take up a larger fraction of the total volume that the gas occupies.

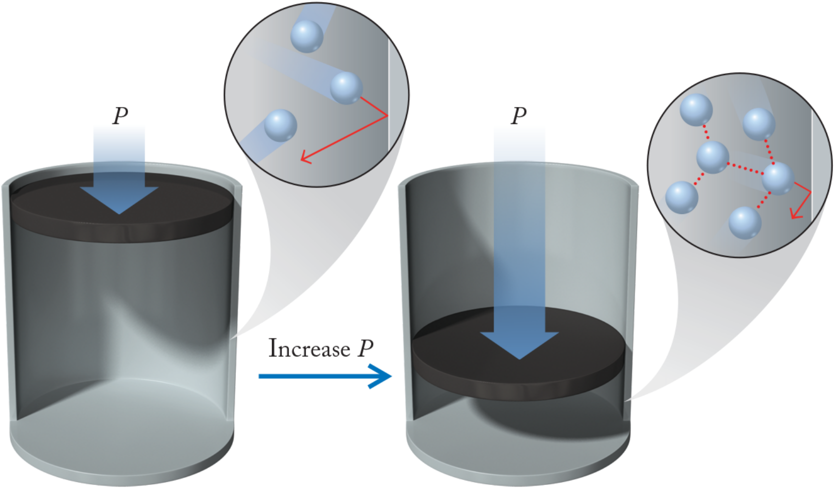

FIGURE 5.41 At high pressures, a larger fraction of the volume of a

gas is occupied by the gas molecules. The larger density of the molecules also results in more interactions between them (broad red arrows in expanded view). These interactions reduce the frequency and force of collisions with the walls of the container (red arrow), thereby reducing the pressure.

$$\left(\frac{PV_{\text{total}}}{RT}\right)_{\text{real gas}} > \left(\frac{PV_{\text{free volume}}}{RT}\right)_{\text{ideal gas}}$$

$$\frac{P_{\text{real}}V}{RT} < \frac{P_{\text{ideal}}V}{RT}$$

$$\left(P + \frac{n^2 a}{V^2}\right)(V - nb) = nRT \tag{5.32}$$

$$\left(P + \frac{n^2 a}{V^2}\right)(V - nb) = nRT \qquad \text{or} \qquad P = \frac{nRT}{V - nb} - \frac{n^2 a}{V^2}$$

$$P_{\text{N}_2} = \frac{(1.00\ \cancel{\text{mol}})\left(0.08206\ \frac{\cancel{\text{L}} \cdot \text{atm}}{\cancel{\text{mol}} \cdot \cancel{\text{K}}}\right)(300.0\ \cancel{\text{K}})}{1.00\ \cancel{\text{L}} - (1.00\ \cancel{\text{mol}})\left(0.0391\ \frac{\cancel{\text{L}}}{\cancel{\text{mol}}}\right)} - \frac{(1.00\ \cancel{\text{mol}})^2\left(1.39\ \frac{\cancel{\text{L}^2} \cdot \text{atm}}{\cancel{\text{mol}^2}}\right)}{(1.00\ \cancel{\text{L}})^2}$$

$$= 24.6\ \text{atm}$$

FIGURE 5.42

5.9 Real Gases

Up to now we have treated all gases as ideal. This is acceptable because, under typical atmospheric pressures and temperatures, most gases *do* behave ideally. We have also assumed, according to kinetic molecular theory, that the volume occupied by individual gas molecules is negligible compared with the total volume occupied by the gas. In addition, we have assumed that no interactions occur between gas molecules other than random elastic collisions. These assumptions are not valid, however, when we begin to compress gases into increasingly smaller volumes.

Deviations from Ideality

How does 1.0 mole of a gas behave as we increase the pressure on it? From the ideal gas law, we know that $PV/RT = n$, so for 1 mole of gas, PV/RT should remain equal to 1.0 regardless of how we change the pressure. The relationship between PV/RT and P for an ideal gas is shown by the purple line in **Figure 5.40**. However, the curves for PV/RT versus P for CH_4, H_2, and CO_2 at pressures above 10 atm are not horizontal, straight lines like this ideal curve. Not only do the curves diverge from the ideal, but the shapes of the curves also differ for each gas, indicating that when we are dealing with real gases, the identity of the gas does matter.

Why don’t real gases behave like ideal gases at high pressure? One reason is that the ideal gas law considers gas molecules to have so little volume compared with the volume of their container that they are assumed to have no volume at all. At high pressures, however, more molecules are squeezed into a given volume (**Figure 5.41**). Under these conditions the volume occupied by the molecules can become significant. What is the impact of this on the graph of PV/RT versus P?

In PV/RT, the V actually refers to the *free volume* ($V_{\text{free volume}}$), the empty space not occupied by gas molecules. Because $V_{\text{free volume}}$ is difficult to measure, we instead measure V_{total}, the total volume of the container holding the gas:

$$V_{\text{total}} = V_{\text{free volume}} + V_{\text{molecules}}$$

In an ideal gas and in a real gas at low pressure, $V_{\text{total}} \approx V_{\text{free volume}}$ because $V_{\text{molecules}}$ is negligible (≈ 0) in relation to the volume of the container (V_{total}). When this condition applies, we can use the ideal gas equation with confidence. Consider, however, what happens to a real gas in a closed but flexible container as we increase the external pressure, causing the container—and hence the volume occupied by the gas—to shrink. As the external pressure increases, the assumption that $V_{\text{molecules}} \approx 0$ becomes less valid because the portion of the container’s volume occupied by the molecules themselves increases. The relationship $V_{\text{total}} = V_{\text{free volume}} + V_{\text{molecules}}$ still applies, but now, $V_{\text{molecules}} \neq 0$, which means $V_{\text{free volume}}$ can no longer be approximated by V_{total}. Because $V_{\text{total}} > V_{\text{free volume}}$, the ratio PV/RT is also larger for a real gas than for an ideal gas:

As a consequence, the curve for a real gas in Figure 5.40 diverges upward from the line for an ideal gas.

A second factor also causes the ratio PV/RT to diverge from 1. Kinetic molecular theory assumes that molecules do not interact, but real molecules do attract one another. These attractive forces function over short distances, so the assumption that molecules behave independently is a good one as long as the molecules are far apart. However, as pressure increases on a population of gas molecules and they are pushed closer together, intermolecular attractive forces can become significant. Likewise, lowering the temperature causes molecules to move more slowly, resulting in more attractions and more deviations from ideal behavior. In fact, as we see in Chapter 10, a sufficiently cooled gas will condense because of such attractions. These attractive forces cause the molecules to associate with one another, which decreases the force of their collisions with the walls of their container, thereby decreasing the pressure exerted by the gas. If the value of P in PV/RT is smaller in the real gas than the ideal value, the value of the ratio decreases:

In this case, the curve for a real gas diverges from the ideal gas line by moving below it on the graph.

CONCEPT TEST

For which gases in Figure 5.40 does the impact of molecular interactions outweigh the impact of molecular volume on PV/RT at 200 atm?

(Answers to Concept Tests are in the back of the book.)

The van der Waals Equation for Real Gases

Because the ideal gas equation does not hold at high pressures or low temperatures, we need another equation that can be used under these conditions—one that accounts for the following facts:

1. The free volume of a real gas is less than the total volume because its molecules occupy significant space.
2. The observed pressure is less than the pressure of an ideal gas because of intermolecular attractions.

The van der Waals equation,

---

includes terms to correct for pressure (n^2a/V^2) and volume (nb). The values of a and b, called *van der Waals constants*, have been determined experimentally for many gases (**Table 5.5**). Both a and b increase with increasing molar mass and with the number of atoms in each molecule of a gas.

SAMPLE EXERCISE 5.17 Calculating Pressure with the van der

Waals Equation LO8

Calculate the pressure of 1.00 mol of N_2 in a 1.00 L container at 300.0 K, using first the van der Waals equation and then the ideal gas equation.

Collect and Organize We are given the amount of nitrogen, its volume, and its temperature, and we need to calculate its pressure by using both the van der Waals equation and the ideal gas equation. Using the van der Waals equation means we need to know the values of the van der Waals constants for nitrogen.

Analyze The van der Waals constants for nitrogen gas are $a = 1.39$ $L^2 \cdot atm/mol^2$ and $b = 0.0391$ L/mol in Table 5.5. The values of a and b represent experimentally determined corrections for the interactions between molecules and the portion of the total volume occupied by the gas molecules. One mole of ideal gas at STP occupies 22.4 L. Compressing the gas to a volume of about 1/20 of the initial volume requires a pressure of about 20 atm. Heating it to 300 K at constant volume causes a relatively minor change in the pressure. We can estimate the effect of a pressure of about 20 atm on the ideality of the nitrogen from the curves in Figure 5.40. Although we do not know which curve best describes the behavior of N_2, the scale of the x-axis is rather large. At a pressure of 20 atm, none of the curves deviates substantially from ideality, so we expect a relatively small difference in the pressure calculated for N_2 as an ideal gas or by using the van der Waals equation.

Solve Begin with Equation 5.32 then solve it for pressure:

If nitrogen behaved as an ideal gas, we would have

Think About It This pressure is about 25 times greater than normal atmospheric pressure, so we expect some difference in the calculated pressures. However, the small deviation from ideality, $0.4/24.6 \times 100 = 2\%$, supports our prediction. Furthermore, because of the likely deviation from ideal behavior, we expect the pressure calculated using the ideal gas equation to be too high, which turns out to be true: $P_{\text{ideal}} > P_{\text{real}}$.

Practice Exercise Assuming the conditions stated in Sample Exercise 5.17, use the van der Waals equation to calculate the pressure for 1.00 mol He gas. Compare the real-gas pressures of He and N_2 and suggest why they differ.

(Answers to Practice Exercises are in the back of the book.)

We began this chapter with a description of our atmosphere as an invisible necessity. Looking back, we can now answer the questions we raised about gases and our atmosphere. We now understand how elevation affects the quantity of gas available, making pressurized cabins on commercial airliners a necessity for safe, comfortable travel. We have seen the chemical reactions used to supply oxygen in aircraft under emergency conditions and applied the principles of stoichiometry to calculate the quantity of reactant needed to generate a given quantity of emergency oxygen gas. Undersea explorers carry a different mixture of gases in a scuba tank from what we breathe under normal conditions because the high pressures under water increase the partial pressures of oxygen and nitrogen to unhealthy levels. Hot-air balloons rise because volume is directly proportional to temperature and because the density of air decreases as temperature rises. Understanding the physical properties of gases, especially their compressibility and their responses to changing conditions, makes their use in many everyday items, from automobile tires to weather balloons and fire extinguishers, possible because their behavior is reliable and predictable.

SAMPLE EXERCISE 5.18 Integrating Concepts: Scuba Diving

The air bubbles exhaled by a scuba diver (**Figure 5.42**) expand as they rise to the surface. The lungs of a diver behave similarly unless certain precautions are taken, and serious medical consequences may result if divers deviate from these precautions. In the following calculations, assume that the pressure at sea level is 1.00 atm and that the pressure increases by 1.0 atm for every 10 m increase in depth beneath the surface. Assume a diver's lungs have an air volume of 5.1 L and that the dry air in a scuba tank is 78.1% N_2, 20.9% O_2, and 1.00% Ar by volume. (a) What is the partial pressure of each gas in the diver's lungs as she begins her dive? (b) What is the partial pressure of each gas in the diver's lungs at a depth of 30.0 m? (c) Suppose the scuba diver is accompanied during her descent by a diver without a supplemental air supply. This breath-hold diver also has a lung air capacity of 5.1 L and dives to 30.0 m and ascends back to the surface, all without exhaling. What is the volume of air in the breath-hold diver's lungs at a depth of 30.0 m and upon the return to the surface? (d) What would happen to the volume of air in the scuba diver's lungs if she held her breath while ascending from 30.0 m to the surface?

Air may be used in scuba tanks for shallow dives. However, nitrogen narcosis (the symptoms of which include dulling of the senses, inactivity, and even unconsciousness) can result during deeper dives because of the anesthetic qualities of nitrogen under pressure. Breathing pure oxygen is not a solution because oxygen at high levels is quite toxic to the central nervous system and other parts of the body. Therefore, mixtures of N_2, O_2, and He, generically called Trimix, are used to minimize nitrogen narcosis and oxygen toxicity. For most dives, the oxygen concentration in the tank is adjusted to a maximum partial pressure of 1.5 atm at the working depth; the "equivalent narcotic depth" (END) for N_2 pressure is normally set at 4.0 atm. Helium is added as needed to achieve these values. (e) What Trimix composition (in percent by volume) achieves these values for a dive to 70.0 m below the surface?

Collect and Organize We are given initial and final conditions for mixtures of gases and desired partial pressures for gases at known total pressures. Boyle's law relates the volume and pressure of a quantity of a gas at constant temperature, and Dalton's law of partial pressures relates the partial pressures of the gases in a mixture to its total pressure and the gases' mole fractions in the mixture.

Analyze We can convert percent composition data into partial pressures at 1 atm and then into partial pressures under other conditions. The pressure at 30.0 m is about 4 atm, so the partial pressures of gases in the scuba diver's lungs will increase by a factor of 4. The air in the scuba diver's lungs will have the same volume at 30 m; the breath-holding diver's lungs will be compressed to about $\frac{1}{4}$ their volume on the surface. As the two ascend, both divers' lungs will expand as pressure drops, but the scuba diver's lungs start at a much higher volume than the breath-hold diver's. A dive to 70.0 m means experiencing an ambient pressure of 8.0 atm. Using that as the total pressure:

$$P_{\text{total}} = 8.0\text{ atm} = P_{N2} + P_{O2} + P_{He} = 4.0\text{ atm} + 1.5\text{ atm} + P_{He}$$

Therefore, P_{He} should be 2.5 atm.

Solve

1. The percent composition by volume can be converted into mole fractions by recognizing, for example, that 78.1% nitrogen means 0.781 moles of nitrogen for every 1 mole of gas: $X_{N_2} = \frac{n_{N_2}}{n_{\text{total}}} = \frac{0.781}{1} = 0.781$

   The mole fraction of oxygen in the scuba diver's lungs is 0.209, and that of argon is 0.010.

2. For every 10 m of descent below the surface, the pressure increases by 1.0 atm. At 30.0 m, the pressure would increase by 3.0 atm, so the total pressure is 3.0 atm + 1.0 atm = 4.0 atm. The partial pressure of each gas at 4.0 atm total pressure is:

   $$P_{N2} = X_{N2}P_{\text{total}} = 0.781 \times 4.0\text{ atm} = 3.1\text{ atm}$$

   $$P_{O2} = X_{O2}P_{\text{total}} = 0.209 \times 4.0\text{ atm} = 0.84\text{ atm}$$

   $$P_{Ar} = X_{Ar}P_{\text{total}} = 0.010 \times 4.0\text{ atm} = 0.040\text{ atm}$$

3. The breath-hold diver does not breathe in more air, so the quantity of gas in her lungs remains constant. As the pressure increases, Boyle's law predicts her lungs will decrease in volume: $V_{\text{final}} = V_{\text{initial}} \times \frac{P_{\text{initial}}}{P_{\text{final}}} = 5.1\ \text{L} \times \frac{1.0\ \cancel{\text{atm}}}{4.0\ \cancel{\text{atm}}} = 1.3\ \text{L}$

   Upon return to the surface, her lungs will re-expand to their original volume of 5.1 L.

4. Because the scuba diver has been breathing air supplied by her scuba tank, her lungs retain their volume of 5.1 L at a depth of 30 m. If she holds her breath as she ascends to the surface, her lungs will expand (or try to):

$$5.1\ \text{L} \times \frac{4.0\ \cancel{\text{atm}}}{1.0\ \cancel{\text{atm}}} = 20\ \text{L}$$

5. The pressure change during a dive to 70.0 m would be

$$70.0\ \cancel{\text{m}} \times \frac{1.0\ \text{atm}}{10\ \cancel{\text{m}}} = 7.0\ \text{atm}$$

   The total pressure at 70.0 m, then, would be 7.0 atm + 1.0 atm = 8.0 atm.

   The partial pressure of helium in the tank must be

$$\begin{aligned} 8.0\ \text{atm} &= 4.0\ \text{atm} + 1.5\ \text{atm} + x \\ x &= 2.5\ \text{atm} \end{aligned}$$

   To achieve these partial pressures at a depth of 70.0 m, the percent composition of the gas mixture in the scuba tank must be:

$$\text{N}_2\text{:}\quad \frac{P_{\text{N}_2}}{P_{\text{total}}} \times 100\% = \frac{4.0\ \cancel{\text{atm}}}{8.0\ \cancel{\text{atm}}} \times 100\% = 50 = 50\%$$

$$\text{O}_2\text{:}\quad \frac{P_{\text{O}_2}}{P_{\text{total}}} \times 100\% = \frac{1.5\ \cancel{\text{atm}}}{8.0\ \cancel{\text{atm}}} \times 100\% = 18.8 = 19\%$$

$$\text{He:}\quad \frac{P_{\text{He}}}{P_{\text{total}}} \times 100\% = \frac{2.5\ \cancel{\text{atm}}}{8.0\ \cancel{\text{atm}}} \times 100\% = 31.3 = 31\%$$

Think About It An important rule in scuba diving is “never hold your breath.” If the scuba diver held her breath on an ascent from 30 m, the resulting expansion of air in her lungs could rupture them or force air into blood vessels, causing embolisms. A breath-hold diver is not immune to damage from pressure changes either. During deep dives, a condition called thoracic squeeze may develop, which could also result in hemorrhage of lung tissues.

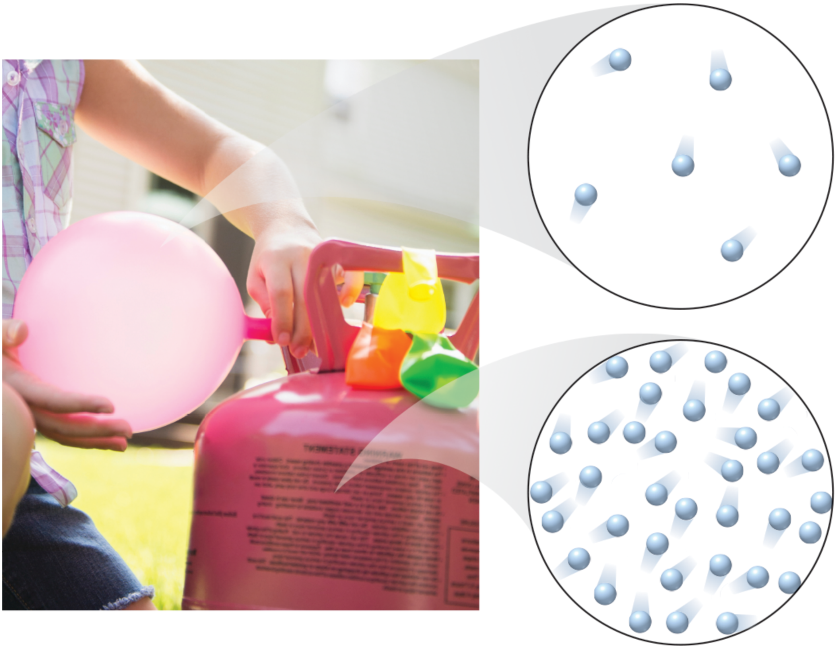
Glossary

van der Waals equation

an equation that includes experimentally determined factors *a* and *b* that quantify the contributions of non-negligible molecular volume and non-negligible intermolecular interactions to the behavior of real gases with respect to changes in *P*, *V*, and *T*.

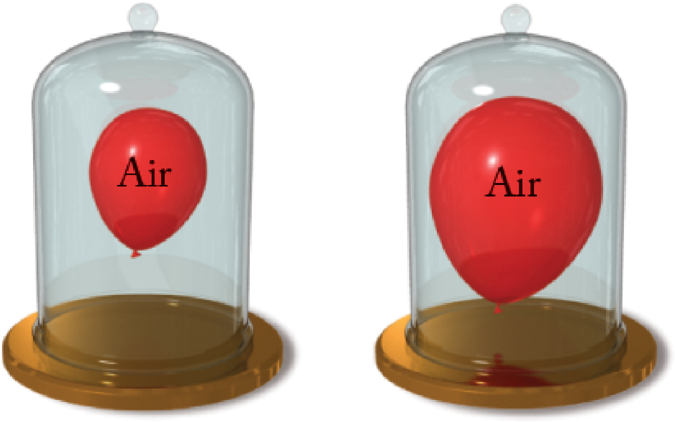
Learning Objectives

- Explain the molecular origins of nonideal behavior of real gases at high temperatures and low pressures and relate such behavior to the terms in the van der Waals equation **Return to Sample Exercise 5.17**

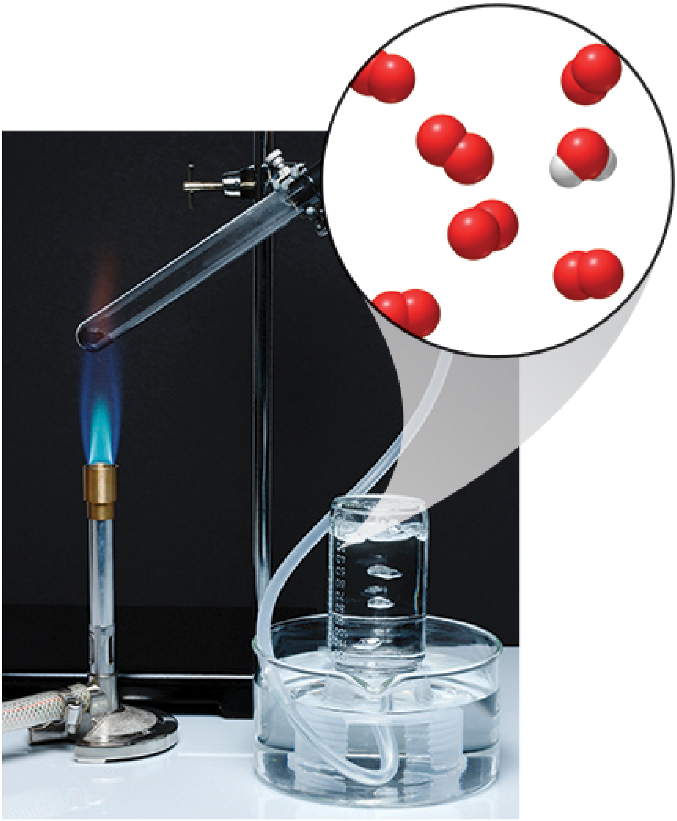


SUMMARY

LO1 Gases diffuse to occupy the entire volume of their container. The volume occupied by a gas changes significantly with pressure and temperature. Gases are miscible, mixing in any proportion. They are much less dense than liquids or solids. Pressure is defined as the ratio of force to surface area, and gas pressure is measured with barometers and manometers. Pressure can be expressed in a variety of units, and we can convert between them by using dimensional analysis. (Sections 5.1 and 5.2)

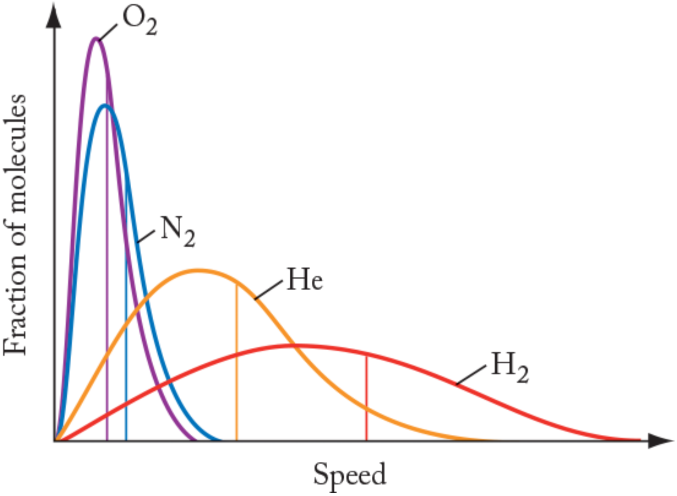


- LO2 Boyle's law, Charles's law, Avogadro's law, and Amontons's law describe the behavior of gases under different conditions. They may be used individually or in a combined form called the ideal gas law ($PV = nRT$) to calculate the volume, temperature, pressure, or number of moles of a gas. (Sections 5.3 and 5.4)
- LO3 The ideal gas equation and the stoichiometry of a chemical reaction can be used to calculate the volumes of gases required or produced in the reaction. (Section 5.5)

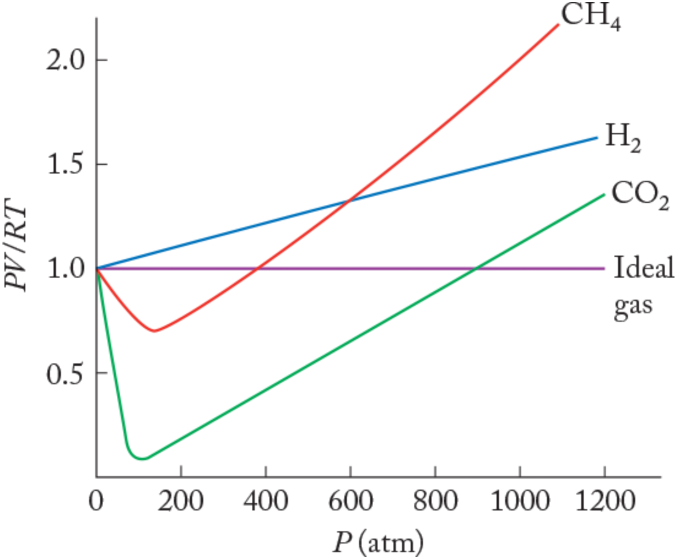


- LO4 The density of a gas can be calculated for a given set of conditions of volume, temperature, and pressure. The density of a gas can also be used to calculate its molar mass. (Section 5.6)
- LO5 In a gas mixture, the contribution each component gas makes to the total gas pressure is called the partial pressure of that gas. Dalton's law of partial pressures allows us to calculate the partial pressure (P_x) of any constituent gas x in a gas mixture if we know its mole fraction (X_x) and the total pressure. (Section 5.7)
- LO6 Kinetic molecular theory describes gases as particles in constant random motion. This motion is associated with an average kinetic energy that is proportional to the absolute temperature of the gas. Pressure arises from elastic collisions between gases and the walls of their container. All relationships between P, V, T, and n can be derived from

kinetic molecular theory. (Section 5.8)



- LO7 Particles move at root-mean-square speeds(u_{rms}) that are inversely proportional to the square root of their molar masses and directly proportional to the square root of their temperature. Graham's law of effusion states that the rate of effusion (escape through a pinhole) or diffusion (spreading) of a gas at a fixed temperature is inversely proportional to the square root of its molar mass. (Section 5.8)



- LO8 At high pressures, the behavior of real gases deviates from the predictions of the ideal gas law. The van der Waals equation, a modified form of the ideal gas equation, accounts for real gas properties. (Section 5.9)

PARTICULATE PREVIEW WRAP-UP

Helium atoms fill both the tank and the balloon, but there are more atoms in the same volume of gas in the tank than in a single balloon because the tank contains enough helium to fill many balloons. The drawing for the gas in the tank in a car trunk on a hot day does not change because the quantity and volume of the gas does not change significantly. However, the helium-filled balloons in the trunk will expand because higher temperatures increase the kinetic energies of the helium atoms. More collisions between the atoms and the walls of the balloons cause the balloons to expand. The same number of He atoms would occupy a larger volume, or a particulate view of the same balloon volume would contain fewer helium atoms.

PROBLEM-SOLVING SUMMARY

Type of Problem	Concepts and Equations	Sample Exercises
Calculating the pressure of any gas, including atmospheric pressure	Divide the force by the area over which it is applied, using the equation $P = \frac{F}{A}$ (5.1)	5.1, 5.2
Calculating changes in P, V, or T in response to changing conditions	Rearrange $\frac{P_1V_1}{T_1} = \frac{P_2V_2}{T_2}$ (5.18) for whichever variable is sought and then substitute given values. (T must be in kelvins, and n must be constant.)	5.3, 5.4, 5.5, 5.6
Determining n from P, V, and T	Rearrange $PV = nRT$ (5.15) for n and then substitute given values of P, T, and V. (T must be in kelvins.)	5.7, 5.8, 5.9
Calculating the density of a gas and calculating molar mass from density	Substitute the given values into the equation	5.10, 5.11

$$d = \frac{P\mathcal{M}}{RT} \qquad (5.21)$$

Substitute values for pressure, absolute temperature, and density into the equation

$$\mathcal{M} = \frac{dRT}{P} \qquad (5.22)$$

5.12 Calculating mole fractions for one component gas in a mixture

Divide the number of moles of the component gas by the total number of moles in the mixture:

$$X_x = \frac{n_x}{n_{total}} \qquad (5.24)$$

5.13, 5.14 Calculating partial pressure of one component gas in a mixture and total pressure in the mixture

Substitute the mole fraction of one component gas and the total pressure into the equation

$$P_x = X_x P_{\text{total}} \qquad (5.25)$$

Solve the equation

$$P_{\text{total}} = P_1 + P_2 + P_3 + P_4 + \ldots \qquad (5.23)$$

for the partial pressure of the component gas and then substitute given values for other partial pressures and total pressure.

5.15 Calculating root-mean-square speeds

Substitute absolute temperature, molar mass, and the value 8.314 kg · m^2/(s^2 · mol · K) for *R* in the equation

$$u_{\text{rms}} = \sqrt{\frac{3RT}{\mathcal{M}}} \qquad (5.28)$$

5.16 Calculating relative rates of effusion or diffusion from molar masses

Substitute values for molar masses into the equation

$$\frac{r_x}{r_y} = \sqrt{\frac{\mathcal{M}_y}{\mathcal{M}_x}} \qquad (5.31)$$

5.17 Calculating *P* for a real gas

Solve the van der Waals equation

$$\left(P + \frac{n^2a}{V^2}\right)(V - nb) = nRT \qquad (5.32)$$

for *P* and substitute given values of *n*, *V*, and *T* (in kelvins), plus values of *a* and *b* from Table 5.5.

VISUAL PROBLEMS

(Answers to boldface end-of-chapter questions and problems are in the back of the book.)

Shown in Figure P5.1 are three barometers. The one in the center is located at sea level. Which barometer is most likely to reflect the atmospheric pressure in Denver, CO, where the elevation is approximately 1500 m? Explain your answer.

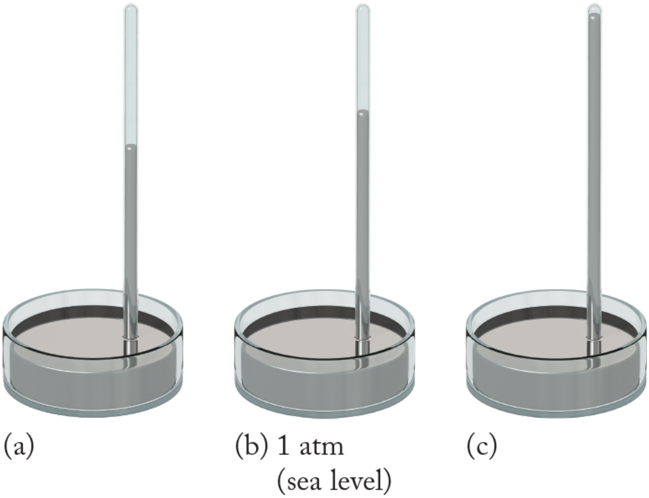


FIGURE P5.1

A flask is filled with purple iodine vapor. Which of the drawings in Figure P5.2 most accurately reflects the gas in the flask?

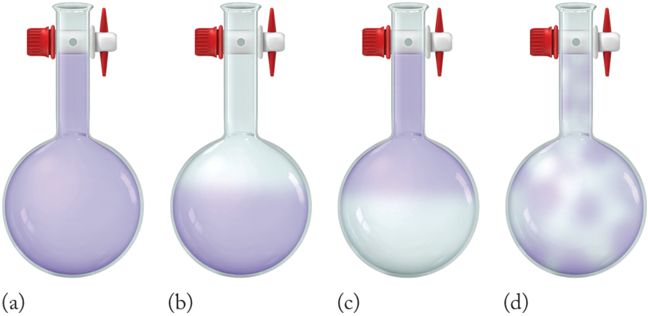

FIGURE P5.2

Which of the three changes shown in Figure P5.3 best illustrates what happens when (1) the atmospheric pressure on a helium-filled balloon is increased at constant temperature and (2) the temperature of a helium-filled balloon is increased at constant pressure?

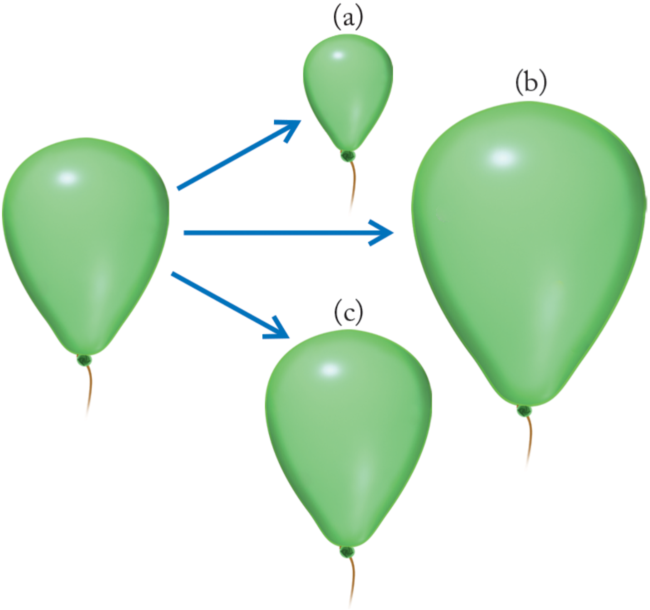

FIGURE P5.3

Figure P5.4 illustrates the relationship between density and pressure for two gases: methane and nitrogen.

1. Which line should be labeled CH_4?
2. Add lines for the density of He and NO.

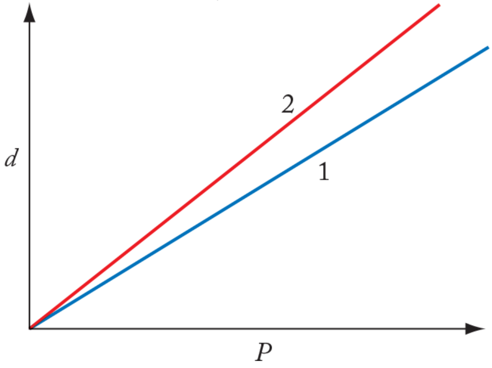

FIGURE P5.4

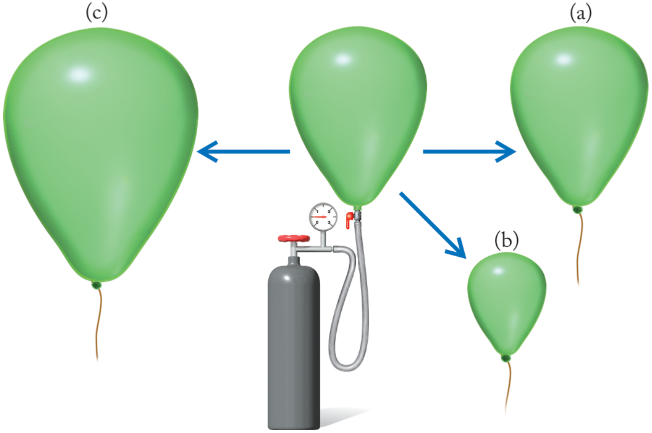
Which of the three changes shown in Figure P5.5 best illustrates what happens when the amount of gas in a helium-filled rubber balloon is increased at constant temperature and



pressure?

FIGURE P5.5

Which line in the plot of volume versus reciprocal pressure in **Figure P5.6** corresponds to the higher temperature?

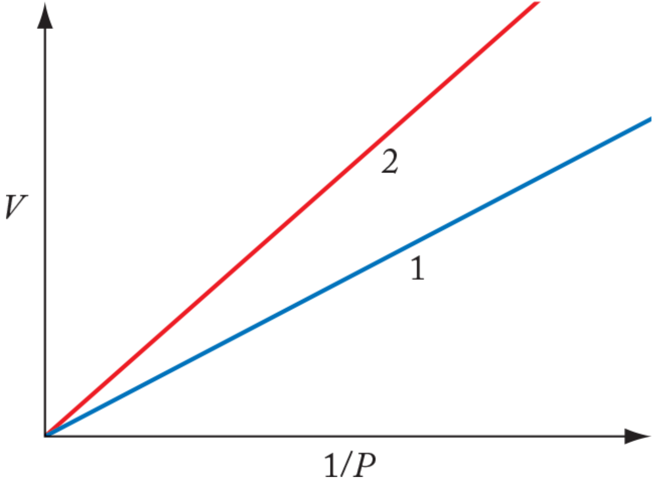


FIGURE P5.6

In Figure P5.7, which line in the plot of volume versus temperature represents a gas at higher pressure? Is the *x*-axis an absolute temperature scale?

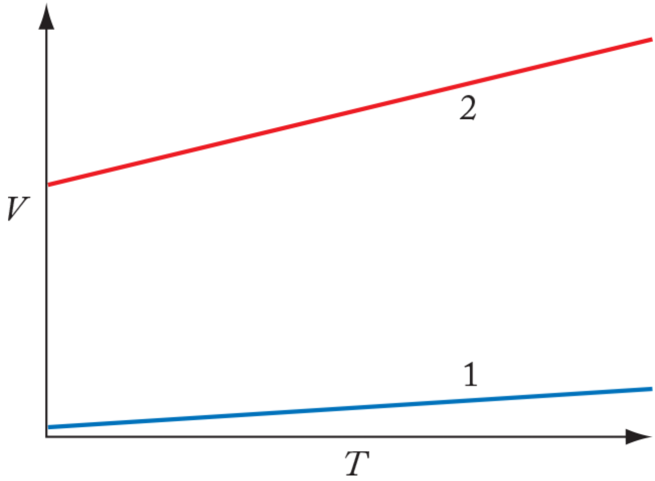

FIGURE P5.7

In Figure P5.8, which of the two plots of volume versus pressure at constant temperature is *not* consistent with the ideal gas law?

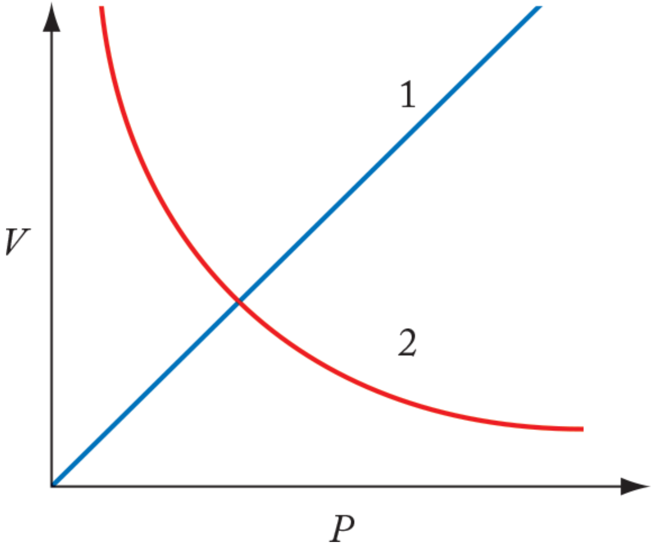

FIGURE P5.8

In Figure P5.9, which of the two plots of volume versus temperature at constant pressure is *not* consistent with the ideal gas law?

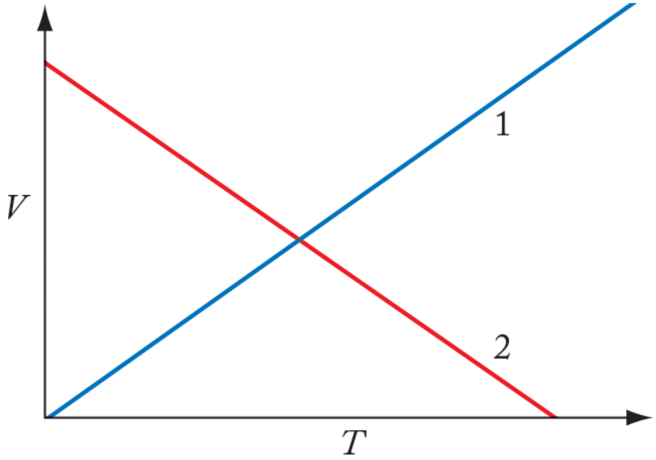

FIGURE P5.9

Passing an electric current through water decomposes the water into hydrogen and oxygen gas. A simple apparatus for this reaction is shown in Figure P5.10. Which buret contains hydrogen?

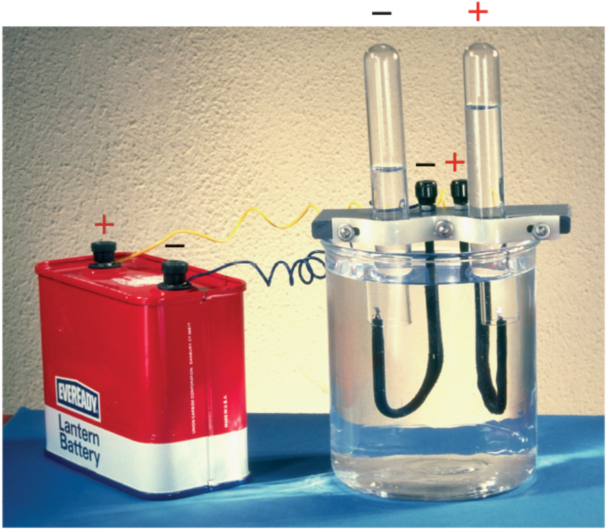

FIGURE P5.10

Passing an electric current through cold ($-37^\circ C$) liquid ammonia decomposes the ammonia into nitrogen and hydrogen gas. Which tube in Figure P5.11 contains nitrogen?

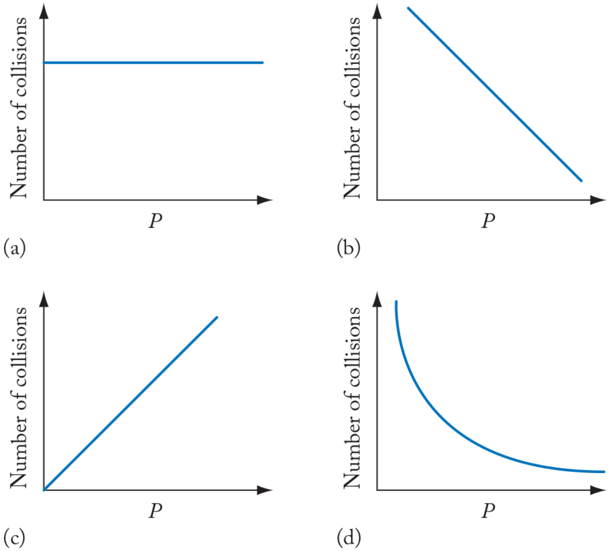
FIGURE P5.11

Which of the graphs in Figure P5.12 best represents the relationship between number of collisions with the container and pressure?



(a) (b) (c) (d)

FIGURE P5.12

Which of the particulate views in Figure P5.13 best depicts the arrangement of molecules in a mixture of gases? The blue and pink spheres represent atoms of helium and neon, respectively.

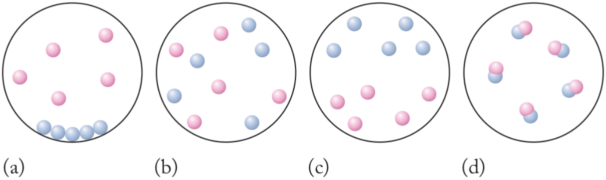


FIGURE P5.13

The particulate views of Figure P5.14 represent equal volumes of four mixtures of N_2 and O_2 at the same temperature. Is the total pressure in the samples the same? Which has the highest partial pressure of N_2?

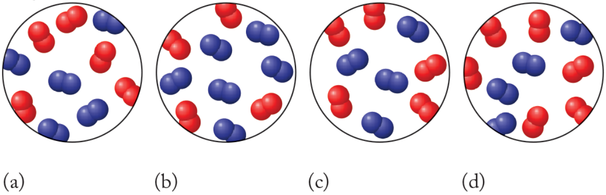

FIGURE P5.14

Figure P5.15 shows the distribution of molecular speeds of CO_2 and SO_2 molecules at 25°C. Which curve is the profile for SO_2? Which of these profiles should match that of propane (C_3H_8), a common fuel in portable grills?

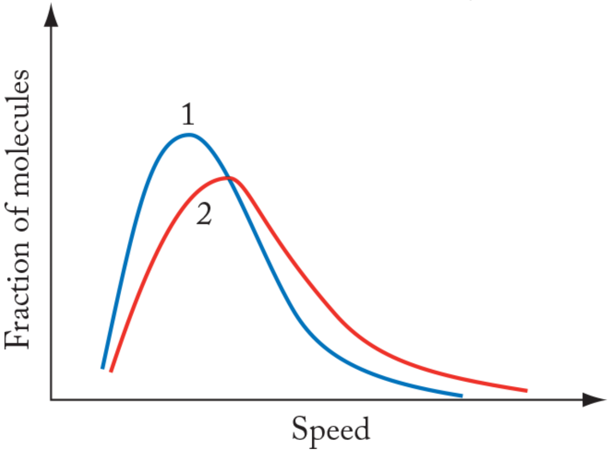

FIGURE P5.15

How would a graph showing the distribution of molecular speeds of CO_2 at − 100°C differ from the graph for CO_2 shown in Figure P5.15?

A container with a pinhole leak contains a mixture of the elements highlighted in Figure P5.17. Which element leaks the most slowly from the container?

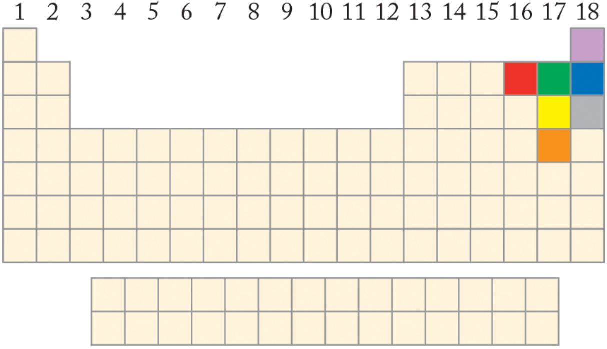

FIGURE P5.17

A container with a pinhole leak contains a mixture of the elements highlighted in Figure P5.17. Which element has the smallest root-mean-square speed?

The rate of effusion of a gas increases with temperature. Which graph in Figure P5.19 best describes the ratio of the rates of effusion of two gases (*x* and *y*) as a function of temperature?

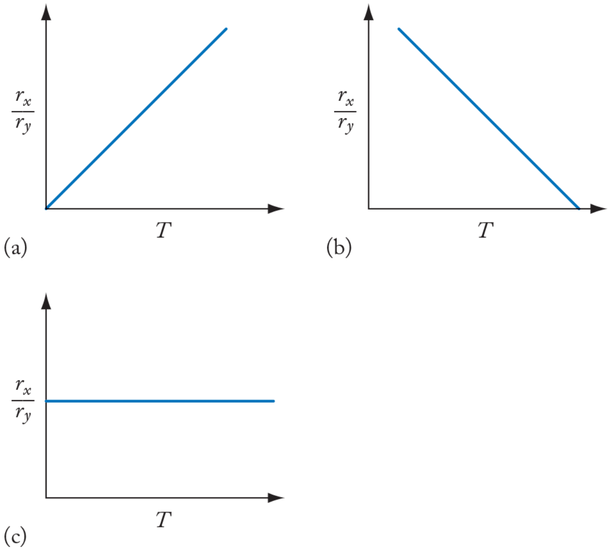

FIGURE P5.19

Which of the two possibilities in Figure P5.20 more accurately illustrates the effusion of helium from a balloon at constant atmospheric pressure?

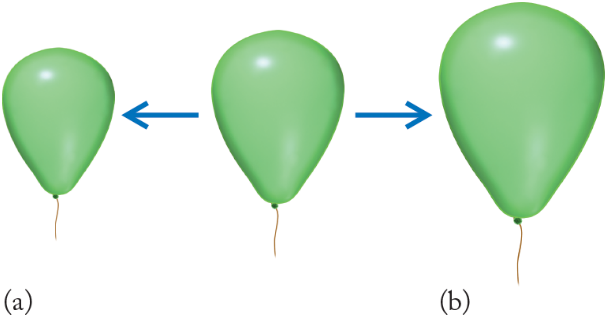

FIGURE P5.20

Which of the two outcomes shown in Figure P5.21 more accurately illustrates the effusion of gases from a balloon at constant atmospheric pressure if the blue spheres have a greater root-mean-square speed than the pink spheres?

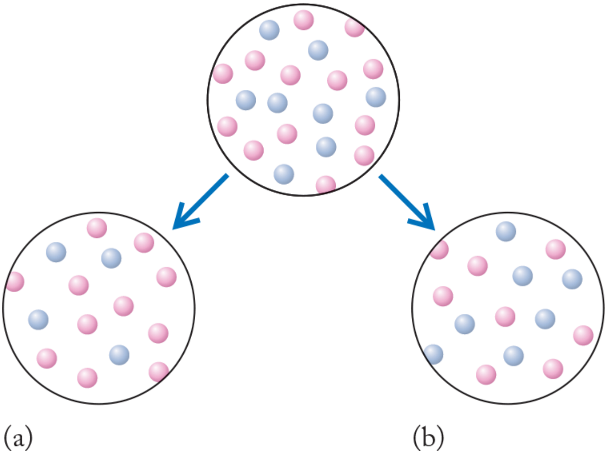

FIGURE P5.21

Use representations [A] through [I] in Figure P5.22 to answer questions (a)–(f). The pink balloons contain hydrogen, the yellow balloons contain nitrogen, and the gray balloons contain oxygen.

1. Identify three different changes that could be responsible for the change in size of the pink balloon from [A] to [C].
2. If the smaller pink balloon in [A] corresponds to the particulate view in [B], which of the changes identified in part (a) would result in the larger pink balloon in [C] also corresponding to the particulate view in [B]?
3. If the smaller yellow balloon in [D] corresponds to the particulate view in [E], which particulate view corresponds to the larger yellow balloon in [F] if no additional nitrogen has been added?
4. If the larger gray balloon in [I] corresponds to the particulate view in [E], which particulate view represents the gas at a lower temperature?
5. If each gray balloon contains 1 mol of gas at 25°C, in which balloon are the collisions between the oxygen molecules and the inside of the balloon more frequent?

Which6balloon contains the gas with the shortest mean free path?

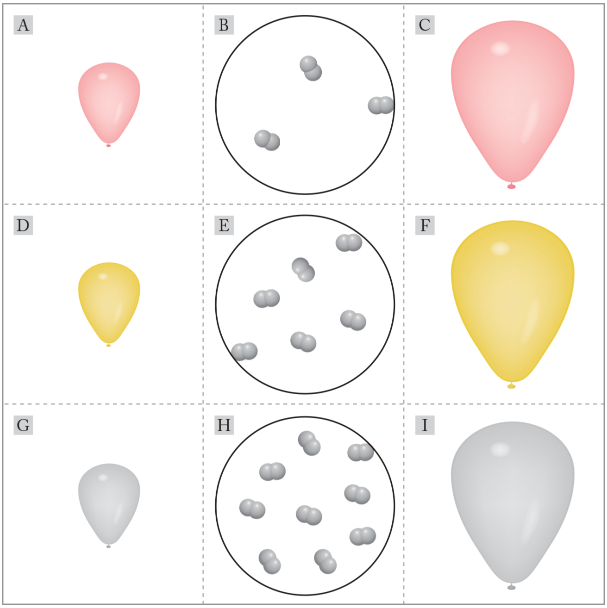

FIGURE P5.22

QUESTIONS AND PROBLEMS

Atmospheric Pressure and Collisions

Concept Review

Describe the difference between force and pressure.

Describe the role of collisions in generating pressure.

How does Torricelli’s barometer measure atmospheric pressure?

What is the relationship between *torr* and *atmospheres* of pressure?

Which quantity represents the larger pressure, 10 torr or 10 atm?

In which balloon do He atoms experience more collisions at room temperature: a 1 L balloon at 0.1 atm of pressure or a 0.5 L balloon at 0.1 atm of pressure?

What is the relationship between *millibars* and *pascals* of pressure?

Three barometers based on Torricelli's design are constructed using water ($d = 1.00$ g/mL), ethanol ($d = 0.789$ g/mL), and mercury ($d = 13.546$ g/mL). Which barometer contains the tallest column of liquid?

Why does an ice skater exert more pressure on ice when wearing newly sharpened skates than when wearing skates with dull blades?

Why is it easier to travel over deep snow when wearing snowshoes over your boots (Figure P5.32) rather than just your boots?

FIGURE P5.32

Why does atmospheric pressure decrease with increasing elevation?

Pieces of different metals have the same mass but different densities. Could these objects ever exert the same pressure?

Problems

Air Pressure and the Eiffel Tower In his book *Caesar's Last Breath*, author Sam Kean states that a column of air around the Eiffel Tower in Paris (Figure P5.35) weighs more than the tower itself. The tower reaches a height of 324 m and occupies a square base 125 m on a side. The pressure exerted by the Eiffel Tower is estimated to be 4.5 kg/cm^2. If the density of air is taken to be 1.19 g/L, what is the pressure exerted by a column of air, 324 × 125 × 125 m?

FIGURE P5.35

The gold block represented in Figure P5.36 has a mass of 38.6 g. Calculate the pressure exerted by the block when it is on (a) a square face and (b) a rectangular face.

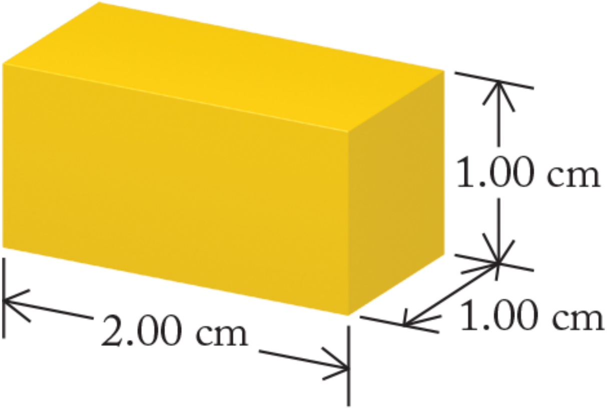

FIGURE P5.36

Convert the following pressures into atmospheres: (a) 2.0 kPa; (b) 562 torr.

Convert the following pressures into millimeters of mercury: (a) 0.541 atm; (b) 2.8 kPa.

Record High Atmospheric Pressure The highest atmospheric pressure recorded on Earth was measured at Tosontsengel, Mongolia, on December 19, 2001, when the barometer read 108.6 kPa. Express this pressure in (a) millimeters of mercury, (b) atmospheres, and (c) millibars.

Record Low Atmospheric Pressure Hurricane Irene registered an atmospheric pressure of 982 mbar in August 2011. Hurricane Katrina registered an atmospheric pressure of 86.2 kPa in September 2005. What was the *difference* in pressure between the two hurricanes in (a) millimeters of mercury, (b) atmospheres, and (c) millibars?

Pressure on Venus Venus is similar to Earth in size and distance from the Sun but has an atmosphere inhospitable for human life that consists of 96.5% CO_2 and 3.5% N_2 by mass.

1. Calculate the atmospheric pressure on Venus given the mass of the Venusian atmosphere (4.8×10^{20} kg), the surface area (4.6×10^{14} m^2), and the acceleration due to gravity (8.87 m/s^2).
2. Given the similarity between Venus and Earth in surface area, why do you suppose atmospheric pressure on Venus is so much higher than on Earth?

Pressure on Uranus Uranus is much larger than Earth, with a surface area of 8.1×10^{15} m^2. The atmosphere on Uranus is composed of low-density gases: 82.5% H_2, 15.2% He, and 2.3% CH_4. The acceleration due to gravity is similar to that on Earth, 8.7 m/s^2, yet the atmospheric pressure on Uranus is estimated to exceed 10^8 Pa. What is the mass of the atmosphere on Uranus?

The Gas Laws

Concept Review

If the quantity of helium in a weather balloon is increased by a factor of 5 at constant pressure and temperature, by how much does the volume of the balloon change?

How do we explain Boyle’s law on a molecular basis?

A balloonist is rising too fast for her taste. Should she increase the temperature of the gas in the balloon or decrease it?

Could the pilot of the balloon in Problem 5.45 reduce her rate of ascent by allowing some gas to leak out of the balloon? Explain your answer.

The volume of a quantity of gas decreases by 50% when it cools from 20°C to 10°C. Does the pressure of the gas increase, decrease, or remain the same?

If the volume of gasoline vapor and air in an automobile engine cylinder is reduced to 1/10 of its original volume before ignition, by what factor does the pressure in the cylinder increase? (Assume there is no change in temperature.)

Problems

What is the final pressure of 1.00 mol of ammonia gas, initially at 1.00 atm, if the volume is

1. gradually decreased from 78.0 mL to 39.0 mL at constant temperature?
2. increased from 43.5 mL to 65.5 mL at constant temperature?
3. decreased by 40% at constant temperature?

The behavior of 485 mL of an ideal gas in response to pressure is studied in a vessel with a movable piston. What is the final volume of the gas if the pressure on the sample is

1. increased from 715 torr to 3.55 atm at constant temperature?
2. decreased from 1.15 atm to 520 torr at constant temperature?
3. increased by 26% at constant temperature?

Underwater Archeology A scuba diver releases a balloon containing 153 L of helium attached to a tray of artifacts at an underwater archeological site (Figure P5.51). When the balloon reaches the surface, it has expanded to a volume of 352 L. The pressure at the surface is 1.00 atm; what is the pressure at the underwater site? Pressure increases by 1.0 atm for every 10 m of depth; at what depth was the diver working? Assume the temperature remains constant.

FIGURE P5.51

Breath-Hold Diving The world record for diving without supplemental air tanks is about 125 m, a depth at which the pressure is about 12.5 atm. If a diver's lungs contain 6.0 L of air at the surface of the water, what is this volume at a depth of 125 m?

Use the data in the first two columns of the table that follows to plot a graph of the volume (*V*) of 1.00 mol H_2 as a function of the reciprocal of its pressure (1/*P*) at 298 K; use the data in the second two columns to plot a graph of the volume (*V*) of 1.00 mol H_2 as a function of its absolute temperature (T) at $P = 1.00$ atm.

1. How would these graphs differ if 1.00 mol Ar had been used instead of 1.00 mol H_2?
2. How would these graphs differ if 0.50 mol H_2 had been used instead of 1.00 mol H_2?
3. How would the second graph differ if the pressure of the gas had been 3.00 atm?

A cylinder with a piston (Figure P5.55) contains a sample of gas at 25°C. The piston moves to keep the pressure constant inside the cylinder. At what gas temperature would the piston move so that the volume inside the cylinder doubled?

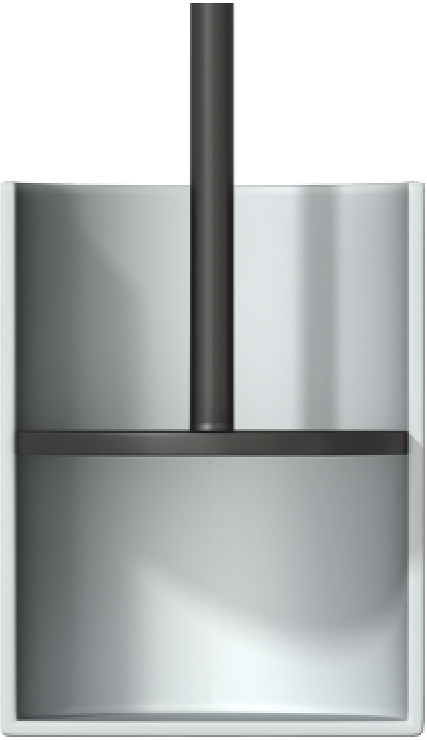

FIGURE P5.55

The temperature of the gas in Problem 5.55 is reduced to a temperature at which the volume inside the cylinder has decreased by 25% from its initial volume at 25.0°C. What is the new temperature?

Calculate the volume of a 2.68 L sample of gas in the cylinder shown in Figure P5.55 after it is subjected to the following changes in conditions:

1. The gas is warmed from 250 K to a final temperature of 398 K at constant pressure.
2. The pressure is increased by 33% at constant temperature.
3. Ten percent of the gas leaks from the cylinder at constant temperature and pressure.

Calculate the temperature of a 5.6 L sample of gas in the cylinder in

Figure P5.55 after it is subjected to the following changes in conditions:

1. The gas, at constant pressure, is cooled from 78°C to a temperature at which its volume is 4.3 L.
2. The external pressure is doubled at constant volume.
3. The number of molecules in the cylinder is increased by 15% at constant pressure and volume.

Which of the following actions would produce the greater increase in the volume of a gas sample: (a) lowering the pressure from 760 torr to 720 torr at constant temperature or (b) raising the temperature from 10°C to 40°C at constant pressure?

Which of the following actions would produce the greater increase in the volume of a gas sample: (a) doubling the amount of gas in the sample at constant temperature and pressure or (b) raising the temperature from 244°C to 1100°C at constant pressure?

What happens to the volume of gas in a cylinder with a movable piston under the following conditions?

1. Both the absolute temperature and the external pressure on the piston double.
2. The absolute temperature is halved and the external pressure on the piston doubles.
3. The absolute temperature increases by 75% and the external pressure on the piston increases by 50%.

What happens to the pressure of a gas under the following conditions?

1. The absolute temperature is halved and the volume doubles.
2. Both the absolute temperature and the volume double.

Liquid Nitrogen–Powered Car Students at the University of North

Texas and the University of Washington built a car propelled by compressed nitrogen gas. The gas was obtained by boiling liquid nitrogen stored in a 182 L tank. What volume of nitrogen is released at 0.927 atm of pressure and 25°C from a tank full of liquid nitrogen (d = 0.808 g/mL)?

Fuel for Camp Stoves The fuel canister for a portable camping stove (Figure P5.64) contains 190 g of pressurized butane (C_4H_{10}). What volume of butane does this represent at 25°C if it escapes into the air at 750 torr?

Temperature Effects on Bicycle Tires A bicycle racer inflates his tires to 7.1 atm on a warm autumn afternoon when temperatures reached 27°C. By morning the temperature has dropped to 5.0°C. What is the pressure in the tires if we assume that the volume of each tire does not change significantly?

A balloon vendor at a street fair is using a tank of helium to fill her balloons. The tank has a volume of 145 L and a pressure of 136 atm at 25°C. After a while, she notices that the valve has not been closed properly and the pressure has dropped to 94 atm. How many moles of gas have been lost?

The Ideal Gas Law; Gases in Chemical Reactions

Concept Review

What is meant by standard temperature and pressure (STP)? What is the volume of 1 mole of an ideal gas at STP?

Which of the following are *not* characteristics of an ideal gas?

1. The molecules of gas have little volume compared with the volume that they occupy.
2. Its volume is independent of temperature.
3. The density of all ideal gases is the same.
4. Gas atoms or molecules do not interact with one another.

What does the slope represent in a graph of pressure as a function of $1/V$ at constant temperature for an ideal gas?

How would the graph in Problem 5.69 change if we increased the temperature to a larger but constant value?

Problems

How many moles of air are there in a bicycle tire with a volume of 2.36 L if it has an internal pressure of 6.8 atm at 17.0°C?

At what temperature will 1.00 mole of an ideal gas in a 1.00 L container exert a pressure of

1. 1.00 atm?
2. 2.00 atm?
3. 0.75 atm?

Hyperbaric Oxygen Therapy Hyperbaric oxygen chambers are used to treat divers suffering from decompression sickness (the “bends”) with pure oxygen at greater than atmospheric pressure. Other clinical uses include treatment of patients with thermal burns, necrotizing fasciitis, and CO poisoning. What is the pressure in a chamber with a volume of 2.36×10^3 L that contains 4635 g of $O_2(g)$ at a temperature of 298 K?

Hydrogen holds promise as an “environment friendly” fuel. How many grams of $H_2(g)$ are present in a 50.0 L fuel tank at $P = 25.0$ bar and $T = 20°\text{C}$?

A weather balloon with a volume of 200.0 L is launched at 20°C at sea level, where the atmospheric pressure is 1.00 atm.

1. What is the volume of the balloon at 20,000 m where atmospheric pressure is 63 torr and the temperature is 220 K?
2. What is the percent change in volume for the balloon in part (a)?
3. At even higher elevations (the stratosphere, up to 50,000 m), the temperature of the atmosphere increases to 270 K but the pressure decreases to 0.80 torr. What is the volume of the balloon under these conditions?
4. If the balloon is designed to rupture when the volume exceeds 400.0 L, will the balloon break under either of these sets of conditions?

A sealed, flexible foil bag of potato chips containing 0.500 L of air is carried from Boston ($P_{\text{atm}} = 1.0$ atm) to Denver ($P_{\text{atm}} = 0.83$ atm).

1. What would the volume of the bag be upon arrival in Denver?
2. What is the percent change in volume for the balloon in part

(a)?

3. If the structural limitations of the bag allow for only a 10% expansion in the volume of the bag, what is the pressure in the bag?
4. If the bag is placed in checked luggage, the pressure and temperature in the hold will decrease considerably during flight to $T = 210$ K and $P = 126$ torr. Calculate the pressure in the bag during flight.

Miners' Lamps Before the development of reliable batteries, miners' lamps burned acetylene (C_2H_2) produced by the reaction of calcium carbide with water:

$CaC_2(s) + H_2O(\ell) \rightarrow C_2H_2(g) + CaO(s)$

A lamp uses 1.00 L of acetylene per hour at 1.00 atm pressure and 18°C.

1. How many moles of C_2H_2 are used per hour?
2. How many grams of calcium carbide must be in the lamp for a 4-h shift?

Acid precipitation dripping on limestone produces carbon dioxide by the following reaction:

$CaCO_3(s) + 2\ H_3O^+(aq) \rightarrow Ca^{2+}(aq) + CO_2(g) + 3\ H_2O(\ell)$

If 15.0 mL of CO_2 was produced at 25°C and 760 torr, then

1. how many moles of CO_2 were produced?
2. how many milligrams of $CaCO_3$ were consumed?

Air is about 78% nitrogen by volume and 21% oxygen. Pure nitrogen can be produced by the decomposition of ammonium dichromate:

$(NH_4)_2Cr_2O_7(s) \rightarrow N_2(g) + Cr_2O_3(s) + 4\ H_2O(g)$

Oxygen can be generated by the thermal decomposition of potassium chlorate:

$2\ KClO_3(s) \rightarrow 2\ KCl(s) + 3\ O_2(g)$

How many grams of ammonium dichromate and how many grams of potassium chlorate would be needed to make 200.0 L of “air” at 0.85 atm and 273 K?

Nitrogen can be produced from sodium metal and potassium nitrate by the reaction:

$10\ Na(s) + 2\ KNO_3(s) \rightarrow K_2O(s) + 5\ Na_2O(s) + N_2(g)$

If we generate oxygen by the thermal decomposition of potassium chlorate,

$2\ KClO_3(s) \rightarrow 2\ KCl(s) + 3\ O_2(g)$

how many grams of potassium nitrate and how many grams of potassium chlorate would be needed to make 200.0 L of gas containing 160.0 L of N_2 and 40.0 L of O_2 at 1.00 atm and 290 K?

Healthy Air for Sailors The CO_2 that builds up in the air of a submerged submarine can be removed by reacting it with sodium peroxide:

$2\ Na_2O_2(s) + 2\ CO_2(g) \rightarrow 2\ Na_2CO_3(s) + O_2(g)$

If a sailor exhales 150.0 mL of CO_2 per minute at 20°C and 1.02 atm, how much sodium peroxide is needed per sailor in a 24-h period?

Rescue Breathing Devices Self-contained, self-rescue breathing devices, like the one shown in Figure P5.82, convert CO_2 into O_2 according to the following reaction:

$4\ KO_2(s) + 2\ CO_2(g) \rightarrow 2\ K_2CO_3(s) + 3\ O_2(g)$

How many grams of KO_2 are needed to produce 100.0 L of O_2 at 20°C and 1.00 atm?

FIGURE P5.82

Gas Density

Concept Review

Do all gases at the same pressure and temperature have the same density? Explain your answer.

Birds and sailplanes take advantage of thermals (rising columns of warm air) to gain altitude with less effort than usual. Why does warm air rise?

How does the density of a gas sample change when (a) its pressure is increased and (b) its temperature is decreased?

Which will increase the density of a gas: doubling its temperature or doubling its pressure?

Problems

Biological Effects of Radon Exposure Radon is a naturally occurring radioactive gas found in the ground and in building materials. It is easily inhaled and emits α particles when it decays. Cumulative radon exposure is a significant risk factor for lung cancer.

1. Calculate the density of radon at 298 K and 1.00 atm of pressure.
2. Are radon concentrations likely to be greater in the basement or on the top floor of a building?

Four empty balloons, each with a mass of 10.0 g, are inflated to a volume of 20.0 L. The first balloon contains He; the second, Ne; the third, CO_2; and the fourth, CO. If the density of air at 25°C and 1.00 atm is 0.00117 g/mL, which of the balloons float in this air?

A 150.0 mL flask contains 0.391 g of a volatile oxide of sulfur. The pressure in the flask is 750 torr and the temperature is 22°C. Is the gas SO_2 or SO_3?

A 100.0 mL flask contains 0.193 g of a volatile oxide of nitrogen. The pressure in the flask is 760 torr at 17°C. Is the gas NO, NO_2, or N_2O_5?

A 0.375 g sample of benzene vapor has a volume of 149 mL measured at 95.0°C and 740.0 torr. Calculate the molar mass of benzene.

Calculate the density of toluene vapor (molar mass 92 g/mol) at 1.00 atm pressure and 227.0°C.

Dalton’s Law and Mixtures of Gases

Concept Review

What is meant by the *partial pressure* of a gas?

Can a barometer be used to measure just the partial pressure of oxygen in the atmosphere? Why or why not?

Which gas sample has the largest volume at 25°C and 1.00 atm pressure? (a) 0.500 mol of dry H_2; (b) 0.500 mol of dry N_2; (c) 0.500 mol of wet H_2 (i.e., H_2 collected over water)

Two identical balloons are filled to the same volume at the same pressure and temperature. One balloon is filled with air and the other with helium. Which balloon contains more particles (atoms and molecules)?

A mixture of gases has a partial pressure of $N_2 = 0.5$ atm and a partial pressure of $O_2 = 1.0$ atm. Which molecules experience more collisions: the molecules of nitrogen or the molecules of oxygen?

Why does the partial pressure of water increase as temperature increases?

Problems

What pressure is exerted by a gas mixture containing 2.00 g of H_2 and 7.00 g of N_2 at 273°C in a 10.0 L container? What is the contribution of N_2 to the total pressure?

A gas mixture contains 7.0 g of N_2, 2.0 g of H_2, and 16.0 g of CH_4. What is the mole fraction of H_2 in the mixture? Calculate the pressure of the gas mixture and the partial pressure of each constituent gas if the mixture is in a 1.00 L vessel at 0°C.

The X-15 and Mach 6 On November 9, 1961, the Bell X-15 test aircraft exceeded Mach 6, or six times the speed of sound. A few weeks later it reached an elevation above 300,000 feet, effectively putting it in space. The combustion of ammonia and oxygen provided the fuel for the X-15.

1. Write a balanced chemical equation for the combustion of ammonia given that nitrogen ends up as nitrogen dioxide.
2. What ratio of partial pressures of ammonia and oxygen is needed for this reaction?

Rocket Fuels Before settling on hydrogen as the fuel of choice for space vehicles, several other fuels were explored, including hydrazine (N_2H_4) and pentaborane (B_5H_9). Both are gases under conditions in space.

1. Write balanced chemical equations for the combustion of hydrazine and pentaborane given that the products in addition to water are $NO_2(g)$ and $B_2O_3(s)$, respectively.
2. What ratios of partial pressures of hydrazine to oxygen and pentaborane to oxygen are needed for these reactions?

A sample of oxygen was collected over water at 25°C and 1.00 atm.

1. If the total sample volume was 0.480 L, how many moles of O_2 were collected?

the same volume of oxygen is collected over ethanol instead of water, does it contain the same number of moles of O_2?

Water and ethanol were removed from the O_2 samples in Problem

5.103.

1. What is the volume of the dry O_2 gas sample at 25°C and 1.00 atm?
2. What is the volume of the dry O_2 gas sample at 25°C and 1.00 atm if $P_{\text{ethanol}} = 49$ torr at 25°C?

The following reactions were carried out in sealed containers. Will the total pressure after each reaction is complete be greater than, less than, or equal to the total pressure before the reaction? Assume all reactants and products are gases at the same temperature.

1. $N_2O_5(g) + NO_2(g) \rightarrow 3\ NO(g) + 2\ O_2(g)$
2. $2\ SO_2(g) + O_2(g) \rightarrow 2\ SO_3(g)$
3. $C_3H_8(g) + 5\ O_2(g) \rightarrow 3\ CO_2(g) + 4\ H_2O(g)$
4. $4\ NH_3(g) + 5\ O_2(g) \rightarrow 4\ NO(g) + 6\ H_2O(g)$

The following reactions were carried out in a cylinder with a piston. If the external pressure is constant, in which reactions will the volume of the cylinder increase? Assume all reactants and products are gases at the same temperature.

1. $CH_4(g) + NH_3(g) \rightarrow HCN(g) + 3\ H_2(g)$
2. $H_2S(g) + 2\ O_2(g) \rightarrow H_2O(g) + SO_3(g)$
3. $H_2(g) + Cl_2(g) \rightarrow 2\ HCl(g)$
4. $2\ NO_2(g) \rightarrow 2\ NO(g) + O_2(g)$

High-Altitude Mountaineering Climbers use pure oxygen (Figure P5.107) near the summits of 8000-m peaks, where $P_{\text{atm}} = 0.35$ atm. How much more O_2 is there in a lung full of pure O_2 at this elevation than in a lung full of air at sea level?

FIGURE P5.107

Scuba Diving A scuba diver is at a depth of 50 m, where the pressure is 5.0 atm. What should be the mole fraction of O_2 in the gas mixture the diver breathes to produce the same partial pressure of oxygen as the gas mixture at sea level?

Carbon monoxide at a pressure of 680 torr reacts completely with O_2 at a pressure of 340 torr in a sealed vessel to produce CO_2. What is the final pressure in the flask?

Ozone reacts completely with NO, producing NO_2 and O_2. A 10.0 L vessel is filled with 0.280 mol of NO and 0.280 mol of O_3 at 350 K. Find the partial pressure of each product and the total pressure in the flask at the end of the reaction.

Ammonia Production Ammonia is produced industrially from the reaction of hydrogen with nitrogen under pressure in a sealed reactor. What is the percent decrease in pressure of a sealed reaction vessel during the reaction between 3.60×10^3 mol of H_2 and 1.20×10^3 mol of N_2 if half of the N_2 is consumed?

A mixture of 0.156 mol of C is reacted with 0.117 mol of O_2 in a sealed 10.0 L vessel at 500 K, producing a mixture of CO and CO_2. The total pressure is 0.640 atm. What is the partial pressure of CO?

The Kinetic Molecular Theory of Gases

Concept Review

What is meant by the *root-mean-square speed* of gas molecules?

Why don't all molecules in a sample of air move at exactly the same speed?

How does the root-mean-square speed of the molecules in a gas vary with (a) molar mass and (b) temperature?

Does pressure affect the root-mean-square speed of the molecules in a gas? Explain your answer.

How can Graham's law of effusion be used to determine the molar mass of an unknown gas?

Is the ratio of the rates of effusion of two gases the same as the ratio of their root-mean-square speeds?

Why is it possible to readily separate the group 18 elements by diffusion but not the group 15 elements?

If gas X diffuses faster in air than gas Y, is gas X also likely to effuse faster than gas Y?

Problems

Rank the gases SO_2, CO_2, and NO_2 in order of increasing root-mean-square speed at 0°C.

In a mixture of CH_4, NH_3, and N_2, which gas molecules are, on average, moving fastest?

At 286 K, three gases, A, B, and C, have root-mean-square speeds of 351 m/s, 433 m/s, and 472 m/s, respectively.

1. Which gas is O_2?
2. Are the other gases heavier or lighter than O_2?
3. Which one could be a different diatomic element?

Determine the root-mean-square speeds of CO_2, SO_2, and NO_2 molecules that have an average kinetic energy of 4.2×10^{-21} J per molecule.

The root-mean-square speed of helium gas at 300 K is 1.370×10^3 m/s. Sketch a graph of $u_{\mathrm{rms,He}}$ versus T for $T = 300$, 450, 600, 750, and 900 K. Is the graph linear?

The root-mean-square speed of N_2 gas at 300 K is 516.8 m/s. Why doesn't doubling the temperature also double $u_{\mathrm{rms,N2}}$?

Molecules made out of two atoms of deuterium (^2H, an isotope of hydrogen) have the formula D_2. What is the ratio of the root-mean-square speed of D_2 to that of H_2 at constant temperature?

Enriching Uranium The two isotopes of uranium, ^{238}U and ^{235}U, can be separated by diffusion of the corresponding UF_6 gases. What is the ratio of the root-mean-square speed of $^{238}UF_6$ to that of $^{235}UF_6$ at constant temperature?

A student measured the relative rates of effusion of carbon dioxide and propane (C_3H_8) and found that they effuse at the same rate. Did the student make a mistake?

The density of Ne at 760 torr is exactly half its density at 2.00 atm at constant temperature. Is the root-mean-square speed of Ne at 2.00 atm half, twice, or the same as $u_{\mathrm{rms,Ne}}$ at 760 torr?

An unknown pure gas X effuses at half the rate of effusion of O_2 at the same temperature and pressure. What is the molar mass of gas X?

Decay Products of Uranium Minerals Radon and helium are both by-products of the radioactive decay of uranium minerals. A fresh sample of carnotite, $K_2(UO_2)_2(VO_4)_2 \cdot 3\ H_2O$, is put on display in a museum. Calculate the relative rates of diffusion of helium and radon under fixed conditions of pressure and temperature. Which gas diffuses more rapidly through the display case?

Isotope Use by Plants During photosynthesis, green plants preferentially use $^{12}CO_2$ over $^{13}CO_2$ in making sugars, and food scientists can frequently determine the source of sugars used in foods on the basis of the ratio of ^{12}C to ^{13}C in a sample.

1. Calculate the relative rates of diffusion of $^{13}CO_2$ and $^{12}CO_2$.
2. Specify which gas diffuses faster.

At a fixed temperature, how much faster does NO effuse than NO_2?

One balloon was filled with H_2, another with He. The person responsible for filling them neglected to label them. After 24 h the volumes of both balloons had decreased but by different amounts. Which balloon contained hydrogen?

Compounds sensitive to oxygen are often manipulated in *glove boxes* that contain a pure nitrogen or pure argon atmosphere. A balloon filled with carbon monoxide was placed in a glove box. After 24 h, the volume of the balloon was unchanged. Did the glove box contain N_2 or Ar?

Real Gases

Concept Review

Rearrange the van der Waals equation to solve for P. Why is the pressure exerted by a real gas lower than the pressure for an ideal gas at the same temperature and volume?

Under what conditions is the pressure exerted by a real gas *less* than that predicted for an ideal gas?

The van der Waals equation contains two constants, a and b, that depend on the identity of the gas. Which gas, Ne or Kr, has a higher value of constant a?

Explain why the constant a in the van der Waals equation generally increases with the molar mass of the gas.

Problems

The graphs of PV/RT versus P (see Figure 5.40) for 1 mole of CH_4 and 1 mole of H_2 differ in how they deviate from ideal behavior. For which gas is the effect of the volume occupied by the gas molecules more important than the attractive forces between molecules?

Which noble gas is expected to deviate the most from ideal behavior in a graph of PV/RT versus P?

At high pressures, real gases do not behave ideally. (a) Use the van der Waals equation and data in the text to calculate the pressure exerted by 40.0 g of H_2 at 20°C in a 1.00 L container. (b) Repeat the calculation, assuming that the gas behaves like an ideal gas. (c) Explain the difference between your answers to parts (a) and (b) using kinetic molecular theory.

(a) Calculate the pressure exerted by 1.00 mol of CO_2 in a 1.00 L vessel at 300 K, assuming that the gas behaves ideally. (b) Repeat the calculation using the van der Waals equation. (c) Explain the difference between your answers to parts (a) and (b) using kinetic molecular theory.

Additional Problems

The volume of a sample of propane gas at 12.5 atm is 10.6 L. What volume does the gas occupy if the pressure is reduced to 1.05 atm and the temperature remains constant?

A 22.4 L sample of hydrogen chloride gas is heated from 15°C to 78°C. What volume does it occupy at the higher temperature if the pressure remains constant?

A gas cylinder in the back of an open truck experiences a temperature change from 12°F to 143°F as it is driven from high in the Rocky Mountains of Colorado to Death Valley, CA. If the pressure gauge on the tank reads 2200 psi in Colorado, what will the gauge read in Death Valley to the nearest psi?

The temperature of a quantity of methane gas at a pressure of 761 torr is 18.6°C. Predict the temperature of the gas if the pressure is reduced to 355 torr while the volume remains constant.

A souvenir soccer ball is partially deflated and then put into a suitcase. At a pressure of 0.947 atm and a temperature of 27°C, the ball has a volume of 1.034 L. What volume does it occupy during an airplane flight if the pressure in the baggage compartment is 0.235 atm and the temperature is − 35°C?

Asthma Therapy A gas mixture used experimentally for asthma treatments contains 17.5 mol of helium for every 0.938 mol of oxygen. What is the mole fraction of oxygen in the mixture?

Blood Pressure A typical blood pressure in a resting adult is “120 over 80,” meaning 120 mmHg with each beat of the heart and 80 mmHg of pressure between heartbeats. Express these pressures in the following units: (a) torr;

(b) atm; (c) bar; (d) kPa.

Scuba Tanks A popular scuba tank is the “aluminum 80,” so named because it can deliver 80 cubic feet of air at “normal” temperature (72°F) and pressure (1.00 atm, 14.7 psi) when filled with air at a pressure of 3000 psi. A particular aluminum 80 tank has a mass of 15 kg when empty. What is its mass when filled with air at 3000 psi?

The flame produced by the burner of a gas (propane, C_3H_8) grill is a pale blue color when enough air mixes with the propane to burn it completely. For every gram of propane that flows through the burner, what volume of air is needed to burn it completely? Assume that the temperature of the burner is 200°C, the pressure is 1.00 atm, and the mole fraction of O_2 in air is 0.21.

Which noble gas effuses at about half the effusion rate of O_2? Are there any that effuse at twice the effusion rate of O_2?

Anesthesia A common anesthesia gas is halothane, with the structure shown in Figure P5.155. Liquid halothane boils at 50.2°C and 1.00 atm. If halothane behaved as an ideal gas, what volume would 10.0 mL of liquid halothane (d = 1.87 g/mL) occupy at 60°C and 1.00 atm of pressure? What is the density of halothane vapor at 55°C and 1.00 atm of pressure?

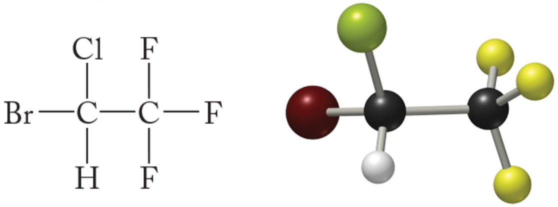

FIGURE P5.155

One cotton ball soaked in ammonia and another soaked in hydrochloric acid were placed at opposite ends of a 1.00

m glass tube (Figure P5.156). The vapors diffused toward the middle of the tube and formed a white ring of ammonium chloride where they met.

1. Write the chemical equation for this reaction.
2. Will the ammonium chloride ring form closer to the end of the tube with ammonia or the end with hydrochloric acid? Explain your answer.
3. Calculate the distance from the ammonia end to the position of the ammonium chloride ring.

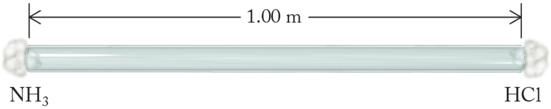

FIGURE P5.156

The same apparatus described in Problem 5.156 was used in another series of experiments. A cotton ball soaked in either hydrochloric acid (HCl) or acetic acid (CH_3COOH) was placed at one end. Another cotton ball soaked in one of three amines—CH_3NH_2, $(CH_3)_2NH$, or $(CH_3)_3N$—was placed in the other end (Figure P5.157).

1. In one combination of acid and amine, a white ring was observed almost exactly halfway between the two ends. Which acid and which amine were used?
2. Which combination of acid and amine would produce a ring closest to the amine end of the tube?
3. Do any two of the six combinations result in the formation of product at the same position in the ring? Assume measurements can be made to the nearest centimeter.

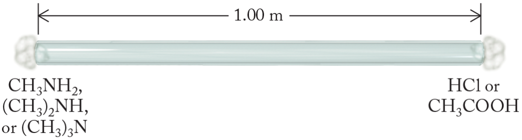

FIGURE P5.157

Early Earth Atmosphere Life as we know it on Earth depends on a constant atmospheric composition of 21% O_2 and 79% N_2 by volume. Over the past ~3 billion years, the amount of oxygen in the atmosphere has ranged from as low as 15% to as high as 35% by volume.

1. What partial pressures of oxygen correspond to this range?
2. How much does the density of air change over this range of oxygen concentrations if the balance of the atmosphere is assumed to be nitrogen?

Hydrogen-Powered Vehicles Combustion of hydrogen supplies a great deal of energy per gram. One challenge in designing hydrogen-powered vehicles is storing hydrogen. The pressure limit for carbon fiber–reinforced gas cylinders is 10,000 psi (1 atm = 14.7 psi). A fuel tank capable of holding up to 10 kg of H_2 is required to meet a reasonable driving range for a vehicle. If we limit the volume of the fuel tank to 400 L, what pressure must the hydrogen be under at 300 K? Does your answer conform to the safety requirements?

A sample of 11.4 L of an ideal gas at 25.0°C and 735 torr is compressed and heated so that the volume is 7.9 L and the temperature is 72.0°C. What is the pressure in the container?

A sample of a gas has a mass of 2.889 g and a volume of 940 mL at 735 torr and 31°C. What is its molar mass?

Uranus has a total atmospheric pressure of 130 kPa and its atmosphere consists of 83% $H_2(g)$, 15% $He(g)$, and 2% $CH_4(g)$ by volume. Calculate the partial pressure of each gas in Uranus’s atmosphere.

A sample of $N_2(g)$ requires 240 s to diffuse through a porous plug. It takes 530 s for an equal number of moles of an unknown gas X to diffuse through the plug under the same conditions of temperature and pressure. What is the molar mass of gas X?

The rate of effusion of an unknown gas is 0.10 m/s and the rate of effusion of $SO_3(g)$ is 0.052 m/s under identical experimental conditions. What is the molar mass of the unknown gas?

Derive an equation that describes the relationship between root-mean-square speed, u_{rms}, of a gas and its density.

Derive an equation that expresses the ratio of the densities (d_1 and d_2) of a gas under two different combinations of temperature and pressure, (T_1, P_1) and (T_2, P_2).

Denitrification in the Environment In some aquatic ecosystems, nitrate (NO_3^-) is converted to nitrite (NO_2^-), which then decomposes to nitrogen and water. As an example of this second reaction, consider the decomposition of ammonium nitrite:

$$NH_4NO_2(aq) \rightarrow N_2(g) + 2\ H_2O(\ell)$$

What would be the change in pressure in a sealed 10.0 L vessel caused by the formation of N_2 gas when the ammonium nitrite in 1.00 L of 1.0 *M* NH_4NO_2 decomposes at 25°C?

When sulfur dioxide bubbles through a solution containing nitrite, chemical reactions that produce gaseous N_2O and NO may occur.

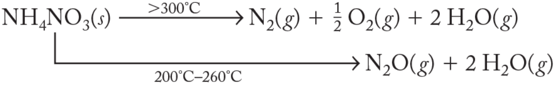
1. How much faster, on average, would NO molecules be moving than N_2O molecules in such a reaction mixture?
2. If these two nitrogen oxides were to be separated based on differences in their rates of effusion, would unreacted SO_2 interfere with the separation? Explain your answer.

Using Wetlands to Treat Agricultural Waste Wetlands can play a significant role in removing fertilizer residues from rain runoff and groundwater; one way they do this is through denitrification, which converts nitrate ions to nitrogen gas:

$$2\ NO_3^-(aq) + 5\ CO(g) + 2\ H^+(aq) \rightarrow N_2(g) + H_2O(\ell) + 5\ CO_2(g)$$

Suppose 200.0 g of NO_3^- flows into a swamp each day. What volume of N_2 would be produced at 17°C and 1.00 atm if the denitrification process were complete? What volume of CO_2 would be produced? Suppose the gas mixture produced by the decomposition reaction is trapped in a container at 17°C; what is the density of the mixture if we assume that $P_{total} = 1.00$ atm?

Ammonium nitrate decomposes on heating. The products depend on the reaction temperature:



A sample of NH_4NO_3 decomposes at an unspecified temperature, and the resulting gases are collected over water at 20°C.

1. Without completing a calculation, predict whether the volume of gases collected can be used to distinguish between the two reaction pathways. Explain your answer.
2. The gas produced during the thermal decomposition of 0.256 g of NH_4NO_3 displaces 79 mL of water at 20°C and 760 torr of atmospheric pressure. Is the gas N_2O or a mixture of N_2 and O_2?

Hydrogen-Producing Enzymes Generating hydrogen from water or methane is energy intensive. A non-natural enzymatic process has been developed that produces 12 moles of hydrogen per mole of glucose by the reaction:

$$C_6H_{12}O_6(aq) + 6\ H_2O(\ell) \rightarrow 12\ H_2(g) + 6\ CO_2(g)$$

What volume of hydrogen could be produced from 256 g of glucose at STP?

Oxygen Generators Several devices are available for generating oxygen. Breathing pure oxygen for any length of time, however, can be dangerous to the human body, so a better rebreathing apparatus would be one that also produces nitrogen. One possible reaction that produces both N_2 and O_2 is the thermal decomposition of ammonium nitrate:

$2\ NH_4NO_3(s) \rightarrow 2\ N_2(g) + O_2(g) + 4\ H_2O(g)$

1. The respiratory rate at rest for an average, healthy adult is 12 breaths per minute. If the average breath takes in 500 mL of gas into our lungs, what mass in grams of NH_4NO_3 is needed to satisfy these needs for 1 h if $P = 1.00$ atm and $T = 37°C$?
2. What are the partial pressures of N_2 and O_2 in this mixture?

Tropical Storms The severity of a tropical storm is related to the depressed atmospheric pressure at its center. In August 1985, Typhoon Odessa reached maximum winds of about 90 mi/h and the pressure was 40 mbar lower at the center than normal atmospheric pressure. In contrast, the central pressure of Hurricane Andrew (Figure P5.173) was 90 mbar lower than its surroundings when it hit southern Florida with winds as high as 266 km/h (165 mi/h). If a small weather balloon with a volume of 50.0 L at a pressure of 1.0 atm was deployed above the center of Andrew, what was the volume of the balloon when it reached the surface of the ocean?

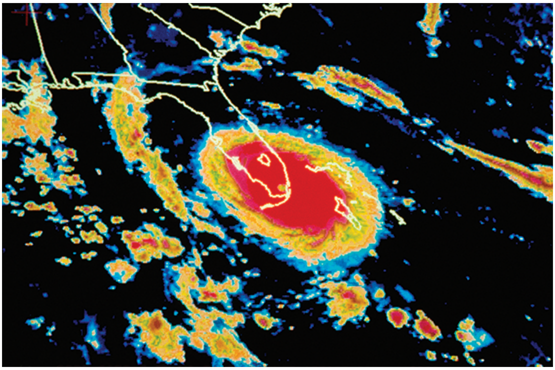


FIGURE P5.173

Manufacturing a Proper Air Bag The overall reaction in an automobile air bag is

$$20\ NaN_3(s) + 6\ SiO_2(s) + 4\ KNO_3(s) \rightarrow 32\ N_2(g) + 5\ Na_4SiO_4(s) + K_4SiO_4(s)$$

Calculate how many grams of sodium azide (NaN_3) are needed to inflate a 40 × 40 × 20 cm bag to a pressure of 1.25 atm at a temperature of 20°C. How much more sodium azide is needed if the air bag must produce the same pressure at 10°C?

Suppose 0.200 L of O_2 is collected over water at 25.0°C and the atmospheric pressure is 750.0 torr. The vapor pressure of water at 25.0°C is 24.0 torr. How many moles of O_2 have been collected?

Use Dalton's law of partial pressures to calculate the mole fraction of water vapor in the gas sample collected over water in Problem 5.175.

Glossary

miscible

capable of being mixed in any proportion.

barometer

an instrument that measures atmospheric pressure.

manometer

an instrument for measuring the pressure exerted by a gas.

Boyle’s law

the principle that the volume of a given amount of gas at constant temperature is inversely proportional to its pressure.

Charles’s law

the principle that the volume of a fixed quantity of gas at constant pressure is directly proportional to its absolute temperature.

Avogadro’s law

the principle that the volume of a gas at a given temperature and pressure is proportional to the quantity of the gas.

Amontons’s law

the principle that the pressure of a quantity of gas at constant volume is directly proportional to its absolute temperature.

partial pressure

the contribution to the total pressure made by one gas in a mixture of gases.

Dalton’s law of partial pressures

the principle that the total pressure of any mixture of gases equals the sum of the partial pressure of each gas in the mixture.

mole fraction (X_x)

the ratio of the number of moles of a component in a mixture to the total number of moles in the mixture.

kinetic molecular theory

a model that describes the behavior of ideal gases; all equations defining relationships between pressure, volume, temperature, and number of moles of gases can be derived from the theory.

Graham’s law of effusion

the principle that the rate of effusion of a gas is inversely proportional to the square root of its molar mass.

effusion

the process by which a gas escapes from its container through a tiny hole into a region of lower pressure.

diffusion

the spread of one substance (usually a gas or liquid) through another.

van der Waals equation

an equation that includes experimentally determined factors a and b that quantify the contributions of non-negligible molecular volume and non-negligible intermolecular interactions to the behavior of real gases with respect to changes in P, V, and T.

pressure (P)

the ratio of a force to the surface area over which the force is applied.

ideal gas equation (also called ideal gas law)

the principle relating the pressure, volume, number of moles, and temperature of an ideal gas; expressed as $PV = nRT$, where R is the universal gas constant.

root-mean-square speed (u_{rms})

the square root of the average of the squared speeds of all the molecules in a population of gas molecules; a molecule possessing the average kinetic energy moves at this speed.

ENERGY PRODUCTION AND CLIMATE CHANGE Melting glaciers in polar regions are among the environmental impacts of climate change linked to the combustion of fossil fuels.

Thermochemistry Energy Changes in Chemical Reactions

PARTICULATE REVIEW

Neutralization Reactions Revisited

In Chapter 6 we consider the energy changes that occur during reactions such as the combustion reactions from Chapter 3 and neutralization reactions from Chapter 4. Here we see the key molecules and ions involved in the titration of a sample containing hydrochloric acid with a standard solution of sodium hydroxide.

- Which of the illustrated particles are present in the buret?
- Which of the particles are present in the flask before any sodium hydroxide has been added?
- Which particles are present after all the acid has been neutralized?
- Write a balanced net ionic equation for the reaction.

(Review Sections 4.5 and 4.6 if you need help.)

(Answers to Particulate Review questions are in the back of the book.)

PARTICULATE PREVIEW

Breaking Bonds and Energy

Ultraviolet rays (UV rays) from the Sun can cause molecules of ozone to break apart into oxygen molecules and oxygen atoms according to the chemical reaction depicted here. As you read Chapter 6, look for ideas that will help you answer these questions:

- When the bonds in O_3 break, is this (a) accompanied by a release of energy or (b) due to the absorption of energy?
- Is energy absorbed or released during this reaction?
- Would energy be absorbed or released if the reaction ran in reverse: $O_2(g) + O(g) \rightarrow O_3(g)$?

Learning Outcomes

- LO1 Explain kinetic energy and potential energy at the atomic and molecular level

  Sample Exercise 6.1

- LO2 Differentiate between a system and its surroundings and identify familiar endothermic and exothermic processes

  Sample Exercise 6.2

- LO3 Calculate changes in the internal energy of a system

  Sample Exercises 6.3, 6.4

- LO4 Calculate the energy changes associated with physical and chemical processes

Sample Exercises 6.5, 6.6, 6.7, 6.8, 6.9

- LO5 Calculate thermochemical values by using data from calorimetry experiments

  Sample Exercises 6.10, 6.11

- LO6 Calculate enthalpies of reaction

  Sample Exercises 6.12, 6.13, 6.15

- LO7 Recognize and write equations for formation reactions

  Sample Exercise 6.14

- LO8 Calculate and compare fuel and food values and fuel densities

  Sample Exercises 6.16, 6.17

identical blocks at different temperatures are brought into contact. (b) Heat is transferred from the block at higher temperature to the block at lower temperature until thermal equilibrium (equal temperature) (c) is reached.

6.1 Sunlight Unwinding

All physical changes of matter, such as ponds freezing in winter and thawing in spring, involve changes in energy, as do the chemical reactions we studied in Chapter 4. Energy—to power an automobile, heat a home, or support life—may seem like an abstract idea because energy has no mass and no volume. However, we see its effects very clearly when matter changes from one state to another—as sunlight melts snow, or a gas flame boils water and converts it into steam—and when energy itself is converted from one form into another, as when the chemical energy of gasoline is converted into mechanical energy to move a car. Part of the energy in the gasoline contributes nothing to moving the vehicle and is lost to the surroundings as heat. The sum of the energy used to move the vehicle and the energy lost as heat equals the energy released during the combustion of the gasoline. That is, energy is neither created nor destroyed during chemical reactions.

We can roast marshmallows by using energy from a campfire, but where does that energy come from? R. Buckminster Fuller (1895–1983), a 20th-century architect, inventor, and futurist, described a burning log like this: trees gather the energy in sunlight and combine it with water and carbon dioxide to make the molecules that compose wood. When the wood is burned, the chemical products are carbon dioxide and water, and the fire is, as Fuller said, “All that sunlight unwinding.” The sunlight unwinding is the net release of chemical energy as bonds break between atoms in the molecules of the wood and bonds form between atoms in the molecules of carbon dioxide and water. Through the transforming power of green plants, sunlight is the source of the chemical energy stored in all the substances we consume as food and fuel.

CONNECTION We introduced energy as the capacity to do work in Chapter 1.

Nearly every chemical reaction, from the combustion of fuels to neutralization reactions to the dissolution of salts, involves energy as either a product or a reactant. For example, the reaction in which hydrogen combines with oxygen to form water releases energy:

$$2\ H_2(g)\ +\ O_2(g) \rightarrow 2\ H_2O(g)\ +\ \text{energy}$$

The energy derived from the reaction between hydrogen and oxygen may be converted into motion, as when a spacecraft fueled by hydrogen lifts off. The study of energy and its transformations from one form to another is called thermodynamics. The part of thermodynamics that deals with changes in energy accompanying chemical reactions is known as thermochemistry.

When we put an ice cube, initially at $-18°C$—the typical temperature of a freezer—into room-temperature water (25°C), the ice cube melts and the water cools because energy moves from the room-temperature water into the colder ice cube and the 0°C water it produces as it melts. The process by which energy moves from warmer to cooler objects is called *heat transfer*, or more generally *energy transfer*. The difference in temperature defines the direction of energy flow when two objects come into contact: energy transfer in the form of heat always flows from the hotter object to the colder one (**Figure 6.1**). The ice cube changes state from solid to liquid as energy is transferred to it from the liquid water. The warmer water remains in the liquid state, but its temperature decreases as energy from it is transferred to the ice cube and its melt water. Ultimately, the warmer and colder water reach the same temperature, which is higher than the initial temperature of the ice cube but lower than the initial temperature of the water. At this point, thermal equilibrium has been reached, and no further energy transfer occurs.

How do we measure the amount of energy involved in physical and chemical processes? We cannot directly measure the amount of energy in a chemical reaction, but by measuring changes in the temperature, we can relate *the change* in energy to the identities and amounts of reactants and products involved in changes of state and in chemical reactions. Studying energy changes gives us important insights into the way nature works and how human activities affect our world.

Glossary

thermodynamics
the study of energy and its transformations.

thermochemistry
the study of the energy changes that occur during chemical reactions.

heat
the energy transferred between objects because of a difference in their temperatures.

thermal equilibrium
a condition in which temperature is uniform throughout a material and no energy flows from one point to another.

$$w = F \times d \tag{6.1}$$
$$\mathrm{PE} = m \times g \times h \tag{6.2}$$

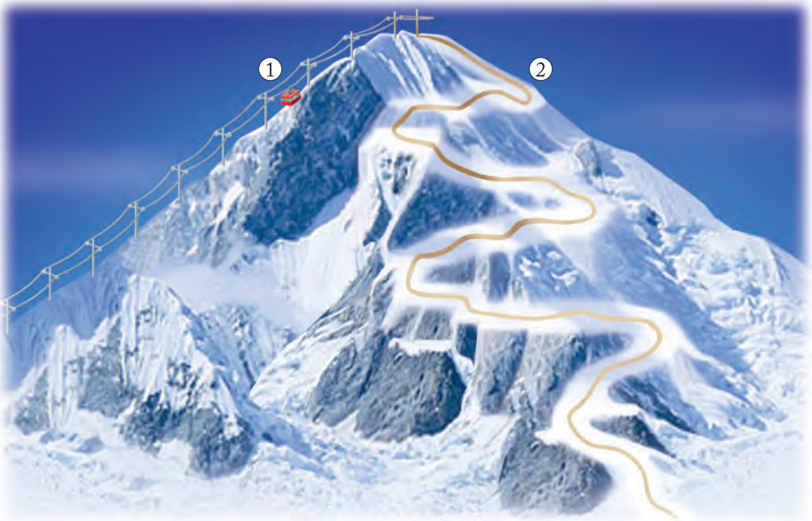

FIGURE 6.2 Work is done as skiers ascend to the top of a mountain. The amount of work may differ, depending on whether the skiers (1) ride a gondola on a direct route to the top or (2) hike to the top along a winding path.

$$T_{\text{water}} = T_{\text{ethanol}}$$

$$\text{KE}_{\text{water}} = \text{KE}_{\text{ethanol}}$$

$$\tfrac{1}{2} m_{\text{water}}(u_{\text{avg.water}})^2 = \tfrac{1}{2} m_{\text{ethanol}}(u_{\text{avg.ethanol}})^2$$

Because $m_{\text{water}} < m_{\text{ethanol}}$, $u_{\text{avg.water}} > u_{\text{avg.ethanol}}$

FIGURE 6.7 Two populations of gas-phase molecules have the same temperature and therefore the same average kinetic energy. Because ethanol molecules have a greater mass than water molecules, the average speed of the water molecules in the water vapor above the liquid water is greater than the average speed of the gas-phase ethanol molecules above the liquid ethanol.

$$E_{\text{el}} \propto \frac{Q_1 \times Q_2}{d} \tag{6.3}$$

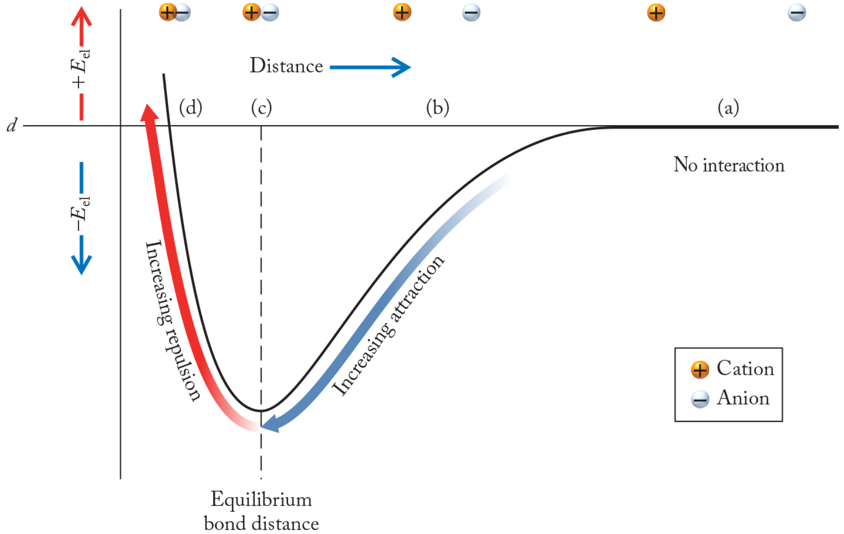

FIGURE 6.8 Ionic interaction. (a) A positive ion and a negative ion are so far apart (*d* is large) that they do not interact at all. (b) As the ions move closer together (*d* decreases), the electrostatic potential energy between them becomes more negative. (c) At this distance, the attraction between them produces an arrangement that is the most favorable energetically because the ions have the lowest electrostatic potential energy. This is also the equilibrium bond distance. (d) If the ions are forced even closer together, the electrostatic potential energy increases because of increasing repulsions.

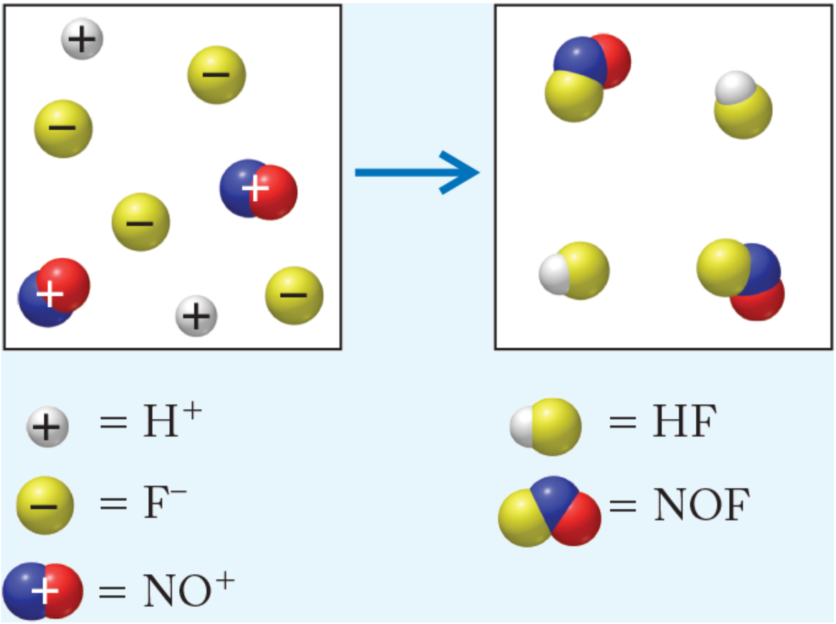

FIGURE 6.9 Protons and nitrosonium ions react with fluoride ions to form HF and NOF, respectively.

FIGURE 6.10 Energy from the combustion of hydrogen can be used

(a) (b)

FIGURE 6.11 (a) Hydrogen reacts with oxygen to produce water. Because this reaction releases energy, the product molecules are at a lower energy than those of the reactants. (b) Fueling a hydrogen-powered vehicle.

6.2 Forms of Energy

The energy produced by a chemical reaction can be used to do work, can be transferred to an object to raise its temperature, or both. Energy that does work includes electrical, mechanical, light, and sound energy. Whatever the form, energy used to do work causes motion: the location or shape of an object changes when an energy source does work on the object. For example, the energy derived from the reaction between hydrogen and oxygen is converted into motion when a hydrogen-fueled spacecraft blasts off.

Work, Potential Energy, and Kinetic Energy

How does the combustion of hydrogen lead to the work done in lifting a spacecraft into orbit? Let's start with the classical view of work and energy from physics and consider a skier poised on top of a steep slope. In the physical sciences, work (w) is done whenever a force (F) moves an object through a distance (d). The amount of mechanical work done is

How does Equation 6.1 relate to skiers ascending a mountain

(**Figure 6.2**)? The work (*w*) done by the gondola on a skier equals the distance of the ride (*d*) times the force (*F*) needed to overcome gravity and transport the skier up the mountain. Some of the work done is stored in the skier as potential energy (PE), which is the energy an object has because of its position or composition. The skier's potential energy depends on her mass (*m*), her height (*h*) above a zero-energy reference point—in this case the bottom of the ski slope—and acceleration due to the force of gravity (*g*):

The kind of potential energy in Equation 6.2 is called *gravitational* potential energy, which is the energy an object has because of its position in a gravitational field. The equation tells us that gravitational PE depends on the position of the skier and not on the path (**Figure 6.3**) she took to reach that position, nor does it depend on the quantity of work done to get her there. This means that gravitational PE, like all forms of potential energy, is a state function, which means it is independent of the pathway followed to acquire the potential energy.

Now let's consider the gravitational potential energy of a skier standing at the top of the ski jump in **Figure 6.4a** and how that energy is converted into kinetic energy (KE; **Figure 6.4b**) from the start of the run and until he stops at the bottom of the hill. The ski jumper's total energy at any position on the hill is the sum of his potential and kinetic energies. The jumper's kinetic energy is proportional to his mass (*m*) times the square of his speed (*u*) as described by Equation 5.27:

A 100 kg (220 lb) jumper has twice the gravitational PE as a 50 kg (110 lb) jumper at the top of the run, and, if moving at the same speed as a lighter jumper at the bottom of the jump, has twice the kinetic energy. According to the law of conservation of energy, energy cannot be created or destroyed. However, it can be converted from one form to another, as the example of the two ski jumpers illustrates.

CONCEPT TEST

Sports competitions such as the X-Games include downhill mountain bike races. Two mountain bikers with masses m_1 and m_2 ($m_1 > m_2$) are poised at the starting gate of a race course (**Figure 6.5**). Is the potential energy of rider 1 the same as that of rider 2? If the energies are different, which rider has more potential energy?

(Answers to Concept Tests are in the back of the book.)

CONCEPT TEST

Two mountain bikers with masses m_1 and m_2, where $m_1 > m_2$, go past the same elevation on parallel race courses at the same time (**Figure 6.6**). At that moment, is the potential energy of rider 1 more than, less than, or equal to the PE of rider 2? If the two are moving at the same speed, which has the greater kinetic energy?

Kinetic Energy and Potential Energy at the Molecular Level

The relationship just described between kinetic energy and potential energy holds for atoms and molecules as well. There is no direct analogy with the kinetic and potential energies of a skier, however, because the gravitational forces that control the skier play no significant role in the interactions of very small objects such as atoms and molecules. At the molecular level, temperature and charge dominate the relation between kinetic and potential energies. Temperature governs motion at this level. Chemical bonds and interactions between particles contribute to the potential energy stored in the arrangements of the atoms, ions, and molecules in matter.

The kinetic energy of an atomic particle depends on its mass and speed, just as with macroscopic objects. However, because the particle's speed depends on temperature, its kinetic energy does, too. As the temperature of a population of particles increases, the average kinetic energy of the particles also increases. Consider, for example, how the molecules in the vapor phase above a liquid behave at different temperatures. We pick the gas phase because the molecules in a gas at normal pressures are widely separated and behave essentially independently of one another, and they all behave the same way regardless of their identities. If we have two samples of water vapor (molecular mass 18.02 u) at room temperature, the two populations of H_2O molecules have the same average kinetic energy. The average speeds of the molecules are the same because their masses are identical. If we increase the temperature of one sample, that population of H_2O molecules acquires a higher average kinetic energy and the average speed of its molecules increases. An equivalent population of ethanol molecules (molecular mass 46.07 u) in the gas phase at room temperature has the same average kinetic energy as the water molecules at room temperature, but the average speed of the ethanol molecules is lower because their mass is higher (**Figure 6.7**).

The kinetic energy associated with the total random motion of molecules is called thermal energy, and the thermal energy of a given sample of matter is proportional to the temperature of the sample. It also depends on the number of particles in the sample. The water in a swimming pool and in a cup of water taken from the pool have the same temperature, so their molecules have the same average kinetic energy. However, the water in the pool has considerably more thermal energy than the water in the cup simply because the pool contains many more molecules of water.

CONCEPT TEST

If we heat a cup of water from a swimming pool almost to the boiling point, will its thermal energy be more than, less than, or the same as the thermal energy of all the water in the pool?

An important form of potential energy at the atomic level arises from electrostatic interactions between charged particles. Just as the potential energy of skiers is determined by their distances above the bottom of the slope, the electrostatic potential energy (E_{el}) of charged particles is related to the distance between them. The magnitude of this electrostatic potential energy, also known as *coulombic interaction*, is directly proportional to the charges (Q_1 and Q_2) on the particles and is inversely proportional to the distance (d) between them:

If the two charges in Equation 6.3 are either both positive or both negative, their product is positive, E_{el} is positive, and the particles repel each other. If one particle is positive and the other negative, E_{el} is negative, and the particles attract each other. Equation 6.3 is called Coulomb's law because it traces back to the work of French engineer Charles Augustin de Coulomb (1736–1806), who first measured the interactions between charged particles. The change in E_{el} that two oppositely charged particles experience as they approach each other is illustrated in **Figure 6.8**. When the ions are far apart (the right end of the curve), there is no attraction between them and $E_{\text{el}} = 0$. As the ions approach each other, E_{el} decreases as electrostatic attractions increase, reaching an energy minimum that corresponds to maximum stability. If the ions are pushed even closer together (to the left of the energy minimum), E_{el} rises and the ion pair becomes less stable as decreasing distance between their positively charged nuclei creates a growing electrostatic repulsion between the ions.

Ions are not the only particles that experience coulombic interactions. Neutral species such as water molecules attract each other as well, because there is an uneven electron distribution throughout the molecule that produces regions of partial positive and negative charges. We will explore this topic in detail in Chapter 10. Whether we are dealing with matter composed of atoms, molecules, or ions, the total energy at the atomic level is the sum of the kinetic energy from the random motion of particles and the potential energy resulting from their arrangement.

SAMPLE EXERCISE 6.1 Kinetic Energy of Gas-Phase Ions LO1

Protons (H^+) and nitrosonium ions (NO^+) react with fluoride ions (F^-) in the gas phase under laboratory conditions (constant temperature and pressure), forming HF and NOF, respectively, as shown in **Figure 6.9**. (a) At a given temperature, which ion has the greatest kinetic energy? (b) Which cation is moving at the higher average speed?

Collect and Organize We are asked to predict which of three gas-phase particles has the greatest kinetic energy, and which of two positively charged particles has the higher average speed.

Analyze Particles of gas at the same temperature have the same kinetic energy (KE), which is related to their average speeds (u) by Equation 5.27, $\mathrm{KE} = \frac{1}{2}mu^2$. For particles of equal kinetic energy, this relationship indicates that a heavier particle will move more slowly than a lighter particle.

Solve

1. Because the temperature is constant, both H^+ and NO^+ ions have the same average kinetic energy.
2. Expressing this equality using Equation 5.27:

$$\frac{1}{2}m_{\mathrm{H}^+} \times u_{\mathrm{H}^+}^2 = \frac{1}{2}m_{\mathrm{NO}^+} \times u_{\mathrm{NO}^+}^2$$

Rearranging the terms and simplifying:

$$\frac{u_{\mathrm{H}^+}}{u_{\mathrm{NO}^+}} = \sqrt{\frac{m_{\mathrm{NO}^+}}{m_{\mathrm{H}^+}}}$$

The mass of a NO^+ ion is much greater than the mass of a proton; therefore, the protons in the reaction mixture have a higher average speed.

Think About It We have confirmed that heavier particles move more slowly than lighter particles with the same kinetic energy.

Practice Exercise Consider two positively charged particles, A^+ and B^+. If A^+ is 33% heavier than B^+, how much slower must it move to equal the kinetic energy of B^+?

(Answers to Practice Exercises are in the back of the book.)

The energy given off or absorbed during a chemical reaction is equal to the difference in the energy of the reactants and products. For example, when hydrogen molecules burn in oxygen, the products are water and a considerable amount of energy (**Figure 6.10**). The energy given off by this reaction can be used to power rockets and is now being used to run some buses and automobiles. Because energy is given off in the reaction, the product molecules must be at a lower potential energy than the reactant molecules. The difference between the energy of the products and the energy of the reactants is the energy released. In the case of hydrogen combustion (**Figure 6.11a**), this energy is now used to fuel passenger cars (**Figure 6.11b**).

Where does the energy released by the reaction between hydrogen and oxygen in Figure 6.11 come from? During the combustion of H_2, the bonds in molecules of H_2 and O_2 must be broken, which requires energy, but even more energy is released when the O–H bonds in H_2O form. The result is a net release of energy.

Glossary

work

a form of energy—specifically, the energy required to move an object through a given distance.

potential energy (PE)

the energy stored in an object because of its position or composition.

state function

a property of an entity based solely on its chemical or physical state or both, but not on how it achieved that state.

kinetic energy

the energy of an object in motion due to its mass (m) and its speed (u): $\mathrm{KE} = \frac{1}{2}mu^2$.

kinetic energy

the energy of an object in motion due to its mass (m) and its speed (u): $\mathrm{KE} = \frac{1}{2}mu^2$.

law of conservation of energy

the principle that energy cannot be created or destroyed but can be converted from one form into another.

thermal energy

the kinetic energy of atoms, ions, and molecules.

electrostatic potential energy (E_{el})

the energy a particle has because of its electrostatic charge and its position with respect to another particle; it is directly proportional to the product of the charges of the particles and inversely proportional to the distance between them.

6.3 Systems, Surroundings, and Energy Transfer

In both thermochemistry and thermodynamics, the specific part of the universe we are studying is called the system and everything else is called the surroundings. Although a system can be as large as a galaxy or as small as a living cell, most of the systems we examine in this chapter fit on a laboratory bench. Typically, we limit our concern about surroundings to that part of the universe that can exchange energy and matter with the system. When evaluating the energy gained or lost in a chemical reaction, the system may be just the particles involved in the reaction, or it may also include the vessel in which the reaction occurs.

Isolated, Closed, and Open Systems

Thermodynamic systems may be isolated, closed, or open (**Figure 6.12**). These designations are important because they define the system we are dealing with and the part of the universe that the system interacts with. In the following discussion, hot soup is the system.

What kind of system is hot soup in an ideal, closed thermos bottle? An ideal thermos bottle takes no energy away from the soup, thereby completely insulating the soup from the rest of the universe, and the soup loses no energy. Such perfect insulation is impossible in practice, but sometimes in thermochemistry we must discuss systems that do not exist in the real world to define the total range of possibilities. The soup in the ideal thermos bottle is an example of an isolated system, which is a system that exchanges no energy or matter with its surroundings. The ideal thermos bottle prevents matter from being exchanged with the surroundings, and the thermal insulation provided by the ideal thermos also prevents heat from being transferred from the system to the surroundings, including the bottle itself. Even the best real thermos bottle cannot maintain the soup as an isolated system over time because heat will leak out, and the contents will cool. But for short periods, the soup in a good thermos bottle *approximates* an isolated system.

Hot soup in a cup with a lid is an example of a closed system, which is a system that exchanges energy but not matter with its surroundings. Because the cup has a lid, no vapor (which is matter) escapes from the soup and no matter can be added. Only energy is exchanged between the soup and its surroundings. Energy from the soup is transferred—first into the cup walls, then into the air and the tabletop—and the soup gradually cools. Many real systems are closed systems.

Soup in an open cup is an open system, one that can exchange both energy and matter with its surroundings. Energy, in the form of heat, from the soup is transferred to the surroundings (cup, air, tabletop), and matter, in the form of water vapor, leaves the system and enters the air. We may add matter to the system from the surroundings by sprinkling on a little grated cheese, some ground pepper, or a few crumbled crackers.

Most of the real systems we deal with are closed, and we may treat some of them as isolated, at which point we assume behavior that is more ideal than real. We do this because isolated and closed systems are easier to model quantitatively than open systems. However, many important systems are open—including cells, organisms, and Earth itself.

CONCEPT TEST

Identify the following systems as isolated, closed, or open: (a) the water in a pond; (b) a carbonated beverage in a sealed bottle; (c) a sandwich wrapped in thermally conducting plastic wrap; (d) a live chicken.

Exothermic and Endothermic Processes

Chemists classify chemical reactions and changes of state based on whether they give off or absorb energy. For example, condensation of a gas is accompanied by a transfer of energy from the gas (the system) to its surroundings (**Figure 6.13a**), which makes condensation exothermic from the point of view of the system. This flow of energy can be detected because it causes the temperature of the surroundings to increase. Combustion reactions are also exothermic because energy flows from hot reaction mixtures (the system) to their surroundings. In contrast, processes that absorb energy from their surroundings are endothermic (**Figure 6.13b**). For example, when ice cubes (the system) are added to a glass of room-temperature water (the surroundings), energy flows spontaneously from the warmer water to the cooler ice cubes, causing them to melt. The melting process is endothermic.

CONNECTION In Chapter 3 we defined combustion as the reaction of oxygen with another element.

In the condensation of water vapor (the system) from humid air, droplets of liquid water form on the outside of a glass containing an ice-cold drink (part of the surroundings) because energy flows from the system to the surroundings. From the point of view of the system, this process is exothermic. If we pour out the cold drink and pour hot coffee into the glass, the water droplets (the system) on the outside surface of the glass absorb energy from the coffee and vaporize in a process that is endothermic from the point of view of the system. This illustrates an important concept: a process that is exothermic in one direction (vapor → liquid; releases energy) is endothermic in the reverse direction (liquid → vapor; absorbs energy).

We use the symbol q to represent the *quantity* of energy transferred during a chemical reaction or a change of state. For historical reasons, q is called heat and represents energy transferred directly because of a difference in temperature. If the reaction or process is endothermic, q is positive, indicating that energy is *gained* by the system. If the reaction or process is exothermic, q is negative, meaning that the system *loses* energy to its surroundings. In **Figure 6.14**, endothermic changes of state are represented by arrows pointing upward: solid → liquid, liquid → gas, and solid → gas. The opposite (i.e., exothermic) changes of state—liquid → solid, gas → liquid, and gas → solid—are represented by arrows pointing downward. To summarize:

Exothermic: $q < 0$Endothermic: $q > 0$

SAMPLE EXERCISE 6.2 Identifying Exothermic and Endothermic Processes LO2

Describe the flow of energy during the purification of water by distillation (**Figure 6.15**), identify the steps in the process as either endothermic or exothermic, and give the sign of q associated with each step. Consider the water being purified to be the system.

Collect and Organize The water is the system, so we must evaluate how the water gains or loses energy during distillation.

Analyze In distillation, energy is transferred during three steps: (1) Liquid water is heated to the boiling point and (2) vaporizes. (3) The vapors are cooled and condense back to a liquid as they pass through the condenser.

Solve Energy flows from the surroundings (the hot plate) to heat the impure water (the system) to its boiling point and then to vaporize it (Figure 6.15a). Therefore, steps 1 and 2 are endothermic. The sign of q is positive for both processes. In step 3, energy flows from the system (the water vapor) into the surroundings (the condenser walls, Figure 6.15b), so this process is exothermic, and the sign of q is negative.

Think About It *Endothermic* means that energy is transferred from the surroundings into the system—the water in the distillation flask. When the water vapor is cooled in the condenser, energy flows from the vapor as it is converted from a gas to a liquid (Figure 6.15b); the process is exothermic.

Practice Exercise What is the sign of q as (a) a match burns, (b) drops of molten candle wax solidify, and (c) perspiration evaporates from skin? In each case, define the system and indicate whether the process is endothermic or exothermic.

CONNECTION In Chapter 1 we discussed the arrangement of molecules in ice, water, and water vapor.

Now let's consider the flow of energy when an ice cube is left on a kitchen counter (**Figure 6.16**). Qualitatively, as the cube (the system) absorbs energy from the air and the counter (the surroundings) and starts to melt, the attractive forces that hold the water molecules in place in solid ice are overcome. The water molecules now have more freedom of motion and more kinetic energy. After all the ice has melted into liquid water at 0°C, the temperature of the water (the system) slowly rises to room temperature. As the temperature increases, the average kinetic energy of the molecules increases, and they move more rapidly. (In Section 6.4 we present a quantitative view of this process.)

The internal energy (E) of a system is the sum of the kinetic and potential energies of all the components of the system (**Figure 6.17**). It is not possible to determine the absolute values of kinetic and potential energies, but *changes* in internal energy (ΔE) can be determined because a change in a system's physical state or temperature is a measure of the change in its internal energy. (The capital Greek delta, Δ, is the standard way scientists symbolize change in a quantity.) The change in internal energy is the difference between the final internal energy of the system and its initial internal energy:

Internal energy is a state function because ΔE depends only on the initial and final states. How the change occurs in the system does not matter.

The law of conservation of energy (Section 6.2) applies to the transfer of energy in materials. The total energy change experienced by a system must be balanced by the total energy change experienced by its surroundings.

P–*V* Work and Energy Units

Doing work *on* a system is a way to *add* to its internal energy. For example, compressing a quantity of gas (the system) into a smaller volume does work on the gas, and that work causes the temperature of the gas to rise, meaning its internal energy increases. The total increase in the internal energy of a closed system is the sum of the work done on it (w) and any other energy (q) gained:

Pressure–Volume Work

Equation 6.5 expresses the first law of thermodynamics: the energy changes ($\Delta E = q + w$) of a closed system and its surroundings are equal in magnitude but opposite in sign, so their sum is zero:

When work is done *by* a system on its surroundings, the internal energy of the system decreases. For example, when fuel in the cylinder of a diesel engine ignites and produces hot gases, the gases (the system) expand and do work on the surroundings by pushing on the piston (**Figure 6.18**).

The hot-air balloon depicted in **Figure 6.19** provides another example of work being done by a system on its surroundings. The air in the balloon, which we define as the system, is heated by a burner located at the balloon's bottom, which is open. Heating this air causes the balloon to expand. As the volume of the balloon increases, the balloon presses against the air outside the balloon, thus doing work on that outside air (the surroundings). This type of work, in which the pressure on a system remains constant but the volume of the system changes, is called pressure–volume (P–V) work. (In this example, we are ignoring the work to lift the mass of the collapsed balloon to the height of the filled balloon.)

What happens to the balloon in terms of heat transferred and work done under constant pressure? First, adding hot air to the balloon increases its internal energy and causes the balloon to expand. Second, the expansion of the balloon against the pressure of its surroundings is P–V work done by the system on its surroundings. The internal energy of the system decreases as it performs this P–V work. We can relate this change in internal energy to the energy gained by the system by heating (q) and by the work done by the system ($P\Delta V$) by writing Equation 6.5 in the form

The negative sign in front of $P\Delta V$ is appropriate in this case because, when the system expands (positive change in volume ΔV), it loses energy (negative change in internal energy ΔE) as it does work on its surroundings. Correspondingly, when the surroundings do work on the system (e.g., when a gas is compressed), the quantity $(-P\Delta V)$ has a positive value.

The sign of q may also be either positive or negative (**Figure 6.20**). If the system is heated by its surroundings, then q is positive ($q > 0$). Energy is added to the balloon, for instance, when it is being inflated, because energy flows from the surroundings (the burner) into the system (the air in the balloon). When the balloon expands, work is done by the system, w is negative ($w < 0$), and the internal energy decreases. If energy is transferred from the system into the surroundings due to a temperature difference, q is negative ($q < 0$), and the internal energy decreases. According to Equation 6.6, the change in internal energy of a system is positive when more energy enters the system than leaves it and negative when more energy leaves the system than enters it. Figure 6.20 also illustrates the first law of thermodynamics: the energy changes ($\Delta E = q + w$) of the system and the surroundings are equal in magnitude but opposite in sign, so their sum is zero.

What units are needed to calculate ΔE by using Equation 6.6? Energy changes that accompany chemical reactions and changes in physical state are sometimes expressed in calories. A calorie (cal) is the quantity of energy required to raise the temperature of 1 g of water from 14.5°C to 15.5°C. The SI unit of energy, used throughout this text, is the joule (J); $1 \text{ cal} = 4.184 \text{ J}$. The *Calorie* (Cal; note the capital *C*) in nutrition is one kilocalorie (kcal): $1 \text{ Cal} = 1000 \text{ cal} = 1 \text{ kcal}$. If the SI unit for energy is a joule, but pressure is measured in atmospheres and volume in liters, how can we calculate work? A conversion factor, $1 \text{ L} \cdot \text{atm} = 101.32 \text{ J}$, connects joules to liter-atmospheres.

SAMPLE EXERCISE 6.3 Calculating Changes in Internal Energy LO3

Figure 6.21 shows a simplified version of a piston and cylinder in an engine. Suppose combustion of fuel injected into the cylinder produces 155 J of energy. The hot gases in the cylinder expand, pushing the piston down and doing 93 J of *P*–*V* work on the piston. If the system is the gases in the cylinder, what is the change in internal energy of the system?

Collect and Organize We are given q and w and asked to calculate ΔE. Are q and w positive or negative according to the sign convention in Figure 6.20?

Analyze The change in internal energy is related to the work done by or on a system and the energy gained or lost by the system (Equation 6.5). The system (gases in the cylinder) absorbs energy by heating, so $q > 0$, and the system does work on the surroundings (the piston), so $w < 0$.

Solve When we substitute values into Equation 6.5, the change in internal energy for the system is

$$\Delta E = q + w = (155\ \text{J}) + (-93\ \text{J}) = 62\ \text{J}$$

Think About It More energy enters the system (155 J) than leaves it (93 J), so a positive value of ΔE is reasonable.

Practice Exercise The piston in Figure 6.21 compresses the air in the cylinder by doing 64 J of work on the gas. As a result, the air gives off 32 J of energy to the surroundings. If the system is the air in the cylinder, what is the change in its internal energy?

SAMPLE EXERCISE 6.4 Calculating *P*–*V* WorkLO3

A tank of compressed helium is used to inflate balloons for sale at a carnival on a day when the atmospheric pressure is 0.99 atm. If each balloon is inflated from an initial volume of 0.0 L to a final volume of 4.8 L, how much *P*–*V* work, in joules, is done on the surrounding atmosphere by 100 balloons when they are inflated?

Collect and Organize Each of the 100 balloons goes from empty ($V = 0.0$ L) to 4.8 L, which means $\Delta V = 4.8$ L, and the atmospheric pressure P is 0.99 atm. Our task is to determine how much $P–V$ work is done by the 100 balloons on the atmosphere surrounding them. To express our answer in units of joules, we will need the conversion factor: $1\ \text{L} \cdot \text{atm} = 101.32\ \text{J}$.

Analyze We focus on the work done on the atmosphere (the surroundings) by the balloons and the helium they contain (the system).

Solve The volume change (ΔV) as all the balloons are inflated is

The work (w) done by the balloons is

Think About It Because work is done *by* the system on its surroundings, the work is negative from the point of view of the system (see Figure 6.20).

Practice Exercise The balloon *Spirit of Freedom* (**Figure 6.22**), flown around the world by American aviator Steve Fossett in 2002, contained 5.50×10^5 cubic feet of helium. How much $P–V$ work was done by the balloon on the surrounding atmosphere while the balloon was being inflated, if we assume that the atmospheric pressure was 1.00 atm? ($1\ \text{m}^3 = 1000\ \text{L} = 35.3\ \text{ft}^3$)

Glossary

system

the part of the universe that is the focus of a thermochemical study.

surroundings

everything that is not part of the system.

isolated system

a system that exchanges neither energy nor matter with the surroundings.

closed system

a system that exchanges energy but not matter with the surroundings.

open system

a system that exchanges both energy and matter with the surroundings.

exothermic process

a thermochemical or physical process in which energy flows from a system into its surroundings.

endothermic process

a thermochemical or physical process in which energy flows from the surroundings into the system.

internal energy (*E*)

the sum of all the kinetic and potential energies of all the components of a system.

first law of thermodynamics

the principle that the energy gained or lost by a system must equal the energy lost or gained by its surroundings.

pressure–volume (*P*–*V*) work

the work associated with the expansion or compression of a gas.

calorie (cal)

the amount of energy necessary to raise the temperature of 1 g of water by 1°C; for example, from 14.5°C to 15.5°C.

joule (J)

the SI unit of energy; 4.184 J = 1 cal.

6.4 Enthalpy and Enthalpy Changes

Many physical and chemical changes occur at constant atmospheric pressure (*P*) because they are done in vessels open to the air. Examples include boiling water for tea or any of the chemical reactions described in Chapter 4. The thermodynamic parameter that relates the flow of energy into or out of a system during chemical reactions or physical changes at constant pressure is called the enthalpy change (ΔH). We symbolize this enthalpy change at constant pressure as q_P, where the subscript P specifies a process taking place at constant pressure. We then rearrange Equation 6.6 to define ΔH as

Thus, the change in enthalpy is the change in the internal energy of the system at constant pressure plus the *P*–*V* work done by the system on its surroundings.

The enthalpy (*H*) of a thermodynamic system is the sum of the internal energy and the pressure–volume product ($H = E + PV$). However, as we saw with internal energy, determining the absolute values of these parameters is difficult, whereas determining *changes* is fairly easy. We therefore concentrate on the *change* in enthalpy (ΔH) of a system or its surroundings. According to Equation 6.7, the enthalpy change for a reaction run at constant pressure is equal to q_P, which is the heat gained or lost by the system during the reaction. This statement also means that the units for ΔH are the same as those for q—namely, enthalpy has units of joules (J), and, if it is reported with respect to the quantity of a substance, J/g or J/mol.

Both ΔH and ΔE represent changes in a state function of a system. These two terms are similar, but the difference between them is important. ΔE includes *all* the energy (heat and work) exchanged by the system with the surroundings: $\Delta E = q + w$. ΔH, on the other hand, is only q, the heat, exchanged at constant pressure: $\Delta H = q_P$. If a chemical reaction does not involve changes in volume, then ΔE and ΔH have very similar values. But if, for example, a reaction consumes or produces gas and the system experiences large changes in volume as a result, then ΔE and ΔH can be quite different.

When energy flows out of a system, q is negative according to our sign convention (Figure 6.20), so the enthalpy change is negative: $\Delta H < 0$. When energy flows into a system, q is positive, so $\Delta H > 0$. As we saw in Section 6.3, positive q values indicate endothermic processes, whereas negative q values indicate exothermic processes. Knowing that, we can relate the terms *exothermic* and *endothermic* to enthalpy changes as well.

For example, the flow of energy into a melting ice cube (the system; **Figure 6.23**) from its surroundings is an endothermic process, meaning that q—and therefore ΔH—are positive. To make ice cubes in a freezer, however, the water (the system) must lose energy, which means the process is exothermic and both q and ΔH are negative. The enthalpy changes for the two processes—melting (fusion) and freezing (solidification)—have different signs but the same absolute value: the enthalpy of fusion (ΔH_{fus}) = 6.01 kJ/mol of ice, but the enthalpy of solidification (ΔH_{solid}) = −6.01 kJ/mol of water. The enthalpies of vaporization and condensation (Figure 6.23) and the enthalpies of sublimation and deposition are similarly paired: equal in magnitude but opposite in sign.

In terms of symbols, we put subscripts on ΔH to clarify not only the specific process but also the part of the universe to which the value applies. If we wish to indicate the enthalpy change associated with the system, we may write ΔH_{sys}.

SAMPLE EXERCISE 6.5 Determining the Value and Sign of ΔH LO4

Between periods of a hockey game, an ice-resurfacing machine (**Figure 6.24**) spreads 855 L of water across the surface of a hockey rink. (a) If the system is the water, what is the sign of ΔH_{sys} as the water freezes? (b) To freeze this volume of water at 0°C, what is the value of ΔH_{sys}? The density of water is 1.00 g/mL. Assume atmospheric pressure is constant.

Collect, Organize, and Analyze We are given the volume and density of the water, and we need to determine the sign and value of ΔH_{sys}. The water from the ice-resurfacing machine is the system, so we can determine the sign of ΔH by determining whether energy transfer is into or out of the water. (a) The freezing takes place at constant pressure, so $\Delta H_{\text{sys}} = q_{\text{P}}$. (b) To calculate the amount of energy lost from the water as it freezes, we must convert 855 L of water into moles of water because the conversion factor between the quantity of energy removed and the quantity of water that freezes is the enthalpy of solidification of water, $\Delta H_{\text{solid}} = -6.01$ kJ/mol.

Solve

1. For the water (the system) to freeze, energy must be removed from it. Therefore, ΔH_{sys} must be a negative value.
2. Converting the volume of water into moles:

$$855\ \cancel{\text{L}} \times \frac{1000\ \cancel{\text{mL}}}{1\ \cancel{\text{L}}} \times \frac{1.00\ \cancel{\text{g}}}{1\ \cancel{\text{mL}}} \times \frac{1\ \text{mol}}{18.02\ \cancel{\text{g}}} = 4.745 \times 10^{4}\ \text{mol}$$

Calculating ΔH_{sys}:

$$\Delta H_{sys} = 4.745 \times 10^4\ \cancel{mol} \times \frac{-6.01\ kJ}{1\ \cancel{mol}} = -2.85 \times 10^5\ kJ$$

Think About It The magnitude of the answer to part (b) is reasonable given the large amount of water that is frozen to refinish the rink's surface.

Practice Exercise The flame in a torch used to cut metal is produced by burning acetylene (C_2H_2) in pure oxygen. If we assume that the combustion of 1 mole of acetylene releases 1251 kJ of energy, what mass of acetylene is needed to cut through a piece of steel if the process requires 5.42×10^4 kJ of energy?

SAMPLE EXERCISE 6.6 The Sign of Δ*H* in a Chemical Reaction LO4

The chemical cold packs (**Figure 6.25**) used to treat minor sports injuries contain a small pouch of water inside a bag of solid ammonium nitrate. To activate the pack, you press on it to rupture the pouch, allowing the ammonium nitrate to dissolve in the water. The result is a cold, aqueous solution of ammonium nitrate. Write a balanced chemical equation describing the dissolution of solid NH_4NO_3. If we define the system as the cold pack and the surroundings as an injured player's sprained ankle (for example), what are the signs of ΔH_{sys} and q_{surr}?

Collect, Organize, and Analyze The solution's temperature drops when we dissolve NH_4NO_3 in water. We want to write a balanced chemical equation for the dissolution of ammonium nitrate and determine the sign of ΔH for the solution (the system) and q_{surr}. The first law of thermodynamics says energy must be conserved, so all the energy must be accounted for between system and surroundings.

Solve According to the solubility rules in Tables 4.4 and 4.5, all ammonium salts are soluble. We can write a balanced chemical equation for the dissolution of NH_4NO_3 as

$NH_4NO_3(s) \rightarrow NH_4^+(aq) + NO_3^-(aq)$

The low temperature of the cold pack (the system) means that heat flows into it from the injured player's sprained ankle). Therefore, the sign of ΔH_{sys} is positive ($\Delta H_{sys} > 0$), and the sign of q_{surr} is negative ($q_{surr} < 0$).

Think About It The first law of thermodynamics dictates that the signs of ΔH_{sys} and q_{surr} are opposite.

Practice Exercise Potassium hydroxide can be used to unclog sink drains. The reaction between potassium hydroxide and water is quite exothermic. What are the signs of ΔH_{sys} and q_{surr}?

Glossary

enthalpy change (ΔH)
the heat absorbed by an endothermic process or given off by an exothermic process occurring at constant pressure.

enthalpy (H)
the sum of the internal energy and the pressure–volume product of a system; $H = E + PV$.

$$\begin{aligned} (2.04\ \text{kJ}/^\circ\text{C})T_{\text{final}} &= -9.26\ \text{kJ} - 83.4\ \text{kJ} + 99.0\ \text{kJ} = 6.34\ \text{kJ} \\ T_{\text{final}} &= 3.1^\circ\text{C} \end{aligned}$$

6.5 Heating Curves, Molar Heat Capacity, and Specific Heat

Many winter hikers use portable stoves fueled by propane to prepare hot meals. Ice or snow may be their only source of water. In this section, we use this scenario to examine the transfer of energy into water that begins as snow and ends up as vapor.

Hot Soup on a Cold Day

What changes of temperature and state does water undergo when hikers melt snow as a first step in preparing soup from a dry soup mix? Suppose they start with a saucepan filled with snow at −18°C at constant pressure. They place the pan above the flame of a portable stove, and energy begins to flow into the snow. The temperature of the snow immediately begins to rise. If the flame is steady, so that energy flow is constant, the temperature of the snow changes as indicated on the graph shown in **Figure 6.26**. First, heating increases the temperature of the snow to its melting point, 0°C. This temperature rise and the energy transfer into the snow are represented by line segment *AB* in Figure 6.26. The temperature of the snow then remains steady at 0°C while the snow continues to absorb energy and melt. This state change that produces liquid water from snow takes place at constant temperature and is represented by the constant-temperature (horizontal) line segment *BC*. Phase changes of pure materials take place at constant temperature and pressure.

When all the snow has melted, the temperature of the liquid water rises (line segment *CD*) until it reaches 100°C. At 100°C, the temperature of the water remains steady while another change of state takes place: liquid water becomes water vapor. This constant-temperature process is represented by line segment *DE*. If all the liquid water in the pan were converted into vapor, the temperature of the vapor would then rise if heat was added, as indicated by the final (slanted) line segment in Figure 6.26.

The difference in the *x*-axis values for the beginning and end of each line segment in Figure 6.26 indicates how much energy is required in each step in this process. In the first step (line segment *AB*), the energy required to raise the temperature of the snow from −18°C to 0°C can be calculated if we know how many moles of snow we have and how much energy is required to change the temperature of 1 mole of snow.

TABLE 6.1 Molar Heat Capacities of Selected Substances at 25°C

Substance	c_p [J/(mol · °C)]
Al(s)	24.4
Cu(s)	24.5

Fe(s) 25.1		
C(s), graphite 8.54		
$CH_3CH_2OH(\ell)$, ethanol 113		
$H_2O(s)$ 37.1		
$H_2O(\ell)$ 75.3		
$H_2O(g)$ 33.6		

Molar heat capacity (c_P) is the quantity of energy required to raise the temperature of 1 *mole* of a substance by 1°C. The symbol we use for molar heat capacity is c_P, where the subscript P again indicates the value for a process taking place at *constant pressure*. Molar heat capacities for several substances are listed in **Table 6.1**. Ice has a molar heat capacity of 37.1 J/(mol · °C) at constant pressure. These units indicate that if we know the number of moles of snow and the temperature change it experiences as we bring it to its melting point, then we can calculate q for the process:

where n is the number of moles of the substance absorbing or releasing energy and ΔT is the temperature change in degrees Celsius.

In addition to molar heat capacity, other measures exist that specify how much energy is required to increase the temperature of a substance, each referring to a specific amount of the substance. For example, some tables of thermodynamic data list values of *specific heat capacity,* or specific heat (c_s), which is the energy required to raise the temperature of 1 *gram* of a substance by 1°C; c_s has units of J/(g · °C). Thus, specific heat is for a specific mass, whereas molar heat capacity is for 1 mole of a substance. Specific heats are useful, for example, when determining temperature changes in bulk materials. We will mostly work with molar heat capacity because 1 mole of any substance contains the same number of particles, whereas 1 gram of different substances will have different numbers of particles. As we saw in Chapters 3 and 4, chemical reactions involve interactions between particles.

Let's assume the hikers decide to cook their meal with 270 g of snow. Dividing that mass by the molar mass of water (18.02 g/mol), we find that they need to melt 15.0 moles of snow. We can use Equation 6.8 to calculate how much energy is needed to raise the temperature of 15.0 moles of $H_2O(s)$ from −18°C to 0°C (line segment *AB*):

This value is positive, which means that the system (the snow) gains energy as it warms up.

The energy absorbed as the snow melts, or *fuses* (line segment *BC* in Figure 6.26), can be calculated using the enthalpy change that takes place as 1 mole of snow melts. This enthalpy change is called the molar enthalpy of fusion (ΔH_{fus}), and the energy absorbed as *n* moles of a substance melts is given by

The molar enthalpy of fusion for water is 6.01 kJ/mol. Using this value and the known number of moles of snow, we get

This value is positive because energy enters the system. It represents the energy needed to overcome the attractive forces between water molecules in the solid as the snow becomes a liquid. No factor for temperature appears in this calculation because state changes of pure substances take place at constant temperature, as the two horizontal line segments in Figure 6.26 indicate. Snow at 0°C becomes liquid water at 0°C.

While the water temperature increases from 0°C to 100°C (line segment *CD*), the relation between temperature and energy absorbed is again defined by Equation 6.8, but this time c_P represents the molar heat capacity of $H_2O(\ell)$, 75.3 J/(mol · °C) (see Table 6.1):

This value is positive because the system takes in energy as its temperature rises.

At this point in our story, our hiker–chefs are ready to make their soup and enjoy a hot meal. However, if they accidentally leave the boiling water unattended, it will eventually vaporize completely. How much heat is needed to boil away all the water in the pot? As line segment *DE* in Figure 6.26 shows, the temperature of the water remains at 100°C until all of it is vaporized. The enthalpy change associated with changing 1 mole of a liquid to a gas is the molar enthalpy of vaporization (ΔH_{vap}), and the quantity of energy absorbed as *n* moles of a substance vaporizes is given by

The molar enthalpy of vaporization for water is 40.67 kJ/mol, so to completely vaporize the water we need an additional 610 kJ of energy:

This value is positive because the system must take in energy to overcome the attractive forces between liquid water molecules and separate them into vapor. Again, no factor for temperature appears because the phase change takes place at constant temperature. Only after all the water has vaporized does its temperature increase above 100°C, along the line above point *E* in Figure 6.26. The molar heat capacity of steam, 33.6 J/(mol · °C) (Table 6.1), is used to calculate the energy required to heat the vapor to any temperature above 100°C.

The c_P values for $H_2O(s)$, $H_2O(\ell)$, and $H_2O(g)$ are different. Nearly all substances have different molar heat capacities in their different physical states.

Notice in Figure 6.26 that line segment *DE*, the phase change from liquid water to water vapor, is much longer than the line segment *BC*, which represents the phase change from solid snow to liquid water. The relative lengths of these lines indicate that the molar enthalpy of vaporization of water (40.67 kJ/mol) is much larger than the molar enthalpy of fusion of snow (6.01 kJ/mol). Why does it take more energy to boil 1 mole of water than to melt 1 mole of snow? The answer is related to the extent to which attractive forces between molecules must be overcome in each process and to the change in the internal energy of the system as energy is added (**Figure 6.27**).

Attractive forces determine both the organization of the molecules in any substance and their relation to their nearest neighbors. In forms of frozen water, like ice and snow, these attractive forces are strong enough to hold the water molecules in place relative to one another. Melting the snow requires overcoming these attractive forces. The energy added to the system at the melting point is sufficient to overcome the attractive forces and change the arrangement (and hence the potential energy).

Intermolecular attractive forces still exist in liquid water, but the energy added at the melting point increases the energy of the molecules and enables them to move with respect to their nearest neighbors. The molecules are closer together in the liquid than they are in the solid, but their relative positions constantly change; they have different nearest neighbors over time.

Once the snow has completely melted, added energy causes the temperature of the liquid water to rise, increasing its internal energy. When water vaporizes at the boiling point, the attractive forces between water molecules must be overcome to separate the molecules from one another as they enter the gas phase. Separating the molecules widely in space requires work (i.e., energy), and the amount required is much larger than that for the solid-to-liquid state change. This difference is consistent with the relative lengths of *BC* and *DE* in Figure 6.26.

SAMPLE EXERCISE 6.7 Calculating the Energy Required to Raise the Temperature of Water LO4

Calculate the amount of energy required to convert 237 g of solid ice at 0.0°C to hot water at 80.0°C. The molar enthalpy of fusion (ΔH_{fus}) of ice is 6.01 kJ/mol. The molar heat capacity of liquid water is 75.3 J/(mol · °C).

Collect, Organize, and Analyze This exercise refers to the process symbolized by segments *BC* and *DE* in **Figure 6.28**. We can calculate the temperature change (ΔT) of the water from the initial and final temperatures. Four mathematical steps are required: (1) calculate n, the number of moles of ice; (2) determine the amount of energy required to melt the ice, using $\Delta H_{\text{fus}} = 6.01$ kJ/mol in Equation 6.9; (3) calculate the amount of energy required to raise the liquid water temperature from 0.0°C to 80.0°C, using $c_{\text{P}} = 75.3$

J/(mol · °C) in Equation 6.8; and (4) add the results of steps (2) and (3). We can calculate the number of moles in 237 g of water by using the molar mass of water ($\mathscr{M} = 18.02$ g/mol).

Solve

1. Calculate the number of moles of water:

$$n = 237\ \cancel{\text{g H}_2\text{O}} \times \frac{1\text{ mol H}_2\text{O}}{18.02\ \cancel{\text{g H}_2\text{O}}} = 13.2\text{ mol H}_2\text{O}$$

2. Determine the amount of energy needed to melt the ice (Equation 6.9):

$$q_1 = n\Delta H_{\text{fus}} = 13.2\ \cancel{\text{mol}} \times 6.01\text{ kJ}/\cancel{\text{mol}} = 79.3\text{ kJ}$$

3. Determine the amount of energy needed to warm the water (Equation 6.8):

$$\begin{aligned} q_2 &= nc_{\text{P}}\Delta T \\ &= 13.2\ \cancel{\text{mol}} \times \frac{75.3\text{ J}}{\cancel{\text{mol}} \cdot \cancel{^\circ\text{C}}} \times (80.0 - 0.0)\cancel{^\circ\text{C}} = 79{,}517\text{ J} = 79.5\text{ kJ} \end{aligned}$$

4. Add the results of parts 2 and 3:

$$q_1 + q_2 = 79.3\text{ kJ} + 79.5\text{ kJ} = 158.8\text{ kJ}$$

Think About It Using the definitions of molar enthalpy of fusion and molar heat capacity, we can also think our way through the solution to this exercise without referring to Equations 6.8 and 6.9. Molar enthalpy of fusion defines the amount of energy needed to melt 1 mole of ice. Multiplying that value (6.01 kJ/mol) by the number of moles (13.2 mol) gives us the energy required to melt the given amount of ice. By the same token, the molar heat capacity of water [75.3 J/ (mol · °C)] defines the amount of energy needed to raise the temperature of 1 mole of liquid water by 1°C. We know the number of moles (13.2 mol), and we know the number of degrees by which we want to raise the temperature (80.0°C − 0.00°C = 80.0°C); multiplying those factors together gives us the energy needed to raise the temperature of the water.

Practice Exercise Calculate the change in energy when 125 g of water vapor at 100.0°C condenses to liquid water and then cools to 25.0°C.

Water is an extraordinary substance for many reasons, one of which is its high molar heat capacity. The ability of water to absorb large quantities of thermal energy is one reason it is used as a *heat sink* both in automobile radiators and in our bodies. The term “heat sink” is often used to identify matter that can absorb energy without changing phase or significantly changing its temperature. Weather and climate changes are largely driven and regulated by cycles involving retention of energy by our planet’s oceans, which serve as giant heat sinks for solar energy.

Cold Drinks on a Hot Day

Suppose we throw a party and plan to chill three cases (72 aluminum cans, each containing 355 mL) of beverages by placing the cans in an insulated cooler and covering them with ice cubes (**Figure 6.29**). If the temperature of the ice (sold in 10-pound bags) is −8.0°C and the temperature of the beverages is initially 25.0°C, how many bags of ice do we need to chill the cans and their contents to 0.0°C (as in “ice cold”)?

You may already have an idea that more than one bag, but probably fewer than ten, will be needed. We can use the energy transfer relationships we have defined to predict more accurately how much ice is required. In doing so, we assume that whatever energy is absorbed by the ice is lost by the cans and the beverages in them. As the ice absorbs energy from the cans and the beverages, the temperature of the ice increases from −8.0°C to 0.0°C, and, as we saw in analyzing Figure 6.26, the resulting liquid water remains at 0.0°C until all the ice has melted. We need enough ice so that the last of it melts just as the temperature of the beverages and the cans reaches 0.0°C. Our analysis of this cooling process is a little simpler than our snow/liquid water/water vapor analysis because here there is no change of state. All the energy transferred goes only into cooling the cans and beverages to 0.0°C. The cans stay in the solid state, and the beverages stay in the liquid state.

First let's consider the energy lost in the cooling process. Two materials are to be chilled: 72 aluminum cans and 72 × 355 mL = 25,600 mL of beverages. The beverages are mostly water. The other ingredients in the beverages are present in such small concentrations that they will not affect our calculations, so we can assume that we need to reduce the temperature of 25,600 mL of water by 25.0°C. We can calculate the amount of energy lost with Equation 6.8 if we first calculate the number of moles of water in 25,600 mL, assuming a density of 1.000 g/mL:

We can use the molar heat capacity of water and Equation 6.8 to calculate the energy lost by 1420 moles of water as its temperature decreases from 25.0°C to 0.0°C:

We must also consider the energy released in lowering the temperature of 72 aluminum cans by 25.0°C. The typical mass of a soda can is 12.5 g. The molar heat capacity of solid aluminum (Table 6.1) is 24.4 J/ (mol · °C), and the molar mass of aluminum is 26.98 g/mol. Thus,

The total quantity of energy that must be removed from the cans and beverages is

This quantity of energy must be absorbed by the ice as it warms to its melting point and then melts. The calculation of the amount of ice needed is an algebra problem. Let *n* be the number of moles of ice needed. The energy absorbed is the sum of (1) the energy needed to raise the temperature of *n* moles of ice from −8.0° to 0.0°C and (2) the energy needed to melt *n* moles of ice. These quantities can be calculated with Equation 6.8 for step 1 and Equation 6.9 for step 2. The c_P values in Table 6.1 have units of joules, whereas ΔH_{fus} values given earlier have units of kilojoules. We need to have both terms in the same units, so we use 0.0371 kJ/(mol · °C) for c_P:

The energy lost by the cans and the beverages balances the energy gained by the ice:

Converting 4.26×10^2 mol of ice into pounds gives us

Thus, we need at least two 10-pound bags of ice to chill three cases of our favorite beverages.

CONCEPT TEST

The energy lost by the beverages inside the 72 cans in the preceding discussion was more than 100 times the energy lost by the aluminum cans themselves. What factors contributed to this large difference between the energy lost by the cans and the energy lost by their contents?

SAMPLE EXERCISE 6.8 Calculating the Temperature of Iced Tea LO4

If you add 250.0 g of ice, initially at −18.0°C, to a cup (237 g) of freshly brewed tea, initially at 100.0°C, and all the ice melts, what is the final temperature of the tea? Assume that the mixture is an isolated system (in an ideal insulated container) and that tea has the same molar heat capacity, density, and molar mass as water.

Collect and Organize We know the mass of the tea, its initial temperature, and the molar heat capacity of tea, for which we use the c_P value for water. We know the amount of ice, its initial temperature, and the molar enthalpy of fusion of ice. Our task is to find the final temperature of the tea–ice-water mixture.

Analyze The amount of energy released when the tea is cooled will be the same as the amount of energy gained by the ice and, once it is melted, the amount gained by the water that is formed as it warms to the final temperature. If we assume that the ice melts completely, the tea loses energy through three processes:

1. q_1: raising the temperature of the ice to 0.0°C
2. q_2: melting the ice
3. q_3: bringing the mixture to the final temperature; the temperature of the water from the melted ice rises and the temperature of the tea ($T_{\text{initial}} = 100.0°\text{C}$) falls to the final temperature of the mixture ($T_{\text{final}} = ?$)

The energy gained by the ice (and ice melt) equals the energy lost by the tea:

$$q_{\text{ice}} = -q_{\text{tea}}$$

From our analysis, we know that

$$q_{\text{ice}} = q_1 + q_2 + q_3$$

Solve The energy lost by the tea as it cools from 100.0°C to T_{final} is, from Equation 6.8,

The transfer of this energy is responsible for the changes in the ice. We can treat the energy transfer from the hot tea to the ice in terms of the three processes we identified in the Analyze step. In step 1, the ice is warmed from $-18.0°\text{C}$ (T_{initial}) to 0.0°C (T_{final} for this step):

In step 2, the ice melts, requiring the absorption of energy:

In step 3, the water from the ice, initially at 0.0°C, warms to the final temperature (where $\Delta T = T_{\text{final}} - T_{\text{initial}} = T_{\text{final}} - 0.0°\text{C}$):

The sum of the quantities of energy absorbed by the ice and the water from it during steps 1 through 3 must balance the energy lost by the tea:

$q_{\text{ice}} = q_1 + q_2 + q_3 = -q_{\text{tea}}$

$9.26\ \text{kJ} + 83.4\ \text{kJ} + (1.045\ \text{kJ/°C})(T_{\text{final}}) = -[(0.990\ \text{kJ/°C})(T_{\text{final}} - 100.0\text{°C})]$

Rearranging the terms to solve for T_{final}, we have

Think About It This calculation was carried out under the assumption that the system (the tea plus the ice) was isolated and the vessel was a perfect insulator. Our answer, therefore, is an “ideal” answer and reflects the coldest temperature we can expect the tea to reach. In the real world, the ice would absorb some energy from the surroundings (the container and the air) and the tea would lose some energy to the surroundings, so the final temperature of the beverage could be different from the ideal value we calculated.

Practice Exercise Calculate the final temperature of a mixture of 350 g of ice, initially at −18.0°C, and 437 g of water, initially at 100.0°C.

Glossary

molar heat capacity (c_P)	the quantity of energy required to raise the temperature of 1 mole of a substance by 1°C at constant pressure.
specific heat (c_s)	the quantity of energy required to raise the temperature of 1 g of a substance by 1°C at constant pressure.
molar enthalpy of fusion (ΔH_{fus})	the energy required to convert 1 mole of a solid substance at its melting point into the liquid state.
molar enthalpy of vaporization (ΔH_{vap})	

the energy required to convert 1 mole of a liquid substance at its boiling point to the vapor state.

A thermometer enables us to observe the temperature of the contents, which we can agitate using a simple stirrer to ensure mixing of solutions. (a) The inside cup contains 25 mL of 1.0 *M* HCl. (b) The rapid addition of 25 mL of 1.0 *M* NaOH causes the temperature to rise because energy is given off in the ensuing neutralization reaction.

$$q_{H_2O} = n_{H_2O} c_P \Delta T$$

$$n_{H_2O} = 50.0\ \cancel{\text{mL H}_2\text{O}} \times \frac{1.00\ \cancel{\text{g H}_2\text{O}}}{1\ \cancel{\text{mL H}_2\text{O}}} \times \frac{1.00\ \text{mol H}_2\text{O}}{18.02\ \cancel{\text{g H}_2\text{O}}} = 2.77\ \text{mol H}_2\text{O}$$

$$q_{H_2O} = n_{H_2O} c_P \Delta T = (2.77\ \cancel{\text{mol H}_2\text{O}}) \times \left(\frac{75.3\ \text{J}}{1\ \cancel{\text{mol H}_2\text{O}} \cdot \cancel{°\text{C}}}\right) \times (25.0\cancel{°\text{C}} - 18.5\cancel{°\text{C}})$$

$$= 1356\ \text{J}$$

$$\Delta H_{rxn} = \frac{-1.356\ \text{kJ}}{0.025\ \text{mol HCl}} = -54\ \text{kJ/mol}$$

6.6 Calorimetry: Measuring Heat Capacity and Enthalpies

# of Reaction

Up to this point we have discussed molar heat capacities (c_P) and the enthalpy changes (ΔH_{fus} and ΔH_{vap}) associated with phase changes, but we have not broached the issue of how we know the values of these parameters. The experimental method of measuring the quantities of energy associated with chemical reactions and physical changes is called calorimetry. The device used to measure the energy released or absorbed during a process is a calorimeter.

Determining Molar Heat Capacity and Specific Heat

When we determined the amount of ice needed to cool 72 aluminum cans of beverage in Section 6.5, we used the molar heat capacity of aluminum to determine how much energy was lost by the cans. How are molar heat capacities determined?

We can apply the first law of thermodynamics to determine the specific heat of aluminum. Recall from Section 6.5 that specific heat c_s is defined as the quantity of energy required to raise the temperature of 1 g of a substance by 1°C. The units of specific heat, J/(g · °C), tell us that we need to determine how much energy it takes to raise or lower the temperature of a mass of aluminum from initial to final temperatures that we can also measure accurately. Suppose we employ the strategy of heating a quantity of Al beads and then using the hot beads to raise the temperature of a known quantity of water from initial to final temperatures that we can measure accurately.

We start by transferring 23.5 g of Al beads to a glass test tube and placing the test tube in a bath of boiling water (**Figure 6.30a**). After several minutes the beads have been warmed to the temperature of the boiling water: 100.0°C. While the metal is warming, 130.0 g of water in a beaker are placed in a Styrofoam box (**Figure 6.30b**), which we will assume effectively insulates its contents from their surroundings. A thermometer allows us to monitor the temperature of the water, which initially is 23.1°C. Next, we remove the test tube containing the Al beads from the boiling water, remove the lid of the insulated box, pour the hot beads into the water in the beaker, and quickly close the lid (**Figure 6.30c**). The hot beads warm the temperature of the water to 26.0°C, producing a change in the temperature of the water in the beaker of $\Delta T_{\text{water}} = 26.0^\circ\text{C} - 23.1^\circ\text{C} = 2.9^\circ\text{C}$, while the temperature of the aluminum beads changes by $\Delta T_{\text{Al}} = 26.0^\circ\text{C} - 100.0^\circ\text{C} = -74.0^\circ\text{C}$.

The measured temperatures were the result of energy transferred from the aluminum beads to the water in the beaker. According to the first law of thermodynamics, the energy lost by the beads and the energy gained by the water are equal in magnitude but opposite in sign:

$$-q_{\text{Al}} = q_{\text{water}}$$

To determine how much energy was lost by the aluminum, we first calculate how much energy was gained by the water. We know the mass of water (130.0 g), its temperature change (2.9°C), and the specific heat of water (see Section 6.3):

We can combine these three values using an equation like Equation 6.8 but based on mass rather than moles:

Inserting the measured values and $c_{\text{s,water}}$:

To find the specific heat of aluminum, we use Equation 6.11 for aluminum and the fact that the energy that increased the temperature of the water came from the aluminum beads. Therefore,

$$q_{\text{Al}} = -q_{\text{water}} = -1.57 \times 10^3\ \text{J} = mc_{\text{s,Al}}\Delta T_{\text{Al}} = (23.5\ \text{g Al})(c_{\text{s,Al}})(-74.0^\circ\text{C})$$

Solving for $c_{\text{s,Al}}$:

From this specific heat value, we can also calculate the molar heat capacity of aluminum, $c_{P,Al}$, by multiplying $c_{s,Al}$ by the molar mass of aluminum:

SAMPLE EXERCISE 6.9 Determining the Specific Heat of a Metal LO4

Brass is the name of an alloy (homogenous mixture of metals) that contains mostly copper and zinc and only minor concentrations of other metals. A 50.0 g sample of brass is heated to 115°C in a labware drying oven and then immersed in 50.0 g H_2O ($T_{initial}$ = 21.4°C) in a beaker housed in an insulated apparatus like that shown in Figure 6.30. The temperature of the H_2O increases to 29.2°C. What is the specific heat of the brass sample?

Collect and Organize We are given the masses and initial and final temperatures of samples of brass and water. We are asked to use these data to calculate the specific heat of the brass sample. The specific heat of water is 4.184 J/g · °C. Equation 6.11, $q = mc_s\Delta T$, relates energy that must be transferred to an object of mass m to raise its temperature by ΔT to the specific heat of the object.

Analyze Following the approach described in the prior discussion to calculate the specific heat of aluminum, we should first calculate the quantity of energy absorbed by the water (q_{water}) using Equation 6.11. This q_{water} value is equal in magnitude but opposite in sign to the energy lost by the brass sample: $q_{water} = -q_{brass}$. We can use m_{brass} and the calculated values of ΔT_{brass} and q_{brass} to calculate $c_{s,brass}$ using Equation 6.11. The masses of the brass and water samples are the same, but the final temperature of the two samples in thermal equilibrium with each other is only about 8°C from the initial water temperature and about 86°C from the initial brass temperature, which means $c_{s,brass}$ is likely to be about $0.1 \times c_{s,water}$ or about 0.4 J/g · °C.

Solve Calculating the energy absorbed by the water sample:

Relating q_{water} to q_{brass} and solving for $c_{s,brass}$

Think About It As predicted, the specific heat of brass is about one-tenth the specific heat of water. This value also makes sense because the molar heat capacity of water in Table 6.1 is about 3.1 times that of copper (75.3/24.5), which is the principal component of brass. This factor coupled with the ratio of their molar masses, 64 g/mol for Cu and 18 g/mol for H_2O, or 3.6, means that the ratio of heat capacities expressed per gram, that is, specific heat values of water and of an alloy that is mostly Cu, should be about 3.1×3.6 or about 11, which matches the ratio obtained using the calculated $c_{s,\text{brass}}$ value: $4.184/0.38 = 11$. Note that only two digits are used to express the value of $c_{s,\text{brass}}$ because that is the number of significant figures in the value of ΔT_{water} that was used in its calculation.

Practice Exercise A student adds 2.55 g of glass beads to a round bottom flask to promote the even boiling of a liquid in the flask. If the specific heat of the glass is 0.83 J/g · °C, how much additional energy is required to raise the temperature of the flask and its contents from 22.5°C to the boiling point of the liquid at 78.4°C?

Enthalpies of Reaction

The energy transfer accompanying any chemical reaction is defined by a quantity known as the enthalpy of reaction (ΔH_{rxn}), also called the *heat of reaction*. The "rxn" subscript may be changed to reflect a specific type of reaction being studied, such as ΔH_{comb} for the enthalpy of a combustion reaction.

Much of the energy we use every day can be traced to combustion of a fuel such as natural gas (mostly methane, CH_4), propane (C_3H_8), or gasoline (a mixture of hydrocarbons). Our bodies obtain energy from respiration, which is essentially the combustion of glucose ($C_6H_{12}O_6$). We have already written balanced chemical equations for the combustion of CH_4, C_3H_8, and $C_6H_{12}O_6$ in

Chapter 3. Now let's consider thermochemical equations for these processes by adding to them their ΔH_{comb} values:

All three of these reactions are *exothermic* in the forward direction, so the enthalpy change for each reaction is less than zero: $\Delta H_{\text{rxn}} < 0$.

Knowing ΔH_{comb} values allows us to compare fuels and to calculate how much fuel is needed to supply a desired quantity of energy. For example, we can calculate how much propane we need to melt the 270 g (15.0 mol) of snow in Figure 6.26 and raise its temperature to 100°C. In the beginning of Section 6.5, we calculated that the energy required to melt this much snow is 113 kJ. If we get 2220 kJ/mol C_3H_8, then we need to burn at least 2.24 g of C_3H_8:

How much energy would we get from burning 2.24 g of glucose? Converting the mass of glucose to moles and multiplying by ΔH_{comb}:

Enthalpies of combustion are best measured with a device called a bomb calorimeter (**Figure 6.31**). To measure the enthalpy of a combustion reaction, the sample is placed in a sealed vessel (called a *bomb*) capable of withstanding high pressures and submerged in a large volume of water in a heavily insulated container. Oxygen is introduced into the bomb, and the mixture is ignited with an electric spark. As combustion occurs, energy generated by the reaction flows into the walls of the bomb and then into the water surrounding the bomb. A good bomb calorimeter keeps the system contained within the bomb and ensures that all energy generated by the reaction stays in the calorimeter. The surroundings consist of the bomb, the water, the insulated container, and minor components (stirrer, thermometer, and any other materials). A bomb calorimeter is a more sophisticated version of the calorimeter shown in Figure 6.30.

The energy produced by the reaction is determined by measuring the temperature of the water before and after the reaction. The water is at the same temperature as the parts of the calorimeter it contacts—the walls of the bomb, the thermometer, and the stirrer—so the temperature change of the water takes the entire calorimeter into account.

Measuring the change in temperature of the water is not the whole story, however. We also need to know the heat capacity (C_P) of the calorimeter, which is the quantity of energy required to increase its temperature by 1°C at constant pressure. There is an important difference between heat capacity and specific heat (c_s) and molar heat capacity (c_P). *Specific heat* [J/(g · °C)] is the energy required to raise the temperature of 1 *gram* of a substance by 1°C, and *molar heat capacity* [J/(mol · °C)] is the energy required to raise the temperature of 1 *mole* of a substance by 1°C. Thus, specific heat and molar heat capacity are intensive properties of substances. However, heat capacity is an extensive property of an object, such as a calorimeter. The heat capacity of a calorimeter is also referred to as a calorimeter constant ($C_{\text{calorimeter}}$) and has units of J/°C. If we know a calorimeter's $C_{\text{calorimeter}}$ value and if we can measure its change in temperature, we can calculate the quantity of energy that flowed from the reactants into the calorimeter ($q_{\text{calorimeter}}$) and caused the temperature change:

Rearranging terms:

Thus, heat capacity is expressed in units of energy divided by temperature—usually kilojoules per degree Celsius (kJ/°C).

Equation 6.13 can be used to determine $C_{\text{calorimeter}}$ for a bomb calorimeter. To do this, we burn a quantity of material in the calorimeter that produces a known quantity of energy when it burns—in other words, a material whose ΔH_{comb} value is already known. Benzoic acid ($C_7H_6O_2$) is often used for this purpose because it can be obtained in a very pure form. Once $C_{\text{calorimeter}}$ has been determined, the calorimeter can be used to determine ΔH_{comb} for other substances. The observed increases in water temperature can be used to calculate the quantities of energy produced by combustion reactions on a per-gram or per-mole basis.

Because there is no change in the volume of the reaction mixture in a bomb calorimeter, this technique is referred to as *constant-volume calorimetry*. No *P–V* work is done, so Equation 6.6:

$$\Delta E_{\text{comb}} = q_{\text{comb}} - P\Delta V_{\text{comb}}$$

is simply

$$\Delta E_{\text{comb}} = q_{\text{comb}}$$

The energy gained by the calorimeter, $q_{\text{calorimeter}}$, equals the energy lost by the combustion reaction system: $-q_{\text{ccomb}}$. Therefore,

---

The pressure inside a bomb calorimeter can change during combustion reactions, and in such cases ΔE_{comb} is not *exactly* the same as ΔH_{comb}. However, the overall pressure change after thermal equilibrium has been achieved is usually so small that ΔE_{comb} is *nearly* the same as ΔH_{comb}. Hence, we discuss enthalpies of reactions (ΔH_{rxn}) throughout and apply the approximate relation:

$$q_{\text{calorimeter}} = -\Delta H_{\text{comb}}$$

or more generally

Other types of calorimeters allow the volume to change while the pressure remains constant, so $q_{\text{calorimeter}}$ in those cases *is* the same as the enthalpy of reaction (ΔH_{rxn}).

SAMPLE EXERCISE 6.10 Determining a Calorimeter Constant and the Value of ΔH_{rxn}LO5

1. What is the calorimeter constant of a bomb calorimeter if burning 1.000 g of benzoic acid in it causes the temperature of the calorimeter to rise by 7.248°C? The enthalpy of combustion of benzoic acid is $\Delta H_{\text{comb}} = -26.38\ \text{kJ/g}$.
2. When 0.500 g of a mixture of hydrocarbons is burned in this bomb calorimeter, the calorimeter’s temperature increases by 6.76°C. What change in enthalpy occurs during the combustion reaction?

3. c. What is ΔH_{comb} for this reaction in kJ/g?

Collect and Organize We are asked to find the heat capacity (calorimeter constant) of a calorimeter based on how much the temperature of the calorimeter increases when a known amount of benzoic acid is burned in it, and then use the calorimeter constant to determine the enthalpy change that accompanies a combustion reaction.

Analyze (a) We need to determine the amount of energy required to raise the temperature of the calorimeter by 1°C. The heat capacity of a calorimeter can be calculated using Equation 6.13 and the knowledge that the combustion of 1.000 g of benzoic acid produces 26.38 kJ of heat. (b) Once we have determined the calorimeter constant, we can combine Equations 6.12 and 6.15 to calculate the enthalpy change that occurs during the combustion reaction. (c) The value of the enthalpy of reaction expressed in kJ/g should be twice the enthalpy change that accompanied the combustion of 0.500 g in part (b).

Solve

1. $$C_{\text{calorimeter}} = \frac{q_{\text{calorimeter}}}{\Delta T} = \frac{26.38\ \text{kJ}}{7.248^\circ\text{C}} = 3.640\ \text{kJ/}^\circ\text{C}$$

2. Determining the enthalpy change during the combustion of the hydrocarbon mixture:
$$\begin{aligned}\Delta H_{\text{rxn}} = -q_{\text{calorimeter}} &= -C_{\text{calorimeter}}\Delta T \\ &= -\frac{3.640\ \text{kJ}}{\cancel{^\circ\text{C}}}(6.76\ \cancel{^\circ\text{C}}) \\ &= -24.6\ \text{kJ}\end{aligned}$$

3. Doubling the ΔH value from part (b):
$$\Delta H_{\text{comb}}\ (\text{kJ/g}) = 2 \times \Delta H_{\text{rxn}} = 2 \times -24.6\ \text{kJ} = -49.2\ \text{kJ/g}$$

Think About It The calorimeter constant is determined for a specific calorimeter. Using the calorimeter constant to determine ΔH_{rxn} values assumes that the constant does not change as the calorimeter is used. However, it makes sense that any alteration that could change its thermal mass, such as replacing a broken temperature sensor or refilling the water jacket surrounding the bomb, would require recalibrating the instrument, that is, determining a new calorimeter constant value (or confirming that it has not changed.)

Practice Exercise After two semesters of use in a university laboratory, a laboratory instructor replaces the water in a bomb calorimeter. Burning 1.000 g of benzoic acid in the calorimeter causes its temperature to rise by 6.009°C. What is the value of $C_{\text{calorimeter}}$? To check the accuracy of $C_{\text{calorimeter}}$, 0.500 g of graphite is burned in the calorimeter and its temperature rises 3.73°C. How much energy (in kilojoules) is released during the combustion reaction?

Calorimetry can be used to measure ΔH_{rxn} for other chemical reactions, such as the neutralization reactions discussed in Chapter 4. A simple laboratory apparatus for measuring the heat of reaction between a strong acid and a strong base is shown in **Figure 6.32**. A nested pair of Styrofoam coffee cups acts as our calorimeter, much like the apparatus in Figure 6.30. The pressure remains constant in this kind of coffee-cup calorimeter, so q_{rxn} will be the same as the enthalpy of reaction (ΔH_{rxn}).

Suppose we place 25.0 mL of 1.0 *M* aqueous HCl in the coffee cup and its temperature is 18.5°C. Rapid addition of 25.0 mL of 1.0 *M* NaOH causes the temperature to rise to 25.0°C. What is ΔH_{rxn} for the reaction? (This is the reaction depicted in the Particulate Review on the first page of this chapter.)

$$\text{HCl}(aq) + \text{NaOH}(aq) \rightarrow \text{NaCl}(aq) + \text{H}_2\text{O}(\ell)$$

The rise in temperature is the result of energy flowing from the reaction (the system) to the water (the surroundings). The amount of heat, q, gained by the surroundings is

First, we need to calculate the moles of water, using the density of H_2O as a reasonable approximation of the density of the solution:

The total volume of the solution is 50.0 mL because we have mixed two 25.0 mL solutions in our calorimeter. Substituting ${}^{n}H_2O$ and the values of c_P and ΔT,

The heat gained by the surroundings must equal the heat lost by the system,

$q_{H2O} = -q_{rxn} = -1356\text{J} = 1.356 \text{ kJ}$

Because 25.0 mL of 1.0 *M* HCl contains 0.025 mol of HCl,

In this experiment we made three important assumptions:

1. The coffee cup does not absorb any of the heat generated by the reaction.
2. The densities of the relatively dilute solutions are the same as that of pure water.
3. The molar heat capacity of the solution is the same as that of pure water.

These assumptions are reasonably valid for our example, but they would not be in cases where the concentrations of the solutions are substantially higher. Calorimeters suitable for accurate determination of ΔH_{rxn} are commercially available.

SAMPLE EXERCISE 6.11 Coffee-Cup Calorimetry: ΔH_{soln} of NH_4NO_3LO5

Dissolving 80.0 g of NH_4NO_3 in 505 g of water in a coffee-cup calorimeter causes the temperature of the water to decrease by 13.3°C. What is the enthalpy change that accompanies the dissolution process, ΔH_{soln}, expressed in kJ/mol?

Collect and Organize We are given the masses of solute and solvent used to prepare a solution of ammonium nitrate. The temperature decreases by 13.3°C. We need to determine the value of ΔH_{soln}.

Analyze Ammonium nitrate is the system, and water represents its surroundings.

1. First, we use $q = nc_{\text{P}}\Delta T$ (Equation 6.8) to find q_{surr}.
2. Then we use the relationship $q_{\text{sys}} = -q_{\text{surr}}$ to obtain q_{sys}.
3. Finally, we calculate ΔH_{soln} by dividing q_{sys} by the number of moles of NH_4NO_3.

Solve

1. The number of moles of water is

$$505\ \cancel{\text{g H}_2\text{O}} \times \frac{1\ \text{mol H}_2\text{O}}{18.02\ \cancel{\text{g H}_2\text{O}}} = 28.0\ \text{mol H}_2\text{O}$$

The heat lost by the water, q_{surr}, is

$$q_{\text{surr}} = n_{\text{H}_2\text{O}}c_{\text{P,H}_2\text{O}}\Delta T = 28.0\ \cancel{\text{mol H}_2\text{O}} \times \frac{75.3\ \text{J}}{\cancel{\text{mol H}_2\text{O}} \cdot \cancel{^\circ\text{C}}} \times (-13.3\cancel{^\circ\text{C}}) = -2.80 \times 10^4\ \text{J}$$

2. The heat gained by the system, q_{sys}, is

$$q_{\text{sys}} = -q_{\text{surr}} = -(-2.80 \times 10^4\ \text{J}) = 2.80 \times 10^4\ \text{J}$$

3. The number of moles of NH_4NO_3 (the system) is

$$80.0\ \cancel{\text{g NH}_4\text{NO}_3} \times \frac{1\ \text{mol NH}_4\text{NO}_3}{80.05\ \cancel{\text{g NH}_4\text{NO}_3}} = 0.999\ \text{mol NH}_4\text{NO}_3$$

and the enthalpy of solution of NH_4NO_3 is

$$\begin{aligned}\Delta H_{\text{soln}} &= \frac{q_{\text{sys}}}{n_{\text{NH}_4\text{NO}_3}} = \frac{2.80 \times 10^4\ \text{J}}{0.999\ \text{mol NH}_4\text{NO}_3} = 2.81 \times 10^4\ \text{J/mol NH}_4\text{NO}_3\\ &= 28.1\ \text{kJ/mol NH}_4\text{NO}_3\end{aligned}$$

Think About It The value for ΔH_{soln}, 28.1 kJ/mol, is positive, which is consistent with the use of ammonium nitrate in chemical cold packs.

Practice Exercise Addition of 114 g of potassium fluoride to 0.600 L of water (d = 1.00 g/mL) causes the temperature to rise by 3.6°C. What is ΔH_{soln} for KF?

Glossary

calorimetry

the measurement of the quantity of energy transferred during a physical change or chemical process.

calorimeter

a device used to measure the absorption or release of energy by a physical change or chemical process.

enthalpy of reaction (ΔH_{rxn})

the energy absorbed or given off by a chemical reaction under conditions of constant pressure; also called *heat of reaction*.

thermochemical equation

the chemical equation of a reaction that includes the change in enthalpy that accompanies that reaction.

bomb calorimeter

a constant-volume device used to measure the energy released during a combustion reaction.

heat capacity (C_P)

the quantity of energy needed to raise the temperature of an object by 1°C at constant pressure.

calorimeter constant ($C_{\text{calorimeter}}$)

the heat capacity of a calorimeter.

Learning Objectives

- Calculate the energy changes associated with physical and chemical processes **Return to Sample Exercises 6.5, 6.6, 6.7, 6.8, 6.9**

- Calculate thermochemical values by using data from calorimetry experiments **Return to Sample Exercises 6.10, 6.11**

- Calculate thermochemical values by using data from calorimetry experiments **Return to Sample Exercises 6.10, 6.11**

$$\mathrm{C_6H_{12}O_6}(s) + 2\,\mathrm{H_2O}(\ell) \rightarrow$$
$$2\,\mathrm{CH_3CO_2H}(\ell) + 4\,\mathrm{H_2}(g) + 2\,\mathrm{CO_2}(g) \qquad \Delta H_1 = +90\text{ kJ} \qquad (6.16)$$

$$\text{A:}\quad \text{maltose}(s) + \cancel{\mathrm{H_2O}(\ell)} \rightarrow \cancel{2\text{ glucose}(s)} \qquad \Delta H_{\mathrm{A}}$$
$$-(2 \times \text{B}):\quad \cancel{2\text{ glucose}(s)} + 12\,\mathrm{O_2}(g) \rightarrow 12\,\mathrm{CO_2}(g) + \overset{11}{\cancel{12}}\,\mathrm{H_2O}(\ell) \qquad -2\Delta H_{\mathrm{B}}$$

$$\text{C:}\quad \text{maltose}(s) + 12\,\mathrm{O_2}(g) \rightarrow 12\,\mathrm{CO_2}(g) + 11\,\mathrm{H_2O}(\ell) \qquad \Delta H_{\mathrm{C}}$$

$$2 \times \text{B:}\quad 2\,\mathrm{CH_4}(g) + \overset{3}{\cancel{4}}\,\mathrm{O_2}(g) \rightarrow \cancel{2\,\mathrm{CO_2}(g)} + 4\,\mathrm{H_2O}(g) \qquad 2\Delta H_{\mathrm{B}} = -1604\text{ kJ}$$
$$\text{C (reversed):}\quad \cancel{2\,\mathrm{CO_2}(g)} \rightarrow 2\,\mathrm{CO}(g) + \cancel{\mathrm{O_2}(g)} \qquad -\Delta H_{\mathrm{C}} = 566\text{ kJ}$$

$$\text{A:}\quad 2\,\mathrm{CH_4}(g) + 3\,\mathrm{O_2}(g) \rightarrow 2\,\mathrm{CO}(g) + 4\,\mathrm{H_2O}(g) \qquad \Delta H_{\mathrm{A}} = -1038\text{ kJ}$$

6.7 Hess's Law

Most organisms rely on glucose as a fuel for their bodies, but not all of them produce CO_2 and water as the only products. The natural world abounds in organisms that metabolize glucose in different ways. For example, some anaerobic bacteria convert glucose to carbon dioxide, acetic acid, and hydrogen in a reaction that has an enthalpy of reaction of $+90$ kJ:

Methanosarcina, a strain of bacteria, converts acetic acid to methane (CH_4) in a reaction that has an enthalpy of reaction of $+16$ kJ:

In a world where fuel supplies are short, could we use these two reactions to prepare methane and hydrogen, two useful fuels? In principle, we can write an overall reaction equation that results from adding the reactions in Equations 6.16 (step 1) and 6.17 (step 2). However, doing so requires that we multiply Equation 6.17 by 2 to balance the production of acetic acid in step 1 with its consumption in step 2.

After simplifying, we obtain the reaction in Equation 6.18: the conversion of glucose to methane, hydrogen, and carbon dioxide (step 3). Just as we obtain the overall chemical equation 3 by adding equations 1 and 2, we obtain the enthalpy of reaction for the overall reaction by adding the ΔH values for reactions 1 and 2. Since we multiplied Equation 6.17 by 2 before adding it to Equation 6.16, we also need to multiply ΔH_2 by 2. The thermochemical equation for the overall reaction is therefore

This calculation for ΔH_{rxn} is an application of Hess's law. Also known as *Hess's law of constant heat of summation*, it states that the enthalpy of reaction ΔH_{rxn} for a process that is the sum of two or more other reactions is equal to the sum of the ΔH_{rxn} values of the constituent reactions.

Hess's law is especially useful for calculating enthalpy changes that are difficult to measure directly. For example, CO_2 is the principal product of the combustion of carbon in the form of charcoal:

Reaction A: $C(s) + O_2(g) \rightarrow CO_2(g) \quad \Delta H_{comb} = -393.5\ kJ$

When the oxygen supply is limited, however, the products include carbon monoxide:

It is difficult to measure the enthalpy of combustion of this reaction directly because, as long as any oxygen is present, some of the $CO(g)$ formed reacts with the O_2 to form $CO_2(g)$, yielding a mixture of CO and CO_2 as the product. However, we can use Hess's law to obtain this value *indirectly* by working with ΔH_{comb} values that we can measure.

Because we can run reaction A with excess oxygen and thereby force it to completion, we can measure the enthalpy of combustion, which is -393.5 kJ. We can also react a sample of pure $CO(g)$ with oxygen and measure ΔH_{comb} for that reaction:

Hess's law gives us a way to calculate ΔH_{comb} for reaction B from the measured values for reactions A and C. To do this, we must find a way to combine the equations for reactions A and C so that the sum equals reaction B. Once we have that combination, we can calculate the ΔH_{comb} value we do not know from the two that we do.

One approach to this analysis is to focus on the reactants and products in the reaction whose ΔH_{comb} value is unknown—reaction B in this example. This reaction has carbon and oxygen as reactants and carbon monoxide as a product. Reaction C has carbon monoxide as a reactant. If we add reaction C to reaction B, the carbon monoxide cancels out, and we end up with reaction A as the sum of C and B:

We now use algebra to find ΔH_{comb} for reaction B:

ΔH is a state function, so we can manipulate equations in two important ways when applying Hess's law, should the need arise. (1) We can multiply the coefficients in a balanced equation and the ΔH for the reaction by the same factor to change the quantity of material we are dealing with, as we did with Equation 6.17. (2) We can reverse a reaction (i.e., make the reactants the products and the products the reactants) if we also change the sign of ΔH.

Hess's law is a direct consequence of the fact that enthalpy is a state function. In other words, for a particular set of reactants and products, the enthalpy change of the reaction is the same whether the reaction takes place in one step or in a series of steps. The concept of enthalpy and its expression in Hess's law are very useful because the enthalpy changes associated with many reactions can be calculated from a few that have been measured.

SAMPLE EXERCISE 6.12 Applying Hess's Law in Biology LO6

One source of energy in our bodies is the conversion of sugars to CO_2 and H_2O (called respiration; see Section 3.5). Maltose is one of the sugars found in foods. Show how we could combine reactions A and B below to get reaction C. How is ΔH_C related to the values of ΔH_A and ΔH_B?

Collect and Organize We are asked to combine two chemical equations to write the equation of an overall reaction and to combine two ΔH_{rxn} values to obtain an overall ΔH_{rxn} value. Hess's law allows us to combine the enthalpy changes that accompany the steps in an overall chemical reaction to calculate the value of ΔH_{rxn} of the overall reaction.

Analyze Maltose is a reactant in reactions A and C, so we can leave reaction A unchanged. The products of reaction C appear as reactants in reaction B, so we need to reverse B to get CO_2 and H_2O on the product side. To balance the moles of glucose produced in reaction A and consumed in reaction B, we also need to multiply the reversed reaction B by 2 before adding it to reaction A. Reversing reaction B and multiplying its coefficients by 2 means that we must also change the sign of ΔH_B and multiply its value by

2.

Solve We start with reaction A as written, and reverse and double reaction B:

Hess's law allows us to add the respective enthalpies: $\Delta H_C = \Delta H_A - 2\Delta H_B$.

Think About It Chemical equations can be added just like algebraic equations, multiplying them by coefficients if necessary, to obtain an equation for a new chemical reaction. A key to applying Hess's law is to treat the values of ΔH the same way that you treat the coefficients in the chemical equations and to change the sign of ΔH if an equation is reversed.

Practice Exercise How would you combine reactions A–C, shown below, to obtain reaction D?

A: $2\ H_2(g) + O_2(g) \rightarrow 2\ H_2O(g)$

B: $H_3BNH_3(s) \rightarrow NH_3(g) + BH_3(g)$

C: $H_3BNH_3(s) \rightarrow 2\ H_2(g) + HBNH(s)$

D: $NH_3(g) + BH_3(g) + O_2(g) \rightarrow 2\ H_2O(g) + HBNH(s)$

SAMPLE EXERCISE 6.13 Calculating Enthalpies of Reaction by Using Hess's Law LO6

Hydrocarbons burned in a limited supply of air may not burn completely, and CO(*g*) may be generated. One reason furnaces and hot-water heaters fueled by natural gas need to be vented is that incomplete combustion can produce toxic carbon monoxide:

Reaction A: $2\ CH_4(g) + 3\ O_2(g) \rightarrow 2\ CO(g) + 4\ H_2O(g)$ $\Delta H_A = ?$

Use reactions B and C to calculate the ΔH_{comb} for reaction A.

Reaction B: $CH_4(g) + 2\ O_2(g) \rightarrow CO_2(g) + 2\ H_2O(g) \qquad \Delta H_B = -802\ \text{kJ}$

Reaction C: $2\ CO(g) + O_2(g) \rightarrow 2\ CO_2(g) \qquad \Delta H_C = -566\ \text{kJ}$

Collect and Organize We are given two reactions (B and C) with thermochemical data and a third (A) for which we are asked to find ΔH_A. All the reactants and products of reaction A are present in reaction B or C or both.

Analyze We can manipulate the equations for reactions B and C so that they sum to give the equation for which ΔH_{comb} is unknown. Then we can calculate this unknown value by applying Hess's law.

The reaction of interest (A) has methane on the reactant side. Because reaction B also has methane as a reactant, we can use B as written. Reaction A has CO as a product. Reaction C involves CO as a reactant, so we must reverse C to get CO on the product side. Once we reverse C, we must change the sign of ΔH_C. If the coefficients as given do not allow us to sum the two reactions to yield reaction A, we can multiply one or both reactions by other factors.

Solve We start with reaction B as written and add the reverse of reaction C, remembering to change the sign of ΔH_C:

B: $CH_4(g) + 2\ O_2(g) \rightarrow CO_2(g) + 2\ H_2O(g) \qquad \Delta H_B = -802\ \text{kJ}$

C (reversed): $2\ CO_2(g) \rightarrow 2\ CO(g) + O_2(g) \qquad -\Delta H_C = 566\ \text{kJ}$

Because methane has a coefficient of 2 in reaction A, we multiply all the terms in reaction B, including ΔH_{comb}, by 2:

$2 \times [CH_4(g) + 2\ O_2(g) \rightarrow CO_2(g) + 2\ H_2O(g)] \qquad 2 \times [\Delta H_B = -802\ \text{kJ}]$

Because the carbon monoxide in reaction A has a coefficient of 2, we do not need to multiply reaction C by any factor. Now we add (2 × B) to the reverse of C and cancel out common terms:

Think About It We used Hess's law to calculate the enthalpy of combustion of methane to make CO. This is impossible to achieve in an experiment because any CO produced will react with O_2 to give CO_2, resulting in a product mixture of CO and CO_2. The answer of -1038 kJ is less negative than the enthalpy change accompanying the complete combustion of 2 moles of CH_4 [$2 \times (-802$ kJ)], so the answer is reasonable.

Practice Exercise It does not matter how you assemble the equations in a Hess's law problem. Show that reactions A and C can be summed to give reaction B and result in the same value for ΔH_B.

Glossary

Hess's law

the principle that the enthalpy of reaction ΔH_{rxn} for a reaction that is the sum of two or more reactions is equal to the sum of the ΔH_{rxn} values of the constituent reactions; also called *Hess's law of constant heat of summation*.

\end{aligned}
$$

6.8 Standard Enthalpies of Formation and Reaction

As noted in Section 6.3, it is impossible to measure the *absolute* value of the internal energy of a substance. The same is true for the enthalpy of a substance. However, we can establish *relative* enthalpy values that are referenced to a convenient standard. This approach is like using the freezing point of water as the zero point on the Celsius temperature scale or to using sea level as the zero point for expressing altitude. The enthalpy value referenced to this zero point is a substance's standard enthalpy of formation (ΔH°_f), or *standard heat of formation*, defined as the enthalpy change that takes place at constant pressure when 1 mole of a substance is formed from its constituent elements in their standard states. A reaction that fits this description is known as a formation reaction.

The adjective *standard*, indicated by the symbol °, as seen in ΔH°_f, indicates that the associated reaction occurs under standard conditions, which means at a constant pressure of 1 bar and at some specified temperature. The value of 1 bar of pressure is very close to 1 atm; for the level of precision used in this book, a standard pressure of 1 bar will be considered equivalent to 1 atm. There is no universal standard temperature, though many tables of thermodynamic data, including those in the appendix of this book, apply to processes occurring at 25°C.

TABLE 6.2 Standard Enthalpies of Formation for Selected Substances at 25°C

Substance	ΔH°_f (kJ/mol)
$Br_2(\ell)$	0
C(*s*, graphite)	0
$CH_4(g)$, methane	−74.8
$C_2H_2(g)$, acetylene	226.7

$C_2H_4(g)$, ethylene	52.26
$C_2H_6(g)$, ethane	−84.68
$C_3H_8(g)$, propane	−103.8
$C_4H_{10}(g)$, butane	−125.6
$CH_3OH(\ell)$, methanol	−238.7
$C_2H_5OH(\ell)$, ethanol	−277.7
$CH_3COOH(\ell)$, acetic acid	−484.5
$CO(g)$	−110.5
$CO_2(g)$	−393.5
$H_2(g)$	0
$H_2O(g)$	−241.8
$H_2O(\ell)$	−285.8
$N_2(g)$	0
$NH_3(g)$, ammonia	−46.1
$N_2H_4(g)$, hydrazine	95.4
$N_2H_4(\ell)$	50.63
$NO(g)$	90.3
$O_2(g)$	0

We also use the term standard state to describe the most stable physical state of a substance under standard conditions. In their standard states, oxygen is a gas, water is a liquid, and carbon is solid graphite. By definition, for a pure element this is its most stable form under standard conditions. It is the zero point of enthalpy values. **Table 6.2** lists standard enthalpies of formation for several substances. (A more complete list can be found in Appendix 4.1)

The general symbol for the enthalpy change associated with a reaction that takes place under standard conditions is $\Delta H^\circ_{\mathbf{rxn}}$, and the value is called either a standard enthalpy of reaction or a *standard heat of reaction*. Implied in our notion of standard states and standard conditions is the assumption that parameters such as ΔH change with temperature and pressure. That assumption is correct, although the changes are so small that we ignore them in the calculations in this textbook.

Because the definition of a formation reaction specifies 1 mole of product, writing balanced equations for formation reactions may require the use of something we typically avoided in Chapter 3—

namely, fractional coefficients in the final form of our balanced equations. For example, the thermochemical equation for the synthesis of ammonia from nitrogen and hydrogen is usually written

$$N_2(g) + 3\ H_2(g) \rightarrow 2\ NH_3(g) \qquad \Delta H^\circ_{\text{rxn}} = -92.2\ \text{kJ}$$

Although all reactants and products in this equation are in their standard states, it is not a formation reaction because 2 moles of product are formed, which is why we denote the enthalpy change of this reaction by $\Delta H^\circ_{\text{rxn}}$ rather than $\Delta H^\circ_{\text{f}}$. The formation reaction for ammonia must, by definition, show 1 mole of product being formed, so we divide each coefficient in the above equation by 2. Because energy is a stoichiometric quantity, the enthalpy of reaction is divided by 2 as well. Thus, the thermochemical equation representing the formation reaction of ammonia is

---

SAMPLE EXERCISE 6.14 Recognizing Formation Reactions LO7

Which of the following reactions are formation reactions at 25°C? For those that are not, explain why not.

1. $H_2(g) + \frac{1}{2}O_2(g) \rightarrow H_2O(g)$
2. $C(s,\ \text{graphite}) + 2\ H_2(g) + \frac{1}{2}O_2(g) \rightarrow CH_3OH(\ell)$

   (CH_3OH is methanol, a liquid in its standard state.)
3. $CH_4(g) + 2\ O_2(g) \rightarrow CO_2(g) + 2\ H_2O(\ell)$
4. $P_4(s) + 2\ O_2(g) + 6\ Cl_2(g) \rightarrow 4\ POCl_3(\ell)$

   (In their standard states, P_4 is a solid, Cl_2 is a gas, and $POCl_3$ is a liquid.)

Collect and Organize We are given four balanced chemical equations and information about the standard states of specific reactants and products. We want to determine which of these are formation reactions.

Analyze For a reaction to be a formation reaction, it must produce 1 mole of a substance from its component elements in their standard states. Therefore, we must evaluate each reaction for the quantity of product and for the state of each reactant.

Solve

1. The reaction shows 1 mole of water vapor formed from its constituent elements in their standard states. This, then, is the formation reaction for $H_2O(g)$, and its heat of reaction is ΔH°_f.
2. The reaction shows 1 mole of liquid methanol formed from its constituent elements in their standard states. This reaction is a formation reaction.
3. This is *not* a formation reaction because the reactants are not elements in their standard states and because more than one product is formed.
4. This is *not* a formation reaction because the product is 4 moles of $POCl_3$. Note, however, that all the constituent elements are in their standard states and that only one compound is formed. We could convert this into a formation reaction by dividing all the coefficients by 4.

Think About It Most chemical equations that describe formation reactions, including the (a) and (b) equations above, contain fractional coefficients on the reactant side. They are needed so that the coefficients for the single products can be 1. Also, these equations sometimes describe reactions that don't happen on their own. Rather, they provide reference values against which the enthalpy changes in reactions that do happen can be evaluated.

Practice Exercise Write formation reactions for (a) $CaCO_3(s)$, (b) $CH_3COOH(\ell)$ (acetic acid), and (c) $KMnO_4(s)$.

The standard enthalpies of formation of acetylene and ethylene are positive, which means that the formation reactions for these compounds are endothermic. The other hydrocarbon fuels in Table

6.2 have negative enthalpies of formation, but the values for all of them are less negative than the values for water and carbon dioxide. Recall that the products of the complete combustion of hydrocarbons are carbon dioxide and water. The more negative the enthalpy of formation ($\Delta H^\circ_{\mathrm{f}}$) of a substance, the more stable it is. The implication of this, as stated earlier, is that the reaction of fuels with oxygen to produce CO_2 and H_2O is exothermic. The reactions produce energy, which is why hydrocarbons are useful as fuels.

Standard enthalpies of formation $\Delta H^\circ_{\mathrm{f}}$ are used to predict standard enthalpies of reaction $\Delta H^\circ_{\mathrm{rxn}}$. We can calculate the standard heat of reaction for any reaction by determining the difference between the $\Delta H^\circ_{\mathrm{f}}$ values of the products and the $\Delta H^\circ_{\mathrm{f}}$ values of the reactants. To see how this approach works, consider the reaction we saw earlier as Equation 6.18:

$$C_6H_{12}O_6(s) + 2\ H_2O(\ell) \rightarrow 4\ H_2(g) + 4\ CO_2(g) + 2\ CH_4(g)$$

In this calculation, we use data from Table 6.2 in the following equation:

where n_{products} is the number of moles of each product in the balanced equation and $n_{\mathrm{reactants}}$ is the number of moles of each reactant. Equation 6.19 states that the value of $\Delta H^\circ_{\mathrm{rxn}}$ for any chemical reaction equals the sum (Σ) of the $\Delta H^\circ_{\mathrm{f}}$ value for each product times the number of moles of that product in the balanced equation, minus the sum of the $\Delta H^\circ_{\mathrm{f}}$ value for each reactant times the number of moles of that reactant in the balanced chemical equation. Thus, we multiply the value of $\Delta H^\circ_{\mathrm{f}}$ for H_2O in Equation 6.18 by 2 before summing with the value of $\Delta H^\circ_{\mathrm{f}}$ for $C_6H_{12}O_6$ because the H_2O coefficient is 2 in the balanced equation. We do the same with the $\Delta H^\circ_{\mathrm{f}}$ values of the products, multiplying them by 4, 4, and 2, respectively.

Once we insert $\Delta H^\circ_{\mathrm{f}}$ values from Table 6.2 for the reactants and the products in Equation 6.18, remembering that $\Delta H^\circ_{\mathrm{f}} = 0$ for $H_2(g)$ because it is a pure element in its most stable form, Equation 6.19 becomes

Now, let's consider the reaction between methane and steam that yields carbon dioxide and hydrogen gas:

$CH_4(g) + 2\ H_2O(g) \rightarrow CO_2(g) + 4\ H_2(g)$

This reaction is used to synthesize the hydrogen used in the steel industry to remove impurities from molten iron and in the chemical industry to make hundreds of compounds, including ammonia (NH_3) for use in fertilizers and as a refrigerant. The reaction is also important in the manufacture of hydrogen fuel for fuel cells, which are used to generate electricity directly from a chemical reaction.

Inserting the appropriate values from Table 6.2 into Equation 6.19, along with the coefficients 2 for H_2O and 4 for H_2,

The positive standard enthalpy of reaction tells us that this reaction between water vapor and methane is endothermic. In other words, energy must be added to make the reaction take place (typically conducted at temperatures near 1000°C).

Enthalpy is a state function, and, as noted in Section 6.2, the value of a state function is independent of the path taken to achieve that state. Thus, values of ΔH_{rxn} are independent of pathway. It does not matter what path we take to get from the reactants to the products; the enthalpy difference between them is always the same. In fact, on an industrial scale, the reaction to produce hydrogen gas from methane is carried out in two steps. In the first step, methane reacts with a limited supply of steam to produce carbon monoxide and hydrogen gas (which is called the *steam reforming reaction*). In the second step, the carbon monoxide reacts with additional steam and more hydrogen gas:

Figure 6.33 depicts the enthalpy changes involved in these two steps, as well as the overall reaction. The enthalpy change for the overall reaction has a value of +165 kJ, the same value we calculated with Equation 6.19 by using enthalpies of formation.

Just as we saw in Section 6.3 with state changes, once we know the value of the energy associated with running a reaction in the forward direction, we also know the value of the energy change when the reaction runs in reverse: it has the same magnitude but the opposite sign. This means that, having calculated a value of $\Delta H°_{\text{rxn}} = +165$ kJ for the steam reforming reaction, we can write

$$CO(g) + 3\ H_2(g) \rightarrow CH_4(g) + H_2O(g) = \Delta H°_{\text{rxn}}\ -206\ \text{kJ}$$

for the exothermic reverse reaction, as illustrated in **Figure 6.34**.

SAMPLE EXERCISE 6.15 Calculating Enthalpies of Reaction LO6

Using the appropriate values from Table 6.2, calculate $\Delta H°_{\text{rxn}}$ for the combustion of the fuel propane (C_3H_8) in air.

Collect and Organize The reactants are propane and elemental oxygen, O_2, and the products are carbon dioxide and water. Even though combustion is an exothermic reaction, we assume that water is produced as liquid, $H_2O(\ell)$, so that all products and reactants are in their standard states. The heats of formation of propane, carbon dioxide, and $H_2O(\ell)$ are given in Table 6.2. The heat of formation of the element O_2 in its standard state is zero. Our task is to use the balanced equation and the data from Table 6.2 to calculate the enthalpy of combustion.

Analyze Equation 6.19 defines the relation between heats of formation of reactants and products and the standard enthalpy of reaction. We also need the balanced equation for the combustion of propane:

$$C_3H_8(g) + 5\ O_2(g) \rightarrow 3\ CO_2(g) + 4\ H_2O(\ell)$$

Solve Inserting $\Delta H°_f$ values for the products [$CO_2(g)$ and $H_2O(\ell)$] and reactants [$C_3H_8(g)$ and $O_2(g)$] from Table 6.2 and the coefficients in the balanced chemical equation into Equation 6.19, we get

---

Think About It The result of the calculation has a large negative value, which means that the combustion reaction is highly exothermic, as expected for a hydrocarbon fuel.

Practice Exercise Calculate $\Delta H^\circ_{\text{rxn}}$ for the *water–gas shift reaction*:

$CO(g) + H_2O(g) \rightarrow CO_2(g) + H_2(g)$

When we use standard enthalpies of formation (ΔH°_f) to determine standard enthalpies of reaction $\Delta H^\circ_{\text{rxn}}$, we are applying Hess's law. Consider, for example, the reaction of ammonia with oxygen to make NO(*g*) and liquid water (this is the first step of the industrial synthesis of nitric acid):

$4\ NH_3(g) + 5\ O_2(g) \rightarrow 4\ NO(g) + 6\ H_2O(\ell)$

First, we write equations for the formation reactions of gaseous NH_3 and NO and liquid H_2O using the ΔH°_f values in Table 6.2:

We reverse the NH_3 equation so that the NH_3 is a reactant and multiply each equation by a factor that matches the product's or reactant's coefficient in the balanced equation.

Their sum yields the reaction of interest:

This is the same mathematical result that we get when we use Equation 6.19:

Glossary

formation reaction

a reaction in which 1 mole of a substance is formed from its component elements in their standard states.

standard conditions

in thermodynamics: a pressure of 1 bar (∼1 atm) and some specified temperature, assumed to be 25°C unless otherwise stated; for solutions, a concentration of 1 *M* is specified.

standard state

the most stable form of a substance under 1 bar pressure and some specified temperature (25°C unless otherwise stated).

standard enthalpy of formation(ΔH°_f)

the enthalpy change of a formation reaction; also called *standard heat of formation* or *heat of formation*.

standard enthalpy of reaction (ΔH°_{rxn})

the energy associated with a reaction that takes place under standard conditions; also called *standard heat of reaction*.

6.9 Fuels, Fuel Values, and Food Values

In Section 6.6 we saw that the enthalpy of combustion of propane (−2220 kJ/mol) is much greater than that of methane (−802 kJ/mol)—that is, much more energy is released in the combustion of 1 mole of propane. Does this make propane an inherently more valuable fuel? Not necessarily because we do not purchase fuels, or anything else for that matter, in units of moles. Depending on the fuel, we buy it either by mass (coal) or by volume (gasoline and diesel oil). Before addressing the question of which fuel is better, let’s take a quick look at the molecular structures of methane, propane, and other related hydrocarbons.

CONNECTION In Chapter 2 we defined hydrocarbons as compounds composed of only carbon and hydrogen atoms, and we saw that alkanes are hydrocarbons in which each carbon atom is bonded to four other atoms.

Alkanes

Methane and propane belong to the family of organic compounds called *alkanes*—hydrocarbons distinguished by the fact that each carbon atom is bonded to four other atoms. Alkanes are classified as saturated hydrocarbons because they contain the maximum ratio of hydrogen atoms to carbon atoms.

TABLE 6.3 Prefixes for Naming Alkanes

Prefix	Name	Condensed Structure
Meth	Methane	CH_4
Eth	Ethane	CH_3CH_3
Prop	Propane	$CH_3CH_2CH_3$
But	Butane	$CH_3(CH_2)_2CH_3$
Pent	Pentane	$CH_3(CH_2)_3CH_3$
Hex	Hexane	$CH_3(CH_2)_4CH_3$
Hept	Heptane	$CH_3(CH_2)_5CH_3$
Oct	Octane	$CH_3(CH_2)_6CH_3$

Nonane	$CH_3(CH_2)_7CH_3$				
Decane	$CH_3(CH_2)_8CH_3$				

Alkanes are also known as *paraffins*, a name derived from Latin meaning "little affinity." This is a perfect description of the alkanes, which tend to be much less reactive than the other hydrocarbon families. *Unreactive* may not seem like the correct term to apply to compounds that are fuels, but alkanes do not react readily, even with oxygen. As evidence of this, most fuels need some source of energy, such as a spark from a spark plug in an engine, to initiate combustion.

The first four members of the alkane family (**Figure 6.35**) are methane (1 carbon atom: a C_1 alkane), ethane (2 carbon atoms: a C_2 alkane), propane (a C_3 alkane), and butane (a C_4 alkane). The names of alkanes with more than 4 carbon atoms are derived from the IUPAC prefix for the number of carbon atoms per molecule, followed by -*ane.***Table 6.3** lists the prefixes for the C_1 through C_{10} alkanes.

Alkanes all have the general formula C_nH_{2n+2}, and each alkane differs from the previous one by one $–CH_2–$ unit, which is called a methylene group. The terminal $–CH_3$ groups are called methyl groups. All the alkanes in the table are straight-chain hydrocarbons, which means a continuous sequence of carbon atoms with no branching. Straight-chain alkanes have a methyl group at each end with methylene groups connecting them. **Table 6.4** lists the melting points and boiling points for some straight-chain alkanes. These data show similar trends—namely, as straight-chain alkanes increase in molar mass, their melting and boiling points increase.

CONCEPT TEST

Alkanes have the general formula C_nH_{2n+2}. If an alkane has a molar mass of 114 g/mol, what is the value of n?

The alkane family would be huge even if it consisted of only straight-chain hydrocarbons, but another structural possibility makes the family even larger. For example, alkanes with four or more carbon atoms can also be branched-chain hydrocarbons, as shown for the C_4 alkanes in **Table 6.5**. A *branch* is a side chain attached to the main carbon chain. The molecular formula of both structures in Table 6.5 is C_4H_{10}, but they represent different compounds with different properties. In recognition of these differences, the two compounds have different formal names (butane and 2-methylpropane).

The principal source of liquid alkanes is crude oil. Natural gas is the major source for the simplest alkane, methane, and also smaller quantities of low-molar-mass alkanes, including ethane, propane, and butane. Methane is also produced during bacterial decomposition of vegetable matter in the absence of air, a condition that frequently arises in swamps. Hence methane's common name is swamp gas or marsh gas (**Figure 6.36**).

TABLE 6.4 Melting Points and Boiling Points for Selected Straight-Chain Alkanes

n.a 72–75
$CH_3(CH_2)_{34}CH_3$ and higher homologs Asphalt

Combustion reactions between hydrocarbons and oxygen power our vehicles, warm our homes, cook our meals, and generate electricity. Gasoline, kerosene, and diesel oils are complex mixtures of alkanes and other hydrocarbons containing up to 18 carbon atoms per molecule, as shown in Table 6.4. The energies released by the combustion of these fuels and several individual alkanes are listed in **Table 6.6**. Alkanes with higher molar masses are viscous liquids that are used as lubricating oils. Low-melting solid alkanes (C_{20}–C_{40}) are used in candles and in manufacturing matches. Very heavy hydrocarbon gums and solid residues (C_{36} and up) are used for paving roads.

Diesel oil (d = 0.846 g/mL)		42.6

Fuel Value

To calculate the energy released when 1 g of a hydrocarbon fuel burns in air, producing CO_2 and water vapor, we divide the absolute value of its standard enthalpy of combustion ($\Delta H^\circ_{\text{comb}}$, kJ/mol) by its molar mass (g/mol). The result is an energy value expressed in kJ/g that is called fuel value.

Fuel values for several alkanes are listed in Table 6.6. Note how they decrease with increasing molar mass. Why is that the case? The answer lies in the hydrogen-to-carbon ratios in these compounds. As the number of carbon atoms per molecule increases, the hydrogen-to-carbon ratio decreases. This is important because hydrogen produces more energy per gram than carbon does. To see why, consider the standard enthalpies of formation of $H_2O(g)$ and $CO_2(g)$:

These equations tell us that the combustion of 1 mol (2.016 g) H_2 releases 241.8 kJ of energy, whereas 1 mol (12.011 g) C releases 393.5 kJ of energy. Expressing these energy values per gram of fuel we get:

Thus, gram for gram, hydrogen has nearly four times the fuel value of carbon (which is why H_2 appears at the top of the list of fuels in Table 6.6).

Table 6.6 also contains fuel values for three common fuels: gasoline, kerosene, and diesel oil. Each is a complex mixture of hydrocarbons whose composition can vary from sample to sample, depending on the source of the crude oil from which it was obtained. This variability can lead to differences in fuel values. Those in Table 6.6 apply to samples of these fuels that have the physical densities (expressed in g/mL) also listed in the table.

Another term frequently used to compare the energy content of liquid fuels is fuel density. Fuel density describes the amount of energy available per unit volume of fuel. They are typically expressed in kJ/mL for liquid fuels and kJ/L for gaseous fuels. Both fuel value and fuel density are reported as positive numbers, but it is understood that these values refer to the energy released from the fuel when it is burned.

CONCEPT TEST

Without doing any calculations, predict which compound in each pair releases more energy during combustion in air: (a) 1 mole of CH_4 or 1 mole of H_2; (b) 1 g of CH_4 or 1 g of H_2.

SAMPLE EXERCISE 6.16 Comparing Fuel Values and Fuel Densities LO8

Most automobiles run on either gasoline or diesel oil. Use the data in Table 6.6 to compare the fuel values (kJ/g) and fuel densities (kJ/mL) of these widely used fuels.

Collect, Organize, and Analyze We are to compare the fuel values and fuel densities of gasoline and diesel oil. Table 6.6 contains the fuel values of both fuels and their physical densities, which we can use to convert their fuel values to fuel densities.

Solve The fuel values of gasoline and diesel oil in Table 6.6 are 43.4 and 42.6 kJ/g, respectively. The ratio of these two values: $43.4/42.6 = 1.019$, tell us that the fuel value of gasoline is about 2% higher than the fuel value of diesel oil. Using the physical densities of the fuels to calculate their fuel densities:

The ratio of these two values is $36.0/32.0 = 1.125$. Thus, the fuel density of diesel oil is about 12% higher than the fuel density of gasoline.

Think About It The trend toward lower fuel values with increasing molar mass among the hydrocarbons in Table 6.6 is reflected in the fuel values of gasoline and diesel oil: the hydrocarbons in gasoline have, on average, smaller molar masses and greater hydrogen-to-carbon ratios (see Table 6.4) than those in diesel oil. However, the difference in the fuel values is small compared to the difference in the physical densities of the two fuels, which leads to the much higher fuel density of diesel oil compared to gasoline. Because both fuels are sold by volume, the higher fuel density of diesel contributes to its overall value as a fuel.

Practice Exercise High purity kerosene (see Table 6.6) is used to fuel jet engines; less pure grades are used in heating systems. Use the data in Table 6.6 to compare the fuel value and fuel density of kerosene to those of gasoline and diesel oil.

Food Value

Food serves the same purpose in living systems as fuel does in mechanical systems. The chemical reactions that convert food into energy resemble combustion but consist of many more steps that are much more highly controlled. Carbon dioxide and water are the ultimate products, however, and in a fundamental way, metabolism of food by a living system and combustion of fuel in an engine are the same process. The food value of what we eat—the amount of energy produced when food is burned completely—can be determined using the same equipment and by applying the same concepts of thermochemistry we have developed to evaluate fuels for vehicles. That is, we can analyze the relative food value of the items we consume by burning material in a bomb calorimeter and measuring the quantity of energy released.

What, for example, is the food value of a serving of peanuts (about 28 g, or 40 peanuts)? To determine its energy content per unit of mass, we burn the peanuts in a calorimeter. A portion of the mass of the peanuts (about 1.5 g) is water, so we first prepare the sample by drying it. This is a necessary step to get an accurate value for the enthalpy of reaction, ΔH_{rxn}, because we need to make sure that all the sample mass is due to the elemental composition of the peanuts alone.

Once the peanuts are dry, suppose they have a mass of 26.5 g. We put them in a calorimeter for which $C_{\text{calorimeter}} = 41.8\ \text{kJ/°C}$ and burn them completely in excess oxygen. If the temperature of the calorimeter rises by 16.0°C, what is the food value of the peanuts?

To answer this question, we use Equation 6.12 to determine the quantity of energy that flowed from the peanuts to the calorimeter:

$$q_{\text{calorimeter}} = C_{\text{calorimeter}}\Delta T = (41.8\ \text{kJ/°C})(16.0\text{°C}) = +669\ \text{kJ}$$

where the plus sign indicates that energy flowed *into* the calorimeter. The energy lost by the peanuts as they burned has the same value but opposite sign:

Just as with fuel values, however, food value is reported as a positive number, and it is understood that the energy contained in the food is released when the food is metabolized. The peanuts' food value is therefore

What is the food value of these peanuts in nutritional Calories (kilocalories)? We can use the definition of Calorie from Section 6.3 to convert energy in kilojoules into the familiar unit used by nutritionists:

A single serving of peanuts represents 6% to 8% of the Calories needed by an adult with normal activity in one day. **Figure 6.37** shows some other foods that have a similar food value.

SAMPLE EXERCISE 6.17 Calculating Food Value LO8

Glucose ($C_6H_{12}O_6$) is a simple sugar formed by photosynthesis in plants. The complete combustion of 0.5763 g of glucose in a calorimeter ($C_{\text{calorimeter}} = 6.20\ \text{kJ/°C}$) raises the temperature of the calorimeter by 1.45°C. What is the food value of glucose in Calories per gram?

Collect and Organize We are asked to determine the food value of glucose, which means the energy given off when 1 g is burned. We have the mass of glucose burned and the calorimeter constant. To convert kilojoules to Calories we use the conversion factor 1 Cal = 4.184 kJ. Equation 6.12 ($q_{\text{calorimeter}} = C_{\text{calorimeter}}\Delta T$) can be used to calculate $q_{\text{calorimeter}}$ from its temperature change and heat capacity (calorimeter constant).

Analyze The quantity of energy absorbed by the calorimeter is equal in magnitude but opposite in sign to the enthalpy change in the reaction mixture as described by Equation 6.15 ($q_{\text{calorimeter}} = -\Delta H_{\text{rxn}}$). However, this sign change is not needed in this case because food (and fuel) values are expressed as positive “energy released” values.

Solve

This positive quantity of energy absorbed by the calorimeter can be converted directly to a food value by dividing by the sample mass:

Converting this value into Calories:

Think About It Using calorimetry to determine food or fuel values is simplified by the fact that the energy transferred to the calorimeter can be used directly to calculate positive food or fuel values. If a 1-gram sample had been combusted, its food (or fuel) value would have been equal to ($C_{\text{calorimeter}} \cdot \Delta T$).

Practice Exercise Sucrose (table sugar) has the formula $C_{12}H_{22}O_{11}$ ($\mathscr{M}$ = 342.30 g/mol) and a food value of 16.4 kJ/g. Determine the calorimeter constant of the calorimeter in which the combustion of 1.337 g of sucrose raises the temperature by 1.96°C.

In this chapter we have considered the flow of energy and its role in defining the behavior of physical, chemical, and biological processes. The interaction of energy with matter—the transfer of energy into and out of materials—causes phase changes and alters the temperature of matter. The magnitude of these changes and the temperature ranges over which they occur are characteristic of the quantity and identity of the matter involved. Energy is also a product or a reactant in virtually all chemical reactions and, as such, behaves stoichiometrically, which means the chemical changes that a specific quantity of material undergoes are characterized by the release or consumption of a specific amount of energy. Understanding the energy contained in fuels is particularly important because fuels provide the bulk of the power needed by the equipment and devices of modern life—from cars and airplanes to computers, air conditioners, and lightbulbs. Just as significant is the energy contained in foods that sustain life. How we deal with the needs for energy in the near future—in terms of both fuel and food—will determine the quality of all our lives and the health of our planet.

SAMPLE EXERCISE 6.18 Integrating Concepts: Recycling Aluminum

Chemical engineers frequently analyze the energy required to carry out industrial procedures to assess costs of operations and support new approaches to producing materials. Over the last century, aluminum—both alone and in combination with other metals—has replaced steel for use where high strength-to-weight ratios and corrosion resistance are paramount. The industrial process for converting Al_2O_3 (alumina) into aluminum, called the Hall–Héroult process after Charles Martin Hall (1863–1914) and Paul Héroult (1863–1914), is based on passing an electric current through a solution of alumina dissolved in molten cryolite (Na_3AlF_6). As electricity passes through the solution, aluminum ions are reduced to aluminum metal at negatively charged electrodes, while positively charged carbon electrodes are oxidized to carbon dioxide. The process is described by the following overall reaction equation:

$2\ Al_2O_3$ (in molten Na_3AlF_6) $+\ 3\ C(s,$ graphite$) \rightarrow$

$4\ Al(\ell) +\ 3\ CO_2(g)$

The principal energy cost of the Hall–Héroult process is the electricity needed to reduce Al_2O_3; the major cost in recycling is the energy required to melt aluminum metal. We can use thermochemistry principles to estimate the energy requirements for the Hall–Héroult process and compare it with the energy needed for recycling.

1. Assign oxidation numbers to the reactants and products in the reaction and determine how many moles of electrons are needed per mole of aluminum produced.
2. Calculate the standard enthalpy of reaction for the reduction reaction of alumina from the standard enthalpies of formation. Use Table A4.3 in Appendix 4 as needed.
3. Estimate the energy required to recycle 1.00 mole of aluminum by heating it from 25°C to its melting point (660°C) until all the aluminum melts.

Collect and Organize We are given a balanced chemical equation. We will need the melting point of aluminum, 660°C; the molar enthalpy of fusion, $\Delta H_{\text{fus,Al}} = 10.79$ kJ/mol; and the molar specific heat of aluminum, $c_{\text{P,Al}}$, 24.4 J/(mol · K). Additional thermodynamic data are available in Appendix 4 to calculate $\Delta H^\circ_{\text{rxn}}$. We are asked to compare the energy savings for recycling aluminum with reducing it from Al_2O_3.

Analyze The energy needed to make 1 mole of aluminum—that is, the standard enthalpy change for the reaction—is calculated using standard enthalpies of formation and Equation 6.19. The energy required to recycle 1 mole of aluminum represents the sum of the energy needed to melt a mole of aluminum (the enthalpy of fusion) and the energy needed to heat the aluminum to its melting point, which can be calculated using its molar heat capacity and Equation 6.8.

Solve

1. The balanced chemical equation is given as:

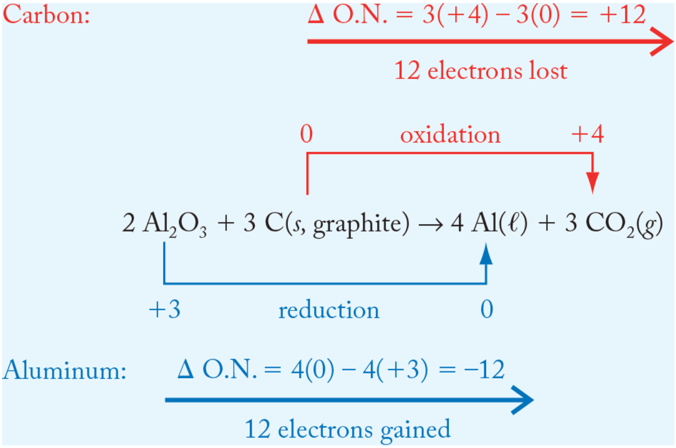
   $$2\ Al_2O_3\,(s) + 3\ C(s,\ \text{graphite}) \rightarrow 4\ Al(\ell) + 3\ CO_2(g)$$

   where we have omitted the “in molten Na_3AlF_6” because the latter is the solvent for the reaction. According to the rules for assigning oxidation numbers (Chapter 4), both liquid Al and solid C have an oxidation number of zero because they are pure elements. Assigning the oxidation number for oxygen as -2 in both Al_2O_3 and CO_2, we can calculate the oxidation numbers for Al and C as follows:

$$\begin{array}{llll} \text{Al:} & 2x + 3(-2) = 0 & \text{C:} & x + 2(-2) = 0 \\ & x = +3 & & x = +4 \end{array}$$

4

To determine how many moles of electrons are needed per mole of aluminum produced, we need to determine the number of electrons transferred in this process:



Carbon:
Δ O.N. = 3(+4) − 3(0) = +12
12 electrons lost
0
oxidation
+4
2 Al₂O₃ + 3 C(s, graphite) → 4 Al(ℓ) + 3 CO₂(g)
+3
reduction
0
Aluminum:
Δ O.N. = 4(0) − 4(+3) = −12
12 electrons gained

A total of 12 moles of electrons are transferred for every 4 moles of aluminum produced, so 3 moles of electrons are required to produce each mole of aluminum.

2. Using Equation 6.19, we can calculate the standard enthalpy of reaction for the reduction reaction of alumina from the standard enthalpies of formation of the reactants and

products:

$$\begin{aligned}\Delta H^\circ_{\mathrm{rxn}} &= [3(\Delta H^\circ_{\mathrm{f,CO_2(g)}}) + 4(\Delta H^\circ_{\mathrm{f,Al(\ell)}})] - [2(\Delta H^\circ_{\mathrm{f,Al_2O_3(s)}}) + 3(\Delta H^\circ_{\mathrm{f,C(s)}})] \\ &= \left[(3\ \cancel{\mathrm{mol\ CO_2}})\left(\frac{-393.5\ \mathrm{kJ}}{1\ \cancel{\mathrm{mol\ CO_2}}}\right) + (4\ \cancel{\mathrm{mol\ Al}})\left(\frac{10.6\ \mathrm{kJ}}{1\ \cancel{\mathrm{mol\ Al}}}\right)\right] \\ &\quad - \left[(2\ \cancel{\mathrm{mol\ Al_2O_3}})\left(\frac{-1675.7\ \mathrm{kJ}}{1\ \cancel{\mathrm{mol\ Al_2O_3}}}\right) + (3\ \cancel{\mathrm{mol\ C}})\left(\frac{0.0\ \mathrm{kJ}}{1\ \cancel{\mathrm{mol\ C}}}\right)\right] \\ &= +2213.3\ \mathrm{kJ}\end{aligned}$$

Dividing this value by the 4 moles of aluminum produced in the reaction as written, we get

$$\frac{2213.3\ \mathrm{kJ}}{4\ \mathrm{mol\ Al}} = 553.3\ \mathrm{kJ/mol}$$

This reaction is endothermic, requiring 553 kJ for every mole of aluminum produced.

3. The energy needed to heat 1 mole of aluminum from 25°C to 660°C can be calculated from its molar heat capacity [24.4 J/(mol · °C), per Table 6.1] and Equation 6.8:

$$\begin{aligned}q &= nc_{\mathrm{P}}\Delta T \\ &= 1.00\ \cancel{\mathrm{mol}} \times 24.4\ \frac{\cancel{\mathrm{J}}}{\cancel{\mathrm{mol}} \cdot \cancel{^\circ\mathrm{C}}} \times (660 - 25)\cancel{^\circ\mathrm{C}} \times \frac{1\ \mathrm{kJ}}{1000\ \cancel{\mathrm{J}}} \\ &= 15.5\ \mathrm{kJ}\end{aligned}$$

Once the aluminum is at its melting point, the energy required to melt 1 mole of Al is its enthalpy of fusion ($\Delta H^\circ_{\mathrm{fus}} = 10.6$ kJ/mol):

$$10.6\ \mathrm{kJ}/\cancel{\mathrm{mol}} \times 1.00\ \cancel{\mathrm{mol}} = 10.6\ \mathrm{kJ}$$

The estimated total energy to heat and melt 1.00 mole of aluminum is

15.5 kJ + 10.6 kJ = 26.1 kJ

This value represents

$$\frac{26.1\ \text{kJ}}{553\ \text{kJ}} \times 100\% = 4.75\%$$

of the energy needed electrically to produce 1 mole of aluminum from its ore. The high cost of electricity makes recycling aluminum economically attractive as well as environmentally sound.

Think About It Other energy costs arise in both the production and recycling of aluminum, and the numbers calculated here should be viewed as estimates based on ideal situations; overall, however, recycling saves aluminum manufacturers about 95% of the energy required to produce the metal from the ore. This energy savings has inspired the rapid growth of a global aluminum recycling industry, and in the United States alone, aluminum recycling is a $1 billion-per-year business. Junkyards in the United States currently recycle 85% of the aluminum in cars and more than 50% of the aluminum in food and beverage containers.

Glossary

saturated hydrocarbon

an alkane; compounds containing the maximum ratio of hydrogen atoms to carbon atoms.

methylene group

($–CH_2–$) a structural unit that can make two bonds.

methyl group

($–CH_3$) a structural unit that can make only one bond.

straight-chain hydrocarbon

a hydrocarbon in which the carbon atoms are bonded together in one continuous carbon chain.

branched-chain hydrocarbon

a hydrocarbon in which the chain of carbon atoms is not linear.

fuel value

the quantity of energy released during the complete combustion of 1 g of a substance.

fuel density

the quantity of energy released during the complete combustion of 1 L of a liquid fuel.

food value

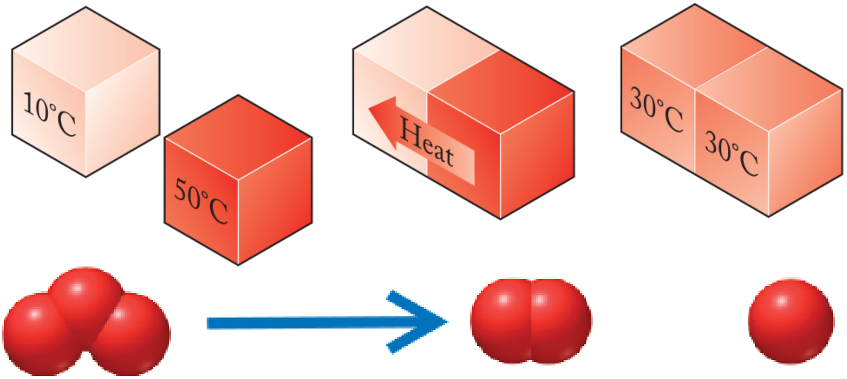
the quantity of energy produced when a material consumed by an organism for sustenance is burned completely; it is typically reported in Calories (kilocalories) per gram of food.

Endnotes

- na = not available; compound decomposes before boiling at 1 atm pressure.Return to reference a

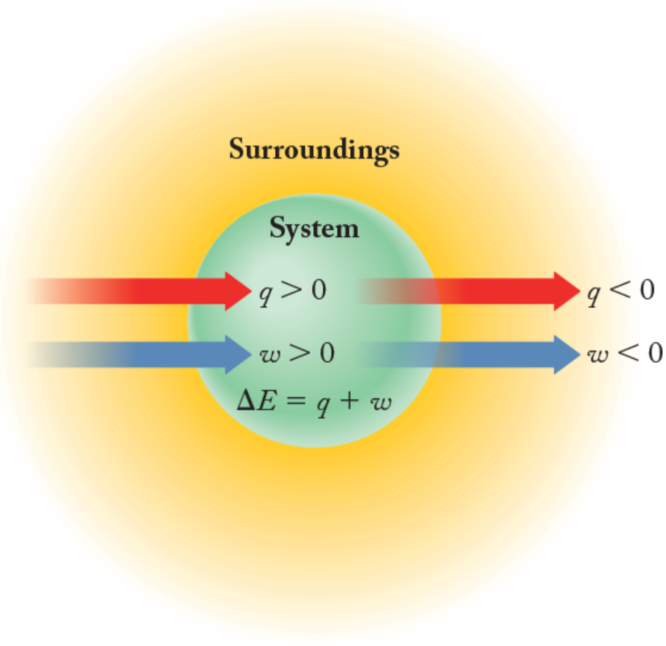
Learning Objectives

- Calculate and compare fuel and food values and fuel densities **Return to Sample Exercises 6.16, 6.17**
- Calculate and compare fuel and food values and fuel densities **Return to Sample Exercises 6.16, 6.17**



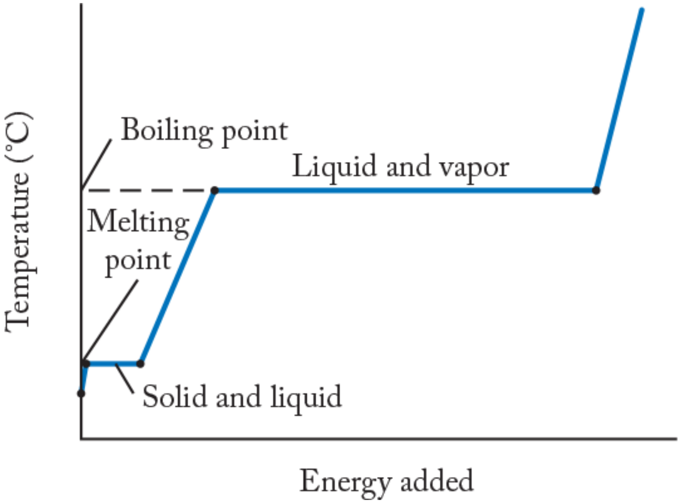
SUMMARY

- LO1 Potential energy (PE) is the energy stored in an object because of its position and is a state function. Kinetic energy (KE) is the energy of motion. Heating a sample increases the average kinetic energy of the atoms in the sample. Energy is stored in compounds, and energy is absorbed or released when they are transformed into different compounds or when a change of state occurs. (Sections 6.1 and 6.2)
- LO2 The focus of a thermochemical study defines a system; everything other than the system is considered surroundings. In an exothermic process, the system loses energy to its surroundings ($q < 0$); in an endothermic process, the system absorbs energy ($q > 0$) from its surroundings. (Section 6.3)

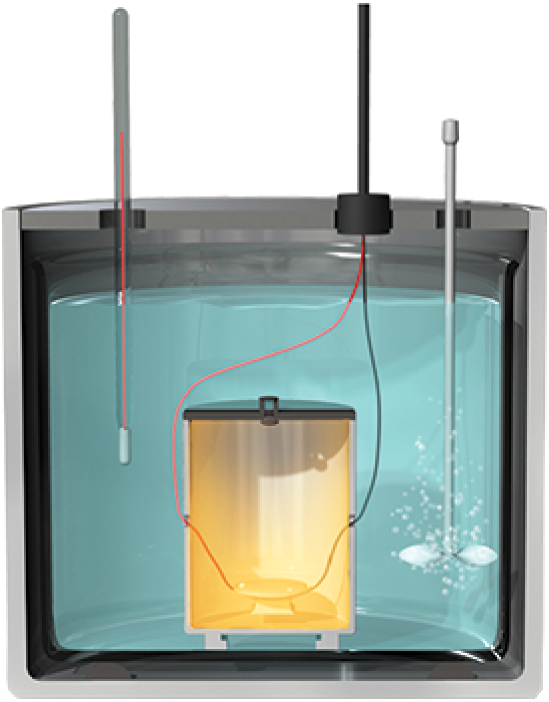


Surroundings
System
$q > 0$
$w > 0$
$\Delta E = q + w$
$q < 0$
$w < 0$

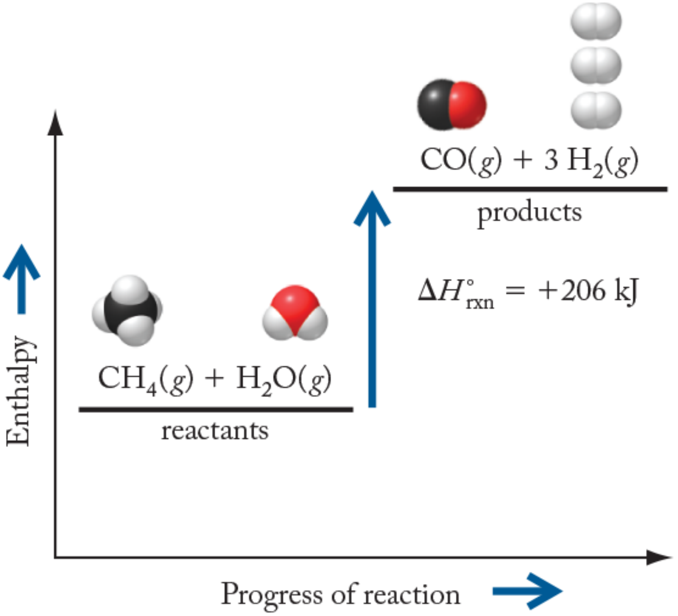
- LO3 The sum of the kinetic and potential energies of a system is called its internal energy (E). The internal energy of a system is increased ($\Delta E = E_{\text{final}} - E_{\text{initial}}$ is positive) when it is heated ($q > 0$) or if work is done on it ($w > 0$). When the pressure on a system is constant but the volume of the system changes, the work done is called pressure–volume (P–V) work. (Section 6.3)



- LO4 The enthalpy (H) of a system is given by $H = E + PV$. The enthalpy change (ΔH) of a system is equal to the energy in the form of heat (q_P) added to or removed from the system at constant pressure: $\Delta H > 0$ for endothermic reactions and $\Delta H < 0$ for exothermic reactions. Thermodynamic values like molar heat capacity (c_P) and specific heat (c_s) can be used to quantify physical and chemical changes in systems. (Sections 6.4 and 6.5)



- LO5 A calorimeter, characterized by its calorimeter constant (its characteristic heat capacity), is a device used to measure the amount of energy involved in physical and chemical processes. The enthalpy change associated with a reaction is defined by the enthalpy of reaction (ΔH_{rxn}). (Section 6.6)
- LO6 Hess's law states that the enthalpy of a reaction (ΔH_{rxn}) that is the sum of two or more other reactions is equal to the sum of the ΔH_{rxn} values of the constituent reactions. It can be used to calculate enthalpy changes in reactions that are hard or impossible to measure directly. (Section 6.7)



- LO7 The standard enthalpy of formation ($\Delta H^\circ f$) of a substance is the amount of energy involved in a formation reaction, in which 1 mole of the substance is made from its constituent elements in their standard states (under standard conditions). Enthalpy changes for physical changes and chemical reactions can be calculated from the enthalpies of formation of the reactants and products. (Section 6.8)
- LO8 Fuel value is the amount of energy released on complete combustion of 1 g of a fuel. Food value is the amount of energy released when a material consumed by an organism for sustenance is burned completely; nutritionists often express food values in Calories (kilocalories) rather than in the SI unit kilojoules. (Section 6.9)

PARTICULATE PREVIEW WRAP-UP

Energy is absorbed by ozone to break its bonds. Bond breaking is endothermic; bond formation is exothermic. Energy is absorbed during this reaction, but energy would be released if the reaction ran in reverse.

PROBLEM-SOLVING SUMMARY

Type of Problem	Concepts and Equations	Sample Exercises
Calculating kinetic and potential energy	$KE = \frac{1}{2}mu^2$ (5.27) $E_{el} \propto \frac{Q_1 \times Q_2}{d}$ (6.3)	6.1
Identifying endothermic and exothermic processes, and calculating internal energy change (ΔE) and P–V work	$\Delta E = q + w$ (6.5) where $w = -P\Delta V$.	6.2, 6.3, 6.4
Predicting the sign of ΔH_{sys} for physical and chemical changes	Exothermic: $\Delta H_{sys} < 0$ Endothermic: $\Delta H_{sys} > 0$	6.5, 6.6
Calculating the flow of energy (q) associated with a change of state or with a change in the temperature of a substance	$q = nc_P\Delta T$ (6.8) or melting a solid at its melting point: $q = n\Delta H_{fus}$ (6.9) or vaporizing a liquid at its boiling point: $q = n\Delta H_{vap}$ (6.10)	6.7, 6.8, 6.9
Measuring the heat capacity (calorimeter constant) of a calorimeter and ΔH_{rxn}	$C_{calorimeter} = q_{calorimeter}/\Delta T$ (6.13) where $C_{calorimeter}$ is the heat capacity of the calorimeter, $q_{calorimeter}$ is the heat released by a standard combustion reaction, and ΔT is the temperature change of the calorimeter.	6.10
Measuring the enthalpy of reaction	The energy change of the system is equal in magnitude, but opposite in sign, to the energy change of the surroundings: $q_{gained,sys} = -q_{lost,surr}$ where the energy depends upon the amount of substance (moles), molar heat capacity, and change in temperature: $q_{gained,sys} = n_{sys}c_{P,sys}\Delta T$ $q_{lost,surr} = n_{surr}c_{P,surr}\Delta T$	6.11
Using Hess's law	Rearrange the information so that the reactions add together as desired. Reversing a reaction changes the sign of the reaction's ΔH_{rxn} value. Multiplying the coefficients in a reaction by a factor requires that the reaction's ΔH_{rxn} value be multiplied by the same factor.	6.12, 6.13
Recognizing and writing formation reactions	In a formation reaction, the reactants are elements in their	6.14

standard states and the product is 1 mole of a single compound.

6.15 **Calculating standard enthalpies of reaction from heats of formation**

$$\Delta H^\circ_{\text{rxn}} = \sum n_{\text{products}} \Delta H^\circ_{\text{f,products}} - \sum n_{\text{reactants}} \Delta H^\circ_{\text{f,reactants}} \quad (6.19)$$

6.16, 6.17 **Calculating fuel value and food value**

The fuel value of a substance is the energy released by the complete combustion of 1 g of the substance.

VISUAL PROBLEMS

(Answers to boldface end-of-chapter questions and problems are in the back of the book.)

A brick lies perilously close to the edge of the flat roof of a building (Figure P6.1). The roof edge is 50 ft above street level, and the brick has 500 J of potential energy with respect to street level. Someone edges the brick off the roof, and it begins to fall. What is the brick’s kinetic energy when it is 35 ft above street level? What is its kinetic energy the instant before it hits the street surface?

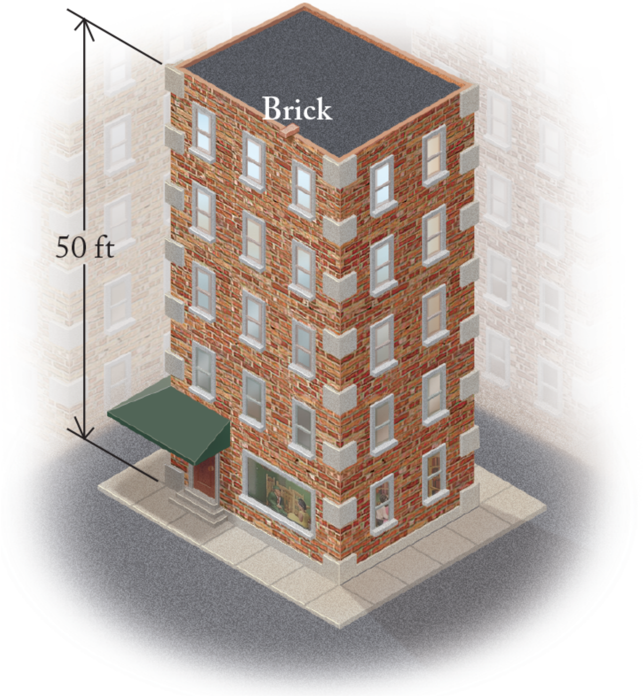


FIGURE P6.1

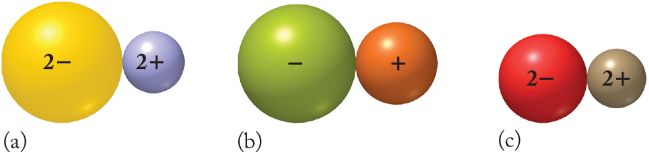
Figure P6.2 shows pairs of cations and anions in contact. The energy of each interaction is proportional to Q_1Q_2/d, where Q_1 and Q_2 are the charges on the cation and anion, and d is the distance between their nuclei. Which pair experiences the greatest attraction, and which experiences the smallest?



(a) (b) (c)

FIGURE P6.2

Figure P6.3 shows a sectional view of an assembly, consisting of a gas trapped inside a stainless-steel cylinder with a stainless-steel piston and a block of iron on top of the piston to keep it in place.

1. If the cylinder is heated for a few seconds with a blowtorch, is the piston higher or lower in the cylinder?
2. Has heat (q) been added to the system?
3. Has the system done work (w) on its surroundings, or have the surroundings done work on the system?

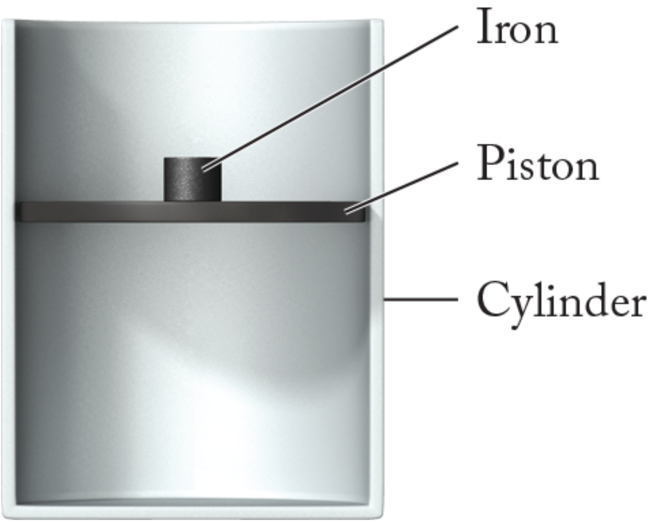


FIGURE P6.3

The closed, rigid, metal box lying on the wooden kitchen table in Figure P6.4 is about to be involved in an accident.

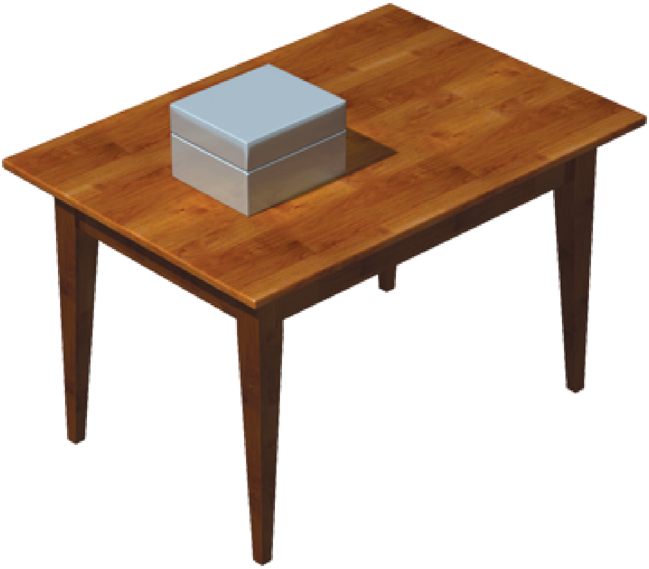

FIGURE P6.4

1. Are the contents of the box an isolated system, a closed system, or an open system?
2. What will happen to the internal energy of the system if the table catches fire and burns?
3. Will the system do any work on the surroundings while the fire is burning or after the table has burned away and collapsed?

The diagram in Figure P6.5 shows how a chemical reaction in a cylinder with a piston affects the volume of the system.

1. In this reaction, does the system do work on the surroundings?
2. If the reaction is endothermic, does the internal energy of the system increase or decrease when the reaction is

proceeding?

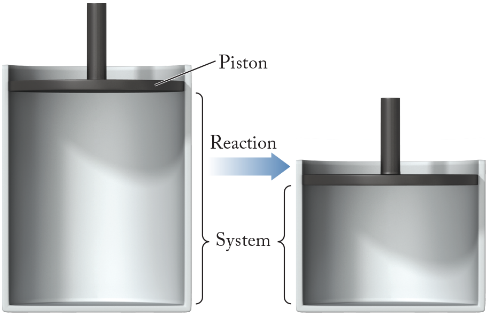

FIGURE P6.5

The enthalpy diagram in Figure P6.6 indicates the enthalpies of formation of four compounds made from the elements listed on the “zero” line of the vertical axis.

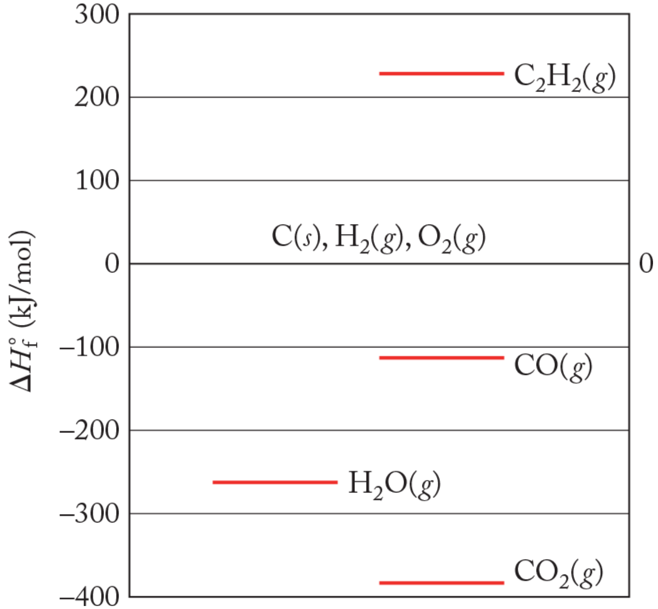

FIGURE P6.6

---

1. Why are the elements all put on the same horizontal line?
2. Why is $C_2H_2(g)$ sometimes called an “endothermic” compound?
3. How could the data be used to calculate the heat of the reaction that converts a stoichiometric mixture of

$C_2H_2(g)$ and $O_2(g)$ to $CO(g)$ and $H_2O(g)$?

The process illustrated in Figure P6.7 takes place at constant pressure.

1. Write a balanced equation for the process.
2. Is w positive, negative, or zero for this reaction?
3. Using data from Appendix 4, calculate $\Delta H^\circ_{\text{rxn}}$ for the formation of 1 mole of the product.

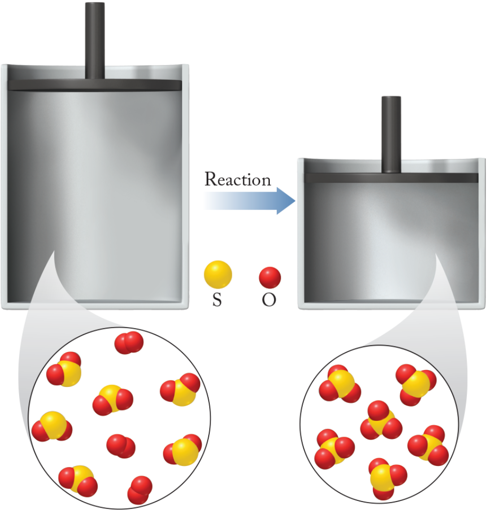

FIGURE P6.7

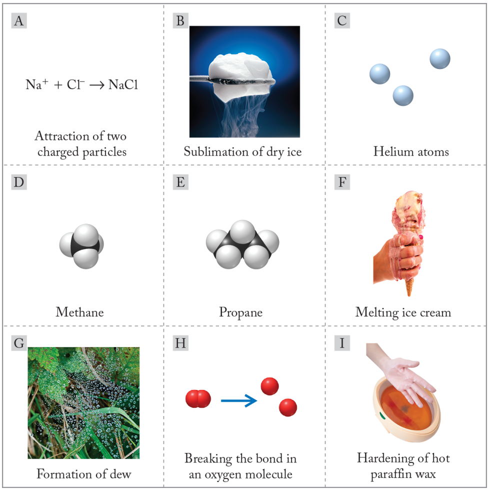
Use representations [A] through [I] in Figure P6.8 to answer questions (a)–(f).

1. Which processes are exothermic?
2. Which processes have a positive ΔH?
3. In which processes does the system gain energy?
4. In which processes do the surroundings lose energy?
5. Compare a flame of methane [D] at 1000°C to a flame of propane [E] at 1000°C in terms of (i) average kinetic energy and (ii) the average speed of the molecules.
6. Which substance(s) would *not* have vibrational motion or rotational motion? Why?



A
$Na^+ + Cl^- \rightarrow NaCl$
Attraction of two charged particles
B
Sublimation of dry ice
C
Helium atoms
D
Methane
E
Propane
F
Melting ice cream
G
Formation of dew
H
Breaking the bond in an oxygen molecule
I
Hardening of hot paraffin wax

FIGURE P6.8

QUESTIONS AND PROBLEMS

Forms of Energy

Concept Review

How are energy and work related?

Explain the difference between potential energy and kinetic energy.

Explain what is meant by a state function.

Are kinetic energy and potential energy both state functions?

Explain the nature of the potential energy in the following: (a) the new battery for your remote control; (b) a gallon of gasoline; (c) the crest of a wave before it crashes onto shore.

Explain the kinetic energy in a stationary ice cube.

Systems, Surroundings, and Energy Transfer

Concept Review

What is meant by the terms *system* and *surroundings*?

Do all exothermic processes that do work on the surroundings have the same sign for ΔE?

Why don't all endothermic processes that do work on the surroundings have the same sign for ΔE?

Does the amount of *P*–*V* work done by a gas on its surroundings depend on the identity of the gas?

Problems

Which of the following processes are exothermic, and which are endothermic? (a) a candle burns; (b) rubbing alcohol feels cold on the skin; (c) a supersaturated solution crystallizes, causing the temperature of the solution to rise

Which of the following processes are exothermic, and which are endothermic? (a) frost forms on a car window in the winter; (b) water condenses on a glass of ice water on a humid summer afternoon; (c) adding ammonium nitrate to water causes the temperature of the solution to decrease

What happens to the internal energy of a liquid at its boiling point when it vaporizes?

What happens to the internal energy of a gas when it expands (with no heat flow)?

Atmospheric Research Atmospheric scientists often use balloons to carry their instruments aloft. How much *P*–*V* work does a gas in a balloon do on its surroundings at a constant pressure of 1.00 atm if the volume of gas increases from 1.250×10^5 L to 1.050×10^6 L? Express your answer in L · atm and joules (J).

An expanding gas does 150.0 J of work on its surroundings at a constant pressure of 1.01 atm. If the gas initially occupied 68 mL, what is the final volume of the gas?

Calculate ΔE for the following situations:

1. $q = 120.0$ J; $w = -40.0$ J
2. $q = 9.2$ kJ; $w = 0.70$ J
3. $q = -3625$ J; $w = -315$ J

Calculate ΔE for

1. the combustion of a gas that releases 210.0 kJ of heat to its surroundings and does 65.5 kJ of work on its surroundings.
2. a chemical reaction that produces 90.7 kJ of heat but does no work on its surroundings.

The following reactions take place in a cylinder equipped with a movable piston at atmospheric pressure (Figure P6.27). Which reactions will result in work being done on the surroundings? Assume the system returns to an initial temperature of 110°C. (*Hint*: The volume of a gas is proportional to number of moles, n, at constant temperature and pressure.)

1. $CH_4(g) + 2\ O_2(g) \rightarrow CO_2(g) + 2\ H_2O(g)$
2. $C_3H_8(g) + 5\ O_2(g) \rightarrow 3\ CO_2(g) + 4\ H_2O(g)$
3. $N_2(g) + 2\ O_2(g) \rightarrow 2\ NO_2(g)$

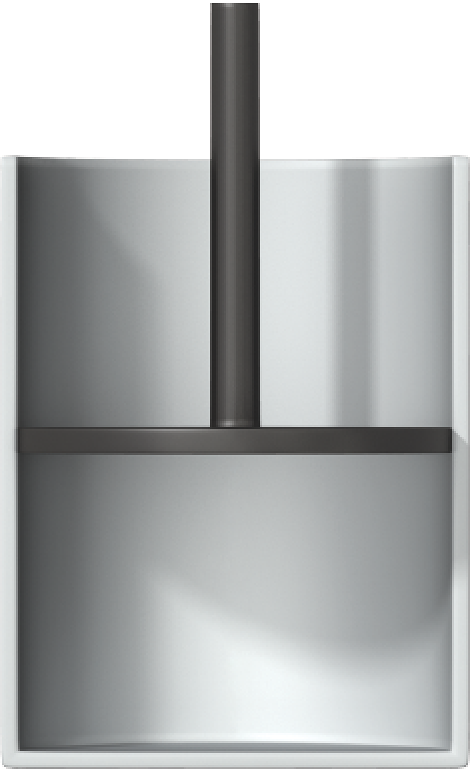


FIGURE P6.27

In which direction will the piston shown in Figure P6.27 move when the following reactions are carried out at atmospheric pressure inside the cylinder and after the system has returned to its initial temperature of 110°C? (*Hint*: The volume of a gas is proportional to number of moles, n, at constant temperature and pressure.)

1. $N_2(g) + 3\ H_2(g) \rightarrow 2\ NH_3(g)$
2. $C(s) + O_2(g) \rightarrow CO_2(g)$
3. $CH_3CH_2OH(g) + 3\ O_2(g) \rightarrow 2\ CO_2(g) + 3\ H_2O(g)$

Filling Air Bags Automobile air bags produce nitrogen gas from the reaction:

$2\ NaN_3(s) \rightarrow 2\ Na(s) + 3\ N_2(g)$

1. If 2.25 g of NaN_3 reacts to fill an air bag, how much *P–V* work will the N_2 do against an external pressure of 1.00 atm given that the density of nitrogen is 1.165 g/L at 20°C?
2. If the process releases 2.34 kJ of heat, what is ΔE for the system?

Black Powder Igniting gunpowder produces nitrogen and carbon dioxide gas that propels the bullet by the reaction:

$$2\ KNO_3(s) + \tfrac{1}{8}\ S_8(s) + 3\ C(s) \rightarrow K_2S(s) + N_2(g) + 3\ CO_2(g)$$

---

1. If 1.00 g of KNO_3 reacts, how much *P–V* work will the gases do against an external pressure of 1.00 atm given that the densities of nitrogen and CO_2 are 1.165 g/L and 1.830 g/L, respectively, at 20°C?
2. If the reaction produces 21.6 kJ of heat, what is ΔE for the system?

Enthalpy and Enthalpy Changes

Concept Review

What is meant by an *enthalpy change*?

Describe the difference between an internal energy change (ΔE) and an enthalpy change (ΔH).

Which symbol, ΔH_{comb} or ΔH_{fus}, refers to a physical change?

Which symbol, ΔH_{f} or ΔH_{fus}, refers to a chemical change?

Problems

A Clogged Sink Adding Drano to a clogged sink causes the drainpipe to get warm. What is the sign of ΔH for this process?

Hot Packs for Cold Fingers Skiers can purchase small packets of finely divided iron that, after reaction with water, provide heat to frozen fingers and toes (Figure P6.36). Define the system and the surroundings in this example and indicate the sign of ΔH_{sys}.

Diatomic Elements The stable forms of hydrogen and oxygen at room temperature and pressure are gas phase, diatomic molecules H_2 and O_2. What is the sign of ΔH for the following processes?

1. A solid with metallic properties is formed when hydrogen gas is compressed under extremely high pressures:

$H_2(g) \rightarrow H_2(s)$

2. High-energy light shines on oxygen gas in the upper reaches of the atmosphere, converting oxygen gas to oxygen atoms:

$O_2(g) \rightarrow 2\ O(g)$

White Phosphorus Elemental phosphorus is found in several allotropes, including white phosphorous, $P_4(s)$. Predict the sign of the enthalpy change for the following reactions:

$P_4(s) \rightarrow P_4(g)$

$P_4(g) \rightarrow 2\ P_2(g)$

$4\ P(g) \rightarrow P_4(s)$

Plaster of Paris Gypsum is the common name of calcium sulfate dihydrate ($CaSO_4 \cdot 2\ H_2O$). When gypsum is heated to 150°C, it loses most of the water in its formula and forms plaster of Paris ($CaSO_4 \cdot 0.5\ H_2O$):

$2\ (CaSO_4 \cdot 2\ H_2O)(s) \rightarrow 2\ (CaSO_4 \cdot 0.5\ H_2O)(s) + 3\ H_2O(g)$

What is the sign of ΔH for making plaster of Paris from gypsum?

Kitchen Chemistry A simple "kitchen chemistry" experiment requires placing some vinegar in a soda bottle. A deflated balloon containing baking soda is stretched over the mouth of the bottle. Adding the baking soda to the vinegar starts the following reaction and inflates the balloon:

$NaHCO_3(aq) + CH_3COOH(aq) \rightarrow CH_3COONa(aq) + CO_2(g) + H_2O(\ell)$

If the contents of the bottle are considered the system, is work being done on the surroundings or on the system?

Heating Curves, Molar Heat Capacity, and Specific Heat

Concept Review

What is the difference between *specific heat* and *molar heat capacity*?

What happens to the molar heat capacity of a material if its mass is doubled? Is the same true for the specific heat?

Are the enthalpies of fusion and vaporization of a given substance usually the same?

An equal amount of energy is added to pieces of metal A and metal B that have the same mass. Why does the metal with the smaller specific heat reach the higher temperature?

Cooling an Automobile Engine Most automobile engines are cooled by water circulating through them and a radiator, but the original Volkswagen Beetle had an air-cooled engine. Why might car designers choose water cooling over air cooling?

Nuclear Reactor Coolants The reactor-core cooling systems in some nuclear power plants use liquid sodium as the coolant. Sodium has a thermal conductivity of 1.42 J/(cm · s · K), which is quite high compared with that of water [6.1×10^{-3} J/(cm · s · K)]. The respective molar heat capacities are 28.28 J/(mol · K) and 75.31 J/(mol · K). What is the advantage of using liquid sodium over water in this application?

Problems

How much energy is required to raise the temperature of 100.0 g of water from 30.0°C to 100.0°C?

Cooking in the Mountains At an elevation where the boiling point of water is 93°C, 100.0 g of water at 30°C absorbs 290.0 kJ of energy from a mountain climber's stove. Is this amount of energy sufficient to heat the water to its boiling point?

Use the following data to sketch a heating curve for 1 mole of methanol. Start the curve at − 100°C and end it at 100°C.

Boiling point	65°C
Melting point	−94°C
ΔH_{vap}	37 kJ/mol
ΔH_{fus}	3.18 kJ/mol
Molar heat capacity (*s*)	48.7 J/(mol · °C)
(*l*)	81.1 J/(mol · °C)
(*g*)	43.9 J/(mol · °C)

Use the following data to sketch a heating curve for 1 mole of octane. Start the curve at -57°C and end it at 150°C.

Boiling point	125.7°C
Melting point	−56.8°C
ΔH_{vap}	41.5 kJ/mol
ΔH_{fus}	20.7 kJ/mol
Molar heat capacity (ℓ)	254.6 J/(mol · °C)
Molar heat capacity (g)	316.9 J/(mol · °C)

Keeping an Athlete Cool During a strenuous workout, an athlete generates 2000.0 kJ of energy. What mass of water would have to evaporate from the athlete's skin to dissipate this much heat?

Hypothermia Damp clothes can prove fatal when outdoor temperatures drop (death by hypothermia).

1. If the clothes you are wearing absorb 1.00 kg of water and then dry in a cold wind on Mount Washington, how much heat would your body lose during this process? $cP,H_2O = 75.3$ J/(mol · °C), and $\Delta H_{vap,HO} = 40.67$ kJ/mol.
2. If the heat lost by your body is not replaced, what will the final temperature of your body be after the 1.00 kg of water has evaporated? Use your own body weight and assume that the specific heat of your body is 4.25 J/g. (The specific heat is given in units of J/g.)

The same quantity of energy is added to 10.00 g pieces of gold, magnesium, and platinum, all initially at 25°C. The molar heat capacities of these three metals are 25.41 J/(mol · °C), 24.79 J/(mol · °C), and 25.95 J/(mol · °C), respectively. Which piece of metal has the highest final temperature?

Which of the following would reach the higher temperature after 10.00 g of iron [$c_P = 25.1$ J/(mol · °C)] at 150°C is added: 100 mL of water [$d = 1.00$ g/mL, $c_P = 75.3$ J/(mol · °C)] or 200 mL of ethanol [CH_3CH_2OH, $d = 0.789$ g/mL, $c_P =$

113.1 J/(mol · °C)]?

Exactly 10.0 mL of water at 25.0°C is added to a hot iron skillet. All the water is converted into steam at 100.0°C. The mass of the pan is 1.20 kg and the molar heat capacity of iron is 25.19 J/(mol · °C). What is the temperature change of the skillet?

A 20.0 g piece of iron and a 20.0 g piece of gold, both at 100.0°C, were dropped into the same 1.00 L of water at 20.0°C. The molar heat capacities of iron and gold are 25.19 J/(mol · °C) and 25.41 J/(mol · °C), respectively. What is the final temperature of the water and the pieces of metal?

Calorimetry: Measuring Heat Capacity and Enthalpies of Reaction

Concept Review

Why is it necessary to know the heat capacity of a calorimeter?

Could an endothermic reaction be used to measure the heat capacity of a calorimeter?

If we replace the water in a bomb calorimeter with another liquid, why do we need to redetermine the heat capacity of the calorimeter?

When measuring the enthalpy of combustion of a very small amount of material, would you prefer to use a calorimeter having a heat capacity that is small or large? Explain your reasoning.

Problems

Designing Cold Packs If you were designing a chemical cold pack, which of the following salts would you choose to provide the greatest drop in temperature per gram: NH_4Cl ($\Delta H_{soln} = 14.6$ kJ/mol), NH_4NO_3 ($\Delta H_{soln} = 25.7$ kJ/mol), or $NaNO_3$ ($\Delta H_{soln} = 20.4$ kJ/mol)?

Dissolving calcium hydroxide ($\Delta H_{soln} = -16.2$ kJ/mol) in water is an exothermic process. How much lithium hydroxide ($\Delta H_{soln} = -23.6$ kJ/mol) would be required to produce the same amount of energy as dissolving 15.00 g of $Ca(OH)_2$?

The standard enthalpy of combustion of benzoic acid (molar mass 122 g/mol) is -3225 kJ/mol. Calculate the heat capacity of a bomb calorimeter if a temperature increase of 2.16°C occurs on combusting 0.500 g of benzoic acid in the presence of excess O_2.

Burning 1.43 g of methane [$CH_4(g)$, molar mass 16.0 g/mol] with excess O_2 raised the temperature of 250 g of water in a bomb calorimeter from 22°C to 98°C. Calculate the molar enthalpy of combustion of methane.

The complete combustion of 1.200 g of cinnamaldehyde (C_9H_8O, one of the compounds in cinnamon) in a bomb calorimeter ($C_{calorimeter} = 3.640$ kJ/°C) produced an increase in temperature of 12.79°C. Calculate the molar enthalpy of combustion of cinnamaldehyde (ΔH_{comb}) in kilojoules per mole of cinnamaldehyde.

Aromatic Spice The aromatic hydrocarbon cymene ($C_{10}H_{14}$) is found in nearly 100 spices and fragrances, including coriander, anise, and thyme. The complete combustion of 1.608 g of cymene in a bomb calorimeter ($C_{calorimeter} = 3.640$ kJ/°C) produced an increase in temperature of 19.35°C. Calculate the molar enthalpy of combustion of cymene (ΔH_{comb}) in kilojoules per mole of cymene.

Hormone Mimics Phthalates, used to make plastics flexible, are among the most abundant industrial contaminants in the environment. Several have been shown to act as hormone mimics in humans by activating the receptors for estrogen, a female sex hormone. In characterizing the compounds completely, the value of ΔH_{comb} for dimethyl phthalate ($C_{10}H_{10}O_4$) was determined to be $-$ 4685 kJ/mol. Assume that 1.00 g of dimethyl phthalate is combusted in a calorimeter whose heat capacity ($C_{\text{calorimeter}}$) is 7.854 kJ/°C at 20.215°C. What is the final temperature of the calorimeter?

Diborane, B_2H_6, was once considered for use as a rocket fuel. It is a highly reactive gas, burning with a green flame in air.

$B_2H_6(g) + 3\ O_2(g) \rightarrow B_2O_3(s) + 3\ H_2O(g)$

The ΔH_{comb} value for diborane is $-$ 1958 kJ/mol. Assume 0.368 g of diborane is combusted in a calorimeter whose heat capacity ($C_{\text{calorimeter}}$) is 7.854 kJ/°C at 20.611°C. What is the final temperature of the calorimeter?

Adding 2.00 g of Mg metal to 95.0 mL of 1.00 *M* HCl in a coffee-cup calorimeter leads to a temperature increase of 9.2°C.

1. Write a balanced net ionic equation for the reaction.
2. If the molar heat capacity of 1.00 *M* HCl is the same as that for water [$c_P = 75.3$ J/(mol · °C)], what is ΔH_{rxn}?

What is ΔH_{rxn} for the precipitation of AgCl if adding 125 mL of 1.00 *M* $AgNO_3$ to 125 mL of 1.00 *M* NaCl at 18.6°C causes the temperature to increase to 26.4°C? (Assume $c_{P,\text{soln}} = c_{P,\text{water}}$.)

How much glucose must be metabolized to completely evaporate 1.00 g of water at 37°C, given $\Delta H_{\text{comb,glucose}} = -$ 2803 kJ/mol?

If all the energy obtained from burning 275 g of propane ($\Delta H_{\text{comb},C_3H_8} = -2220$ kJ/mol) is used to heat water, how many liters of water can be heated from 20.0°C to 100.0°C?

Hess's Law

Concept Review

How is Hess's law consistent with the law of conservation of energy?

Why is it important for Hess's law that enthalpy is a state function?

Problems

How can the first two of the following reactions be combined to obtain the third reaction?

$CO(g)$ 1.+ $NH_3(g) \rightarrow HCN(g) + H_2O(g)$
$CO(g)$ 2.+ $3\ H_2(g) \rightarrow CH_4(g) + H_2O(g)$
$CH_4(g)$3.+ $NH_3(g) \rightarrow HCN(g) + 3\ H_2(g)$

Cleansing the Atmosphere The atmosphere contains the highly reactive molecule OH, which acts to remove selected pollutants. Use the values for ΔH_{rxn} given below to find the ΔH_{rxn} for the formation of OH and H from water.

$$\tfrac{1}{2}\,H_2(g) + \tfrac{1}{2}\,O_2(g) \rightarrow OH(g) \qquad \Delta H_{rxn} = 42.1\text{ kJ}$$
$$H_2(g) \rightarrow 2\,H(g) \qquad \Delta H_{rxn} = 435.9\text{ kJ}$$
$$H_2(g) + \tfrac{1}{2}\,O_2(g) \rightarrow H_2O(g) \qquad \Delta H_{rxn} = -241.8\text{ kJ}$$
$$H_2O(g) \rightarrow H(g) + OH(g) \qquad \Delta H_{rxn} = ?$$

Ozone Layer The destruction of the ozone layer by chlorofluorocarbons (CFCs) can be described by the following reactions:

$ClO(g) + O_3(g) \rightarrow Cl(g) + 2\ O_2(g) \qquad \Delta H_{rxn} = -\ 29.90\text{ kJ}$

$2\ O_3(g) \rightarrow 3\ O_2(g) \qquad \Delta H_{rxn} = 24.18\text{ kJ}$

Determine the value of the heat of reaction for the following:

$Cl(g) + O_3(g) \rightarrow ClO(g) + O_2(g)$ $\Delta H_{rxn} = ?$

Low-Emission Vehicles Adding ammonia to the exhaust gases from motor vehicles can reduce the emissions of nitrogen oxide pollutants through selective catalytic reduction (SCR):

$6\ NO(g) + 4\ NH_3(g) \rightarrow 5\ N_2(g) + 6\ H_2O(g)$ $\Delta H°rxn = -1807$ kJ

$6\ NO_2(g) + 8\ NH_3(g) \rightarrow 7\ N_2(g) + 12\ H_2O(g)$ $\Delta H°rxn = -2730$ kJ

Determine the value of the heat of reaction for the following:

$3\ NO(g) + N_2(g) + 3\ H_2O(g) \rightarrow 3\ NO_2(g) + 2\ NH_3(g)$ $\Delta H°rxn = ?$ kJ

Standard Enthalpies of Formation and Reaction

Concept Review

Explain how the use of $\Delta H°f$ to calculate $\Delta H°rxn$ is an example of Hess's law.

Why is the standard enthalpy of formation of $CO(g)$ difficult to measure experimentally?

Are the standard enthalpies of formation of all allotropes of an element the same? Explain.

Explain why the heats of formation of elements in their standard states are zero.

Problems

For which of the following reactions does $\Delta H°rxn$ represent an enthalpy of formation?

$C(s) + 1O_2(g) \rightarrow CO_2(g)$

2. $CO_2(g) + C(s) \rightarrow 2\ CO(g)$
3. $CO_2(g) + H_2(s) \rightarrow H_2O(g) + CO(g)$
4. $2\ H_2(g) + C(s) \rightarrow CH_4(g)$

For which of the following reactions does ΔH°rxn also represent an enthalpy of formation?

1. $2\ N_2(g) + 3\ O_2(g) \rightarrow 2\ NO_2(g) + 2\ NO(g)$
2. $N_2(g) + O_2(g) \rightarrow 2\ NO(g)$
3. $2\ NO_2(g) \rightarrow N_2O_4(g)$
4. $N_2(g) + 2\ O_2(g) \rightarrow 2\ NO_2(g)$

Use the following standard heats of formation to calculate the molar enthalpy of vaporization of liquid hydrogen peroxide: ΔH°f of $H_2O_2(\ell)$ is − 188 kJ/mol and ΔH°f of $H_2O_2(g)$ is − 136 kJ/mol.

Use the following standard heats of formation to calculate the molar enthalpy of vaporization of acetic acid: ΔH°f of $CH_3COOH(\ell)$ is − 484.5 kJ/mol and ΔH°f of $CH_3COOH(g)$ is − 432.8 kJ/mol.

Methanogenesis Some methanogenic bacteria use acetic acid (CH_3COOH) and hydrogen to make methane. Write a balanced chemical reaction for the synthesis of methane and water from hydrogen and acetic acid and calculate the standard enthalpy of the reaction by using the appropriate enthalpies of formation from Appendix 4.

Military Explosives Explosives called amatols are mixtures of ammonium nitrate and trinitrotoluene (TNT). They were introduced during World War I when TNT was in short supply. The mixtures can provide 30% more explosive power than TNT alone. Above 300°C, ammonium nitrate decomposes to N_2, O_2, and H_2O. Write a balanced chemical equation describing the decomposition of ammonium nitrate and determine the standard enthalpy of reaction by using the appropriate standard enthalpies of formation from Appendix 4.

Improvised Explosives Mixtures of fertilizer (ammonium nitrate) and fuel oil (a mixture of long-chain hydrocarbons such as decane, $C_{10}H_{22}$) can produce powerful explosions. Determine the enthalpy change of the following explosive reaction by using the appropriate enthalpies of formation $(\Delta(\Delta H^\circ{}_{f,C10H22} = 249.7$ kJ/mol):

$3\ NH_4NO_3(s) + C_{10}H_{22}(\ell) + 14\ O_2(g) \rightarrow 3\ N_2(g) + 17\ H_2O(g) + 10\ CO_2(g)$

A Little TNT Trinitrotoluene (TNT) is a highly explosive compound. The thermal decomposition of TNT is described by the following chemical equation:

$2\ C_7H_5N_3O_6(s) \rightarrow 12\ CO(g) + 5\ H_2(g) + 3\ N_2(g) + 2\ C(s)$

If ΔH_{rxn} for this reaction is $-$ 10,153 kJ, how much TNT is needed to equal the explosive power of 1 mole of ammonium nitrate (Problem 6.89)?

How can the standard enthalpy of formation ΔH°f of CO(*g*) be calculated from the standard enthalpy of formation ΔH°f of $CO_2(g)$ and the standard enthalpy of combustion ΔH°comb of CO(*g*)?

The Martian In the motion picture *The Martian*, a stranded astronaut uses hydrazine, N_2H_4, to produce hydrogen, which he then reacts with oxygen to make water. The enthalpy of the reaction between N_2H_4 and O_2 is ΔH°rxn $= -$ 622 kJ. Calculate the standard enthalpy of formation of $N_2H_4(\ell)$ from the standard enthalpy changes of the following reactions:

$N_2H_4(\ell) + O_2(g) \rightarrow N_2(g) + 2\ H_2O(g) \qquad \Delta H^\circ_{rxn} = -622\ kJ$

$H_2(g) + \frac{1}{2}\ O_2(g) \rightarrow H_2O(g) \qquad \Delta H^\circ_{rxn} = -285.8\ kJ$

$N_2(g) + 2\ H_2(g) \rightarrow N_2H_4(\ell) \qquad \Delta H^\circ_{rxn} = ?$

Burning Phosphorus White phosphorus, P_4, ignites in air to form P_4O_{10} in a rapid reaction used in incendiary devices. Red phosphorus, an allotrope of element 15, also reacts with O_2 in air to form the same product, but at a much slower rate. What is ΔH_f for red phosphorus,

$P_4(\mathit{white}, s) \rightarrow 4\ P(\mathit{red}, s) \qquad \Delta H_{\mathrm{rxn}} = ?$

given ΔH_{rxn} for the following reactions?

$P_4(\mathit{white}, g) + 5\ O_2(g) \rightarrow P_4O_{10}(g) \qquad \Delta H_{\mathrm{rxn}} = -\ 3036\ \mathrm{kJ}$

$4\ P(\mathit{red}, g) + 5\ O_2(g) \rightarrow P_4O_{10}(g) \qquad \Delta H_{\mathrm{rxn}} = -\ 3018\ \mathrm{kJ}$

Baking soda decomposes on heating as follows:

$2\ NaHCO_3(s) \rightarrow Na_2CO_3(s) + CO_2(g) + H_2O(\ell)$

$\Delta H^\circ_{\mathrm{rxn}} = -\ 129.3\ \mathrm{kJ}$

Calculate the standard enthalpy of formation of $NaHCO_3(s)$ using the following information:

$\Delta H^\circ_f[CO_2(g)] = -\ 394\ \mathrm{kJ/mol}$

$\Delta H^\circ_f[Na_2CO_3(s)] = -\ 1131\ \mathrm{kJ/mol}$

$\Delta H^\circ_f[H_2O(\ell)] = -\ 286\ \mathrm{kJ/mol}$

Fuels, Fuel Values, and Food Values

Concept Review

What is meant by *fuel value*?

What are the units of fuel values?

How are fuel values calculated from molar enthalpies of combustion?

Is the fuel value of liquid propane the same as that of propane gas?

Problems

Flex Fuel Vehicles An increasing number of vehicles in the United States can run on either gasoline [$C_9H_{20}(\ell)$, $\Delta H_{\mathrm{comb,gasoline}} = -6160$ kJ/mol] or ethanol [$CH_3CH_2OH(\ell)$, $\Delta H_{\mathrm{comb,ethanol}} = -1367$ kJ/mol].

1. Which fuel has the greater fuel value?
2. The densities of C_9H_{20} and CH_3CH_2OH are 0.718 g/mL and 0.794 g/mL, respectively. Which has the greater fuel value expressed as kJ/L?

Arctic Exploration Food contains three main categories of compounds: carbohydrate, protein, and fat. Arctic explorers often eat a high-fat diet because fats have a high food value. The average food values for carbohydrate, protein, and fat are 4 Cal/g, 4 Cal/g, and 9 Cal/g, respectively. A typical fat has the chemical formula $C_{18}H_{36}O_2$, glucose ($C_6H_{12}O_6$) is a representative carbohydrate, and the amino acid alanine ($C_3H_6NO_2$) is a building block of proteins. Express the food values given above as ΔH_{comb} in kJ/mol.

Biofuels The microorganism *C. acetobutylicum* can convert glucose into butanol ($C_4H_{10}O$). Butanol is touted as a better renewable biofuel than ethanol.

1. Calculate the fuel value of $C_4H_{10}O$, given that $\Delta H^{\circ}\mathrm{comb} = -2676$ kJ/mol.
2. How much energy is released during the combustion of 1.00 kg of $C_4H_{10}O$?
3. How many grams of $C_4H_{10}O$ must be burned to heat 1.00 kg of water from 25.0°C to 85.0°C? Assume that all the energy released during combustion is used to heat the water.

Biofuels in Brazil In response to increasing need for energy selfsufficiency, Brazil has managed to convert almost all its automobiles to burn ethanol (CH_3CH_2OH) as fuel.

1. Use the values for ΔH°f from Appendix 4 to calculate the fuel value of ethanol.
2. How much energy is released during the combustion of 1.00 kg of CH_3CH_2OH?
3. How many grams of CH_3CH_2OH are needed to heat 1.00 kg of water from 25.0°C to 85.0°C? Assume that all the energy released during combustion is used to heat the water.
4. Is the amount of CH_3CH_2OH needed greater than or less than the amount of butanol ($C_4H_{10}O$) needed to heat 1.00 kg of water from 25.0°C to 85.0°C (see Problem 6.101)?

Additional Problems

Diagnosing Car Trouble Mechanics sometimes use diethyl ether ($CH_3CH_2OCH_2CH_3$) to diagnose starting problems in vehicles because it has a low ignition temperature. If sprayed into the air intake, it can help determine whether the spark and ignition system of the car are functioning, and the fuel delivery system is not. If the normal fuel is not entering the engine, the engine will run only until the diethyl ether vapors are completely burned. Compare the fuel value and fuel density of diethyl ether ($\Delta H^\circ_{\text{comb}} = -2726.3$ kJ/mol; density $=$ 0.7134 g/mL) to that of diesel oil (determined in Sample Exercise 6.16).

The standard enthalpies of combustion of ethyne [$C_2H_2(g)$], $C(s)$, and $H_2(g)$ are -1299.6, -393.5, and -285.9 kJ/mol, respectively. Use this information to calculate the standard enthalpy of formation of ethyne.

Carbon tetrachloride (CCl_4) was at one time used as a fire-extinguishing agent. It has a molar heat capacity of 131.3 J/(mol · °C). How much energy is required to raise the temperature of 275 g of CCl_4 from room temperature (22°C) to its boiling point (77°C)?

Ethylene glycol ($HOCH_2CH_2OH$) is mixed with the water in radiators to cool car engines. How much heat will 725 g of pure ethylene glycol remove from an engine as it is warmed from 0°C to its boiling point of 196°C? The c_P of ethylene glycol is 149.5 J/(mol · °C).

Sodium may be used as a heat-storage material in some devices. The specific heat (c_s) of sodium metal is 1.23 J/(g · °C). How many moles of sodium metal are required to absorb 1.00×10^3 kJ of energy?

The water in a bomb calorimeter was replaced with the organic compound methylene chloride (CH_2Cl_2). Burning 2.23 g of glucose ($C_6H_{12}O_6$; $\Delta H_{comb} = -2801$ kJ/mol) in the calorimeter causes its temperature to rise 9.64°C. What is the heat capacity of the calorimeter?

The standard enthalpy of formation of NH_3 is $-$ 46.1 kJ/mol. What is ΔH°_{rxn} for the following reactions?

a. $N_2(g) + 3\,H_2(g) \rightarrow 2\,NH_3(g)$

b. $NH_3(g) \rightarrow \frac{3}{2}\,H_2(g) + \frac{1}{2}\,N_2(g)$

Hung Out to Dry Laundry left outside to dry on a clothesline in the winter slowly dries by sublimation. The increase in internal energy of water vapor produced by sublimation is less than the amount of heat absorbed. Explain.

Chlorofluorocarbons (CFCs) such as CF_2Cl_2 are refrigerants whose use has been phased out because of their destructive effect on Earth's ozone layer. The standard enthalpy of vaporization of CF_2Cl_2 is 17.4 kJ/mol, compared with $\Delta H^\circ_{vap} = 40.67$ kJ/mol for liquid water. How many grams of liquid CF_2Cl_2 are needed to cool 200.0 g of water from 50.0°C to 40.0°C? The specific heat of water is 4.184 J/(g · °C).

A 100.0 mL sample of 1.0 *M* NaOH is mixed with 50.0 mL of 1.0 *M* H_2SO_4 in a large Styrofoam coffee cup; the cup is fitted with a lid through which a calibrated thermometer passes. The temperature of each solution before mixing is 22.3°C. After the NaOH solution is added to the coffee cup and the mixed solutions are stirred with the thermometer, the maximum temperature measured is 31.4°C. Assume that the density of the mixed solutions is 1.00 g/mL, the specific heat of the mixed solutions is 4.18 J/(g · °C), and no heat is lost to the surroundings.

1. Write a balanced chemical equation for the reaction that takes place in the Styrofoam cup.
2. Is any NaOH or H_2SO_4 left in the Styrofoam cup when the reaction is over?
3. Calculate the enthalpy change per mole of H_2SO_4 in the reaction.

Varying the scenario in Problem 6.112, assume this time that 65.0 mL of 1.0 *M* H_2SO_4 is mixed with 100.0 mL of 1.0 *M* NaOH and that both solutions are initially at 25.0°C. Assume that the mixed solutions in the Styrofoam cup have the same density and specific heat as in Problem 6.112 and no heat is lost to the surroundings. What is the maximum measured temperature in the Styrofoam cup?

An insulated container is used to hold 50.0 g of water at 25.0°C. A 7.25 g sample of copper is placed in a dry test tube and heated for 30 min in a boiling water bath at 100.1°C. The heated test tube is carefully removed from the water bath with laboratory tongs and inclined so that the copper slides into the water in the insulated container. Given that the specific heat of solid copper is 0.385 J/(g · °C), calculate the maximum temperature of the water in the insulated container after the copper metal is added.

The mineral magnetite (Fe_3O_4) is magnetic, whereas iron(II) oxide is not.

1. Write and balance the chemical equation for the formation of magnetite from iron(II) oxide and oxygen.
2. Given that 318 kJ of heat is released for each mole of Fe_3O_4 formed, what is the enthalpy change of the balanced reaction of formation of Fe_3O_4 from iron(II) oxide and oxygen?

Which of the following substances has a standard enthalpy of formation equal to zero? (a) Pb at 1000°C; (b) $C_3H_8(g)$ at 25.0°C and 1 atm pressure; (c) solid glucose at room temperature; (d) $N_2(g)$ at 25.0°C and 1 atm pressure

The standard enthalpy of formation of liquid water is $-$ 285.8 kJ/mol.

1. What is the significance of the negative sign associated with this value?
2. Why is the magnitude of this value so much larger than the enthalpy of vaporization of water ($\Delta H^\circ_{vap} = 40.67$ kJ/mol)?
3. Calculate the amount of heat produced in making 50.0 mL of water from its elements under standard conditions.

Acetylene, C_2H_2 ($\Delta H^\circ_f = 226.7$ kJ/mol), and benzene, C_6H_6 ($\Delta H^\circ_f = 49.0$ kJ/mol), are sometimes referred to as endothermic compounds.

1. Why are C_2H_2 and C_6H_6 called endothermic compounds?
2. Calculate the standard molar enthalpy of combustion of acetylene and benzene.

Balance the following chemical equation, name the reactants and products, and calculate the standard enthalpy change by using the data in Appendix 4.

$FeO(s) + O_2(g) \rightarrow Fe_2O_3(s)$

Add reactions 1, 2, and 3, and label the resulting reaction 4. Consult Appendix 4 to find the standard enthalpy change for the balanced reaction 4.

(1) $Zn(s) + \frac{1}{8}\,S_8(s) \rightarrow ZnS(s)$

(2) $ZnS(s) + 2\,O_2(g) \rightarrow ZnSO_4(s)$

(3) $\frac{1}{8}\,S_8(s) + O_2(g) \rightarrow SO_2(g)$

Rocket Plane Fuel The X37B surveillance plane under development uses a mixture of hydrazine (N_2H_4) and dinitrogen tetroxide (N_2O_4) as fuel.

1. The standard enthalpies of formation of $N_2H_4(g)$, $N_2O_4(g)$, and $H_2O(g)$ are 95.35, 9.2, and $-$ 241.8 kJ/mol, respectively. Use this information to calculate the standard enthalpy of the following reaction:

$$2\ N_2H_4(g) + N_2O_4(g) \rightarrow 3\ N_2(g) + 4\ H_2O(g)$$

2. Would more energy be released if the hydrazine was in the liquid state if $\Delta\Delta H°_{f,N2H4,l} = 50.63$ kJ/mol?

The specific heat of solid copper is 0.385 J/(g · °C). What thermal energy change occurs when a 35.3 g sample of copper is cooled from 35.0°C to 15.0°C? Be sure to give your answer the proper sign. This amount of energy is used to melt solid ice at 0.0°C. The molar enthalpy of fusion of ice is 6.01 kJ/mol. How many moles of ice are melted?

Metabolism of Methanol Methanol is toxic because it is metabolized in a two-step process *in vivo* to formic acid (HCOOH). Consider the following overall reaction under standard conditions:

$$O_2(g) + 2\ CH_3OH(\ell) \rightarrow 2\ HCOOH(\ell) + 2\ H_2O(\ell)$$

1. Is this reaction endothermic or exothermic?
2. What is the value of $\Delta H°_{rxn}$ for this reaction?

3. How much energy would be absorbed or released if 60.0 g of methanol were metabolized in this reaction?
4. In the first step of metabolism, methanol is converted into formaldehyde (CH_2O), which is then converted into formic acid. Would you expect $\Delta H^\circ_{\text{rxn}}$ for the metabolism of 1 mole of $CH_3OH(\ell)$ producing 1 mole of formaldehyde to be larger or smaller than 509.8 kJ?

Use Hess's law and the following data to calculate the standard enthalpy of formation of ethanol, $CH_3CH_2OH(\ell)$.

$$CH_3CH_2OH(\ell) + 3\,O_2(g) \rightarrow 2\,CO_2(g) + 3\,H_2O(\ell) \qquad \Delta H^\circ_{\text{rxn}} = -1368.2\ \text{kJ/mol}$$

$$C(s) + O_2(g) \rightarrow CO_2(g) \qquad \Delta H^\circ_{\text{f}} = -393.5\ \text{kJ/mol}$$

$$H_2(g) + \tfrac{1}{2}\,O_2(g) \rightarrow H_2O(\ell) \qquad \Delta H^\circ_{\text{f}} = -285.9\ \text{kJ/mol}$$

Use Hess's law and the following data to calculate the standard enthalpy of formation of $CH_4(g)$.

$$C(s) + O_2(g) \rightarrow CO_2(g) \qquad \Delta H^\circ_{\text{f}} = -393.5\ \text{kJ/mol}$$

$$H_2(g) + \tfrac{1}{2}\,O_2(g) \rightarrow H_2O(\ell) \qquad \Delta H^\circ_{\text{f}} = -285.9\ \text{kJ/mol}$$

$$CO_2(g) + 2\,H_2O(\ell) \rightarrow CH_4(g) + 2\,O_2(g) \qquad \Delta H^\circ_{\text{rxn}} = -890.4\ \text{kJ/mol}$$

The reaction of $CH_3OH(g)$ with $N_2(g)$ to give $HCN(g)$ and $NH_3(g)$ requires 164 kJ/mol of heat.

1. Write a balanced chemical equation for this reaction.
2. Should the thermal energy involved be written as a reactant or as a product?
3. What is the enthalpy change in the reaction of 60.0 g of $CH_3OH(g)$ with excess $N_2(g)$ to give $HCN(g)$ and $NH_3(g)$ in this reaction?

Calculate $\Delta H^\circ_{\text{rxn}}$ for the reaction

$$2\,Ni(s) + \tfrac{1}{4}\,S_8(s) + 3\,O_2(g) \rightarrow 2\,NiSO_3(s)$$

from the following information:

(1) $NiSO_3(s) \rightarrow NiO(s) + SO_2(g)$ $\Delta H^\circ_{rxn} = 156$ kJ

(2) $\frac{1}{8} S_8(s) + O_2(s) \rightarrow SO_2(g)$ $\Delta H^\circ_f = -297$ kJ

(3) $Ni(s) + \frac{1}{2} O_2(g) \rightarrow NiO(s)$ $\Delta H^\circ_f = -241$ kJ

Use the following information to calculate the enthalpy change involved in the complete reaction of 3.0 g of carbon to form $PbCO_3(s)$ in reaction 4. Be sure to give the proper sign (positive or negative) with your answer.

(1) $Pb(s) + \frac{1}{2} O_2(g) \rightarrow PbO(s)$ $\Delta H^\circ_{rxn} = -219$ kJ

(2) $C(s) + O_2(g) \rightarrow CO_2(g)$ $\Delta H^\circ_{rxn} = -394$ kJ

(3) $PbCO_3(s) \rightarrow PbO(s) + CO_2(g)$ $\Delta H^\circ_{rxn} = 86$ kJ

(4) $Pb(s) + C(s) + \frac{3}{2} O_2(g) \rightarrow PbCO_3(s)$ $\Delta H^\circ_{rxn} = ?$

Butanol as Automobile Fuel The use of butanol [$CH_3(CH_2)_2CH_2OH$] as a biofuel has been proposed. Calculate the standard molar enthalpy for the complete combustion of liquid butanol by using the standard enthalpies of formation of the reactants and gaseous products as given in Appendix 4. Which has a greater fuel value, butanol or ethanol?

Adding 1.56 g of K_2SO_4 to 6.00 mL of water at 16.2°C causes the temperature of the solution to drop by 7.70°C. How many grams of NaOH ($\Delta H_{soln} = -44.3$ kJ/mol) would you need to add to raise the temperature back to 16.2°C?

Two solids, 5.00 g of NaOH and 4.20 g of KOH, are added to 150 mL of water [$c_P = 75.3$ J/(mol · °C); $T = 23$°C] in a calorimeter. Given that $\Delta H_{soln,NaOH} = -44.3$ kJ/mol and $\Delta H_{soln,KOH} = -56.0$ kJ/mol, what is the final temperature of the solution?

The 100-Meter Dash A 1995 article in *Discover* magazine on world-class sprinters contained the following statement: “In one race, a field of eight runners releases enough energy to boil a gallon jug of ice at 0.0°C in ten seconds!” How much “energy” do the runners release in 10 seconds? Assume that the ice has a mass of 128 ounces.

Specific Heats of Metals In 1819, Pierre Dulong and Alexis Petit reported that the product of the atomic mass of a metal times its specific heat is approximately constant, an observation called the *law of Dulong and Petit*. Use the data in the table below to answer the following questions.

Element	M (g/mol)	c_s [J/(g·°C)]	$M \times c_s$ [J/(mol·°C)]
Bismuth	209.0	0.120	25.08
Lead	207.2	0.123	
Gold	197.0	0.126	
Platinum	195.1		
Tin	118.7	0.125	
		0.233	
Zinc	65.38	0.388	
Copper	63.55	0.397	
		0.433	
Iron	55.85	0.460	
Sulfur	32.1		
Average value:			

1. Complete each row in the table by multiplying each given molar mass and specific heat pair (one result has been entered in the table). What are the units of the resulting values in column 4?
2. Next, calculate the average of the values in column 4.
3. Use the mean value from part (b) to calculate the missing atomic masses in the table. Do you feel confident in identifying the elements from the calculated atomic masses?
4. Use the average value from part (b) to predict the missing specific heat values in the table.

Odor of Urine Urine odor gets worse with time because urine contains the metabolic product urea [$CO(NH_2)_2$]. Urea is slowly converted to ammonia, which has a sharp, unpleasant odor, and carbon dioxide:

$$CO(NH_2)_2(aq) + H_2O(\ell) \rightarrow CO_2(aq) + 2\ NH_3(aq)$$

This reaction is much too slow for the enthalpy change to be measured directly by using a temperature change. Instead, the enthalpy change for the reaction may be calculated from the following data:

Compound	$\Delta H_f°$ (kJ/mol)
Urea(aq)	−319.2
$CO_2(aq)$	−412.9
$H_2O(\ell)$	−285.8
$NH_3(aq)$	−80.3

Calculate the standard molar enthalpy change for the reaction.

Use the following data to determine whether the conversion of diamond into graphite is exothermic or endothermic:

$C(s, \text{diamond}) + O_2(g) \rightarrow CO_2(g)$ $\quad \Delta H° = -395.4$ kJ

$2\ CO_2(g) \rightarrow 2\ CO(g) + O_2(g)$ $\quad \Delta H° = 566.0$ kJ

$2\ CO(g) \rightarrow C(s, \text{graphite}) + CO_2(g)$ $\quad \Delta H° = -172.5$ kJ

$C(s, \text{diamond}) \rightarrow C(s, \text{graphite})$ $\quad \Delta H° = ?$

Rocket Fuels The payload of a rocket includes a fuel and oxygen for combustion of the fuel. Reactions 1 and 2 describe the combustion of dimethylhydrazine and hydrogen, respectively. Kilogram for kilogram, which is the better rocket fuel, dimethylhydrazine or hydrogen?

(1) $(CH_3)_2NNH_2(\ell) + 4\ O_2(g) \rightarrow N_2(g) + 4\ H_2O(g) + 2\ CO_2(g)$ $\quad \Delta H°_{rxn} = -1694$ kJ

(2) $H_2(g) + \frac{1}{2}\ O_2(g) \rightarrow H_2O(g)$ $\quad \Delta H°_{rxn} = -242$ kJ

At high temperatures, such as those in the combustion chambers of automobile engines, nitrogen and oxygen form nitrogen monoxide:

$N_2(g) + O_2(g) \rightarrow 2\ NO(g)\ \Delta H^\circ_{comb} = +180\ kJ$

Any NO released into the environment is oxidized to NO_2:

$2\ NO(g) + O_2(g) \rightarrow 2\ NO_2(g)\ \Delta H^\circ_{comb} = -112\ kJ$

Is the overall reaction,

$N_2(g) + 2\ O_2(g) \rightarrow 2\ NO_2(g)$

exothermic or endothermic? What is ΔH°_{comb} for this reaction?

You are given the following data:

$$\begin{array}{ll} \frac{1}{2} N_2(g) + \frac{1}{2} O_2(g) \rightarrow NO(g) & \Delta H^\circ_{rxn} = +90.3\ kJ \\ NO(g) + \frac{1}{2} Cl_2(g) \rightarrow NOCl(g) & \Delta H^\circ_{rxn} = -38.6\ kJ \\ 2\ NOCl(g) \rightarrow N_2(g) + O_2(g) + Cl_2(g) & \Delta H^\circ_{rxn} = ? \end{array}$$

1. Which of the ΔH°_{rxn} values represent enthalpies of formation?
2. Determine ΔH°_{rxn} for the decomposition of NOCl.

Hydrogen as Fuel Hydrogen is attractive as a fuel because it has a high fuel value and produces no CO_2.

$$H_2(g) + \frac{1}{2} O_2(g) \rightarrow H_2O(g)$$

Unfortunately, the production and storage of hydrogen fuel remain problematic.

1. One problem with hydrogen is its low fuel density. What is the fuel density (kJ/L) for H_2 given that the density of hydrogen gas is 0.0899 g/L? If we could liquefy hydrogen, what would the fuel density of hydrogen be, given that the density of liquid hydrogen is 70.8 g/L?
2. One solution to the problem of hydrogen storage is to use solid, hydrogen-containing compounds that release hydrogen upon heating at low temperature. One

such compound is ammonia borane (H_3NBH_3). Calculate the enthalpy change (ΔH) for the following reactions given that $\Delta H^\circ_{f,H_3NBH_3} = -38.1$ kJ/mol,

$H_3NBH_3(g) \rightarrow NH_3(g) + BH_3(g)$

$H_3NBH_3(g) \rightarrow H_2(g) + H_2NBH_2(g)$

$H_2NBH_2(g) \rightarrow H_2(g) + HNBH(g)$

3. How many kilograms of ammonia borane are needed to supply 10.0 kg of hydrogen?

Industrial Use of Cellulose Research is being carried out on cellulose as a source of chemicals for the production of fibers, coatings, and plastics. Cellulose consists of long chains of glucose molecules ($C_6H_{12}O_6$), so for the purposes of modeling the reaction, we can consider the conversion of glucose to formaldehyde (CH_2O).

1. Is the reaction to convert glucose into formaldehyde an oxidation or a reduction?
2. Calculate the heat of reaction for the conversion of 1 mole of glucose into formaldehyde, given the following thermochemical data:

ΔH°_{comb} of formaldehyde gas $= -572.9$ kJ/mol

ΔH°_f of solid glucose $= -1274.4$ kJ/mol

$C_6H_{12}O_6(s) \rightarrow 6\ CH_2O(g)$

Glucose Formaldehyde

Smelting Iron Iron metal is obtained by reducing iron oxide with carbon. The balanced chemical equation for making iron from Fe_2O_3 is

$2\ Fe_2O_3(s) + 3\ C(s) \rightarrow 4\ Fe(s) + 3\ CO_2(g)$

Iron melts at 1538°C with $\Delta H_{\text{fus}} = 19.4$ kJ/mol. The molar heat capacity of iron is $c_{\text{P,Fe}} = 25.1$ J/(mol · °C). Is the energy required to melt recycled iron less than that needed to reduce the iron in Fe_2O_3 to the free metal?

Recycling Copper How does the energy required to recycle 1.00 mole of copper compare with that required to recover copper from CuO? The balanced chemical equation for the smelting of copper is $CuO(s) + CO(g) \rightarrow Cu(s) + CO_2(g)$. Copper melts at 1084.5°C with $\Delta H^\circ_{\text{fus}} = 13.0$ kJ/mol and a molar heat capacity $c_{\text{P,Cu}} = 24.5$ J/(mol · °C). In addition, $\Delta H^\circ_{\text{f,CuO}} = -155$ kJ/mol.

Converting Diamond to Graphite The standard state of carbon is graphite. $\Delta H^\circ_{\text{f,diamond}}$ is +1.896 kJ/mol. Diamond masses are normally given in carats, where 1 carat = 0.20 g. Determine the standard enthalpy of the reaction for the conversion of a 4-carat diamond into an equivalent mass of graphite. Is this reaction endothermic or exothermic?

Glossary

potential energy (PE)

the energy stored in an object because of its position or composition.

state function

a property of an entity based solely on its chemical or physical state or both, but not on how it achieved that state.

kinetic energy

the energy of an object in motion due to its mass (m) and its speed (u): $\mathrm{KE} = \frac{1}{2}mu^2.$

system

the part of the universe that is the focus of a thermochemical study.

surroundings

everything that is not part of the system.

exothermic process

a thermochemical or physical process in which energy flows from a system into its surroundings.

endothermic process

a thermochemical or physical process in which energy flows from the surroundings into the system.

internal energy (E)

the sum of all the kinetic and potential energies of all the components of a system.

enthalpy (H)

the sum of the internal energy and the pressure–volume product of a system; $H = E + PV$.

specific heat (c_s)

the quantity of energy required to raise the temperature of 1 g of a substance by 1°C at constant pressure.

calorimeter

a device used to measure the absorption or release of energy by a physical change or chemical process.

Hess's law

the principle that the enthalpy of reaction ΔH

rxn for a reaction that is the sum of two or more reactions is equal to the sum of the ΔHrxn values of the constituent reactions; also called *Hess's law of constant heat of summation*.

formation reaction

a reaction in which 1 mole of a substance is formed from its component elements in their standard states.

standard state

the most stable form of a substance under 1 bar pressure and some specified temperature (25°C unless otherwise stated).

standard conditions

in thermodynamics: a pressure of 1 bar (∼1 atm) and some specified temperature, assumed to be 25°C unless otherwise stated; for solutions, a concentration of 1 *M* is specified.

fuel value

the quantity of energy released during the complete combustion of 1 g of a substance.

food value

the quantity of energy produced when a material consumed by an organism for sustenance is burned completely; it is typically reported in Calories (kilocalories) per gram of food.

pressure–volume (P–V) work

the work associated with the expansion or compression of a gas.

enthalpy change (ΔH)

the heat absorbed by an endothermic process or given off by an exothermic process occurring at constant pressure.

molar heat capacity (c_P)

the quantity of energy required to raise the temperature of 1 mole of a substance by 1°C at constant pressure.

calorimeter constant ($C_\text{calorimeter}$)

the heat capacity of a calorimeter.

heat capacity (C_P)

the quantity of energy needed to raise the temperature of an object by 1°C at constant pressure.

enthalpy of reaction (ΔH_rxn)

the energy absorbed or given off by a chemical reaction under conditions of constant pressure; also called *heat of reaction*.

standard enthalpy of formation(ΔH°_f)

the enthalpy change of a formation reaction; also called *standard heat of formation* or *heat of formation*.

RAINBOWS When sunlight passes through water droplets in the sky, a rainbow is often the result. Scientists’ efforts to explain why energy (such as sunlight) interacted with matter (such as raindrops) to produce the colors of a rainbow led to the development of quantum theory and an entirely new way of viewing matter at the atomic level.

A Quantum Model of Atoms Waves, Particles, and Periodic Properties

---

PARTICULATE REVIEW

Atoms, Ions, and Their Electrons

In Chapter 7 we explore periodic trends in the sizes of atoms and monatomic ions, along with the energy changes involved with forming ions from neutral parent atoms.

The spheres shown here represent the charges and relative sizes of the most common monatomic ions formed by

potassium, aluminum, fluorine, and sulfur. Match each element to its ion.
- How many electrons are in a neutral atom of each of these elements?
- How many electrons are in each ion shown here?

(Review Sections 2.3 and 2.6 if you need help.)

(Answers to Particulate Review questions are in the back of the book.)

PARTICULATE PREVIEW

Energy Changes and Ion Formation

In Section 6.2 we learned that ions of opposite charge are attracted to each other. Separating ions that are bonded to one another is an endothermic process. As you read Chapter 7, look for ideas that will help you answer these questions:

- Is an electron gained or lost in each of the two processes depicted here?
- Which process usually emits energy?
- Which process requires the absorption of energy?

Learning Outcomes

- LO1 Interconvert the energies, wavelengths, and frequencies of electromagnetic radiation and correlate their values to the appropriate regions of the electromagnetic spectrum

  Sample Exercises 7.1, 7.2

- LO2 Describe quantum theory and use it to explain the photoelectric effect

Sample Exercise 7.3

- LO3 Calculate the energies and wavelengths of photons absorbed and emitted by atoms in their electron transitions between atomic energy levels

  Sample Exercises 7.4, 7.5

- LO4 Apply the Heisenberg uncertainty principle to particles in motion and calculate their de Broglie wavelengths

  Sample Exercises 7.6, 7.7

- LO5 Assign quantum numbers to orbitals and use their values to describe the sizes, energies, and orientations of orbitals

  Sample Exercises 7.8, 7.9

- LO6 Use the aufbau principle and Hund’s rule to write electron configurations and draw orbital diagrams of atoms and monatomic ions

  Sample Exercises 7.10, 7.11, 7.12, 7.13

- LO7 Use atomic orbitals and the concept of effective nuclear charge to explain the ionization energies and relative sizes of atoms and monatomic ions

  Sample Exercises 7.14, 7.15

- LO8 Relate the electron affinities of the elements to their positions in the periodic table

7.1 Rainbows of Light

Rainbows can put visual exclamation points on passing summer showers. They often appear just after the clouds that brought the shower begin to clear, allowing sunlight to illuminate the trailing edge of the receding rain. A rainbow's colors are nearly always arranged in the same pattern with red on top, violet on the bottom, and the other colors in between. Have you ever wondered why?

The answer has to do with the ways that radiant energy (sunlight) interacts with matter (raindrops). Such interactions are a recurring theme in this chapter. Although humans have enjoyed the colors of rainbows ever since we evolved as an intelligent species, it was only a few hundred years ago that a brilliant Englishman named Isaac Newton (1642–1727) was able to explain how and why rainbows appear. He discovered that passing sunlight through a glass prism

(**Figure 7.1**) separated the light into its component colors in much the way raindrops do. Then he showed how the colors could be recombined into white sunlight with a second prism, thereby proving that white light is a blend of all the colors in a rainbow.

In the decades following Newton's discoveries, the quality of prisms improved dramatically, enabling scientists in Europe and Great Britain to separate sunlight into its component colors with increasing resolution. Then, in 1800, another English scientist named William Hyde Wollaston (1766–1828) made a second discovery about the sun's rainbow of colors: it was not continuous. Rather, it contained dark, narrow lines. Using even better prisms, the German physicist Joseph von Fraunhofer (1787–1826) resolved more than 500 of these lines, which are now called Fraunhofer lines (**Figure 7.2**). He labeled the darkest lines with the letters of the alphabet, starting with *A* at the red end of the Sun's spectrum.

Labeling his lines, however, did not mean that Fraunhofer, or anyone else, knew why they existed. Discovering why would come later in the 19th century with the work of two more German scientists: the chemist Robert Wilhelm Bunsen (1811–1899) and physicist Gustav Robert Kirchhoff (1824–1887). They collaborated on extensive studies of the light emitted (given off) by elements, particularly group 1 and 2 elements, when they are vaporized, and their atoms are heated by the transparent flames produced by a burner designed by Bunsen. Unlike the spectrum of sunlight, which displays narrow gaps in an otherwise continuous spectrum of all colors, the spectra produced by hot atoms in flames consist of only a few bright lines on a dark background, as shown in **Figure 7.3** and **Figure 7.4**. Bunsen and Kirchhoff discovered that many of the lines in these atomic emission spectra exactly matched colors that were missing in the Sun's visible spectrum. For example, the Fraunhofer *D* line corresponded to the yellow-orange light produced by hot sodium vapor (Figure 7.3).

These experiments, and others employing light sources called gas discharge tubes, showed that each element emits a characteristic line spectrum when its atoms are heated to a sufficiently high temperature (Figure 7.4). Other experiments showed that when free atoms of an element are illuminated by a continuous source of light, such as that emitted by a light bulb (**Figure 7.5a**) or the surface of the Sun, the atoms may absorb particular colors of light, producing an atomic absorption spectrum, which consists of dark lines in an otherwise continuous spectrum (**Figure 7.5b**).

A comparison of the spectral lines in Figures 7.4 and 7.5 shows that the dark lines in an element's atomic absorption spectrum exactly match the colors of the lines in its atomic emission spectrum. Atomic absorption also explains the origins of the Fraunhofer lines: gaseous atoms in the outer regions of the Sun absorb characteristic colors of the sunlight passing through them on its way to Earth.

CONCEPT TEST

The top spectrum in **Figure 7.6** is the emission spectrum of mercury vapor. Select the absorption spectrum of mercury vapor from the other four spectra.

(Answers to Concept Tests are in the back of the book.)

In this chapter we explore why the atoms of the elements have unique and complementary atomic emission and absorption spectra. We also link the positions of the lines in these spectra to the internal structure of atoms and to the arrangement and motion of the electrons inside atoms. We begin this exploration of atomic structure by addressing the properties of sunlight and other invisible forms of radiant energy, and how the nature of radiant energy allows it to interact with matter.

Glossary

Fraunhofer lines

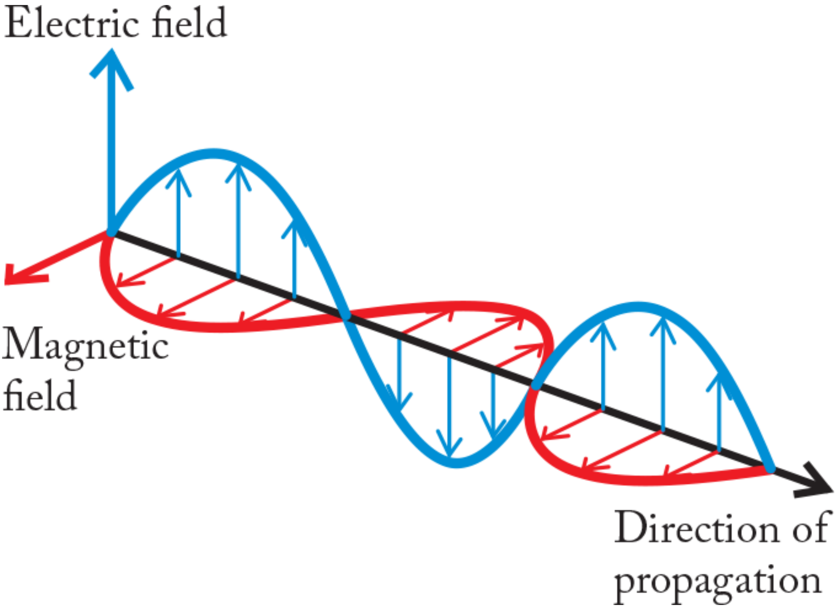
a set of dark lines in the otherwise continuous solar spectrum.

atomic emission spectra

a characteristic series of bright lines produced by high-temperature atoms.

atomic absorption spectrum

a characteristic series of dark lines produced when free, gaseous atoms are illuminated by a continuous source of radiation.



Electric field
Magnetic field
Direction of propagation

$$\nu = \frac{c}{\lambda}$$

$$589\ \cancel{\text{nm}} \times \frac{10^{-9}\ \text{m}}{1\ \cancel{\text{nm}}} = 589 \times 10^{-9}\ \text{m} = 5.89 \times 10^{-7}\ \text{m}$$

$$\nu = \frac{2.998 \times 10^{8}\ \cancel{\text{m}}/\text{s}}{5.89 \times 10^{-7}\ \cancel{\text{m}}}$$

$$= 5.09 \times 10^{14}\ \text{s}^{-1} = 5.09 \times 10^{14}\ \text{Hz}$$

7.2 Waves of Energy

Visible light is a small part of the electromagnetic spectrum (**Figure 7.7**). This spectrum is a continuous range of radiant energy that extends from high-energy gamma rays to low-energy radio waves. All forms of radiant energy are examples of electromagnetic radiation.

CONNECTION In Chapter 1 we discussed the background microwave radiation of the universe, discovered by Penzias and Wilson, which provided evidence for the Big Bang.

The term *electromagnetic* comes from a theory, proposed by the Scottish scientist James Clerk Maxwell (1831–1879), that radiant energy moves through space (or any transparent medium) in a way that resembles waves flowing across a body of water. Unlike water waves, which oscillate only up and down, Maxwell’s waves of radiant energy have two components: an oscillating electric field and an oscillating magnetic field (**Figure 7.8**). These two fields are perpendicular to each other and travel together through space. Maxwell derived a set of equations based on his oscillating-wave model that accurately describes nearly all the observed properties of light.

A wave of electromagnetic radiation, like any wave traveling through any medium, has a characteristic wavelength (λ, the distance from crest to crest) and frequency (ν, the number of crests that pass a stationary point of reference per second), as shown in **Figure 7.9a**. Frequencies have units of hertz (Hz), also called *cycles* *per second* (cps): 1 Hz = 1 cps = 1/s. The product of the wavelength and frequency of any electromagnetic radiation is the universal constant *c*, which is the symbol for the speed of light in a vacuum (2.998×10^8 m/s):

Thus, wavelength and frequency have a reciprocal relationship: as wavelength decreases, frequency increases. Another characteristic of a wave is its amplitude, the height of the crest or the depth of the trough with respect to the center line of the wave (**Figure 7.9b**).

SAMPLE EXERCISE 7.1 Calculating Frequency from Wavelength
LO1

What is the frequency of the yellow-orange light ($\lambda = 589$ nm) produced by sodium-vapor streetlights?

Collect and Organize We are asked to find the frequency of light that has a wavelength of 589 nm. Frequency and wavelength are related by Equation 7.1 ($c = \lambda\nu$), where c is the speed of light = 2.998×10^8 m/s.

Analyze Before using Equation 7.1, we need to convert the wavelength of the light from nanometers to meters (1 nm = 10^{-9} m). The unit labels in Figure 7.7 indicate that frequencies of visible light are in the 10^{14} Hz range, so a correct answer should have a value in this range.

Solve Rearrange Equation 7.1 to solve for frequency:

Convert wavelength from nanometers to meters:

Use this wavelength value to calculate frequency:

Think About It Our calculated frequency is in the range we expected. Remember that wavelengths and frequencies are inversely proportional to each other: as one increases, the other decreases.

Practice Exercise The radio waves transmitted by a radio station have a frequency of 90.9 MHz. What is the wavelength of these waves in meters?

(Answers to Practice Exercises are in the back of the book.)

CONCEPT TEST

The ultraviolet (UV) region of the electromagnetic spectrum contains waves with wavelengths from about 10^{-9} m to 10^{-7} m; the infrared (IR) region contains waves with wavelengths from about 10^{-6} m to 10^{-4} m. Are waves in the UV region higher in frequency or lower in frequency than waves in the IR region?

The electromagnetic properties of radiant energy are related to our discussion of rainbows at the start of Section 7.1. As electromagnetic radiation passes through the air, it interacts with fewer atoms than when passing through a transparent solid (such as a glass prism) or a liquid (such as raindrops). More interactions between the oscillating waves and the electrons within the densely packed atoms and molecules in solids and liquids cause the waves to slow and their path to bend. Shorter wavelengths are bent more than longer wavelengths as they pass between the raindrops, causing the violet end of the visible spectrum to appear on the bottom of rainbows, while the red end appears at the top.

Glossary

electromagnetic spectrum

a continuous range of radiant energy that includes radio waves, microwaves, infrared radiation, visible light, ultraviolet radiation, X-rays, and gamma rays.

electromagnetic radiation

any form of radiant energy in the electromagnetic spectrum.

frequency (ν)

the number of crests of a wave that pass a stationary point of reference per second.

hertz (Hz)

the SI unit of frequency, equivalent to 1 cycle per second, or simply 1/s.

amplitude

the height of the crest or depth of the trough of a wave with respect to the center line of the wave.

wavelength (λ)

the distance from crest to crest or trough to trough on a wave.

Learning Objectives

- Interconvert the energies, wavelengths, and frequencies of electromagnetic radiation and correlate their values to the appropriate regions of the electromagnetic spectrum **Return to Sample Exercises 7.1, 7.2**

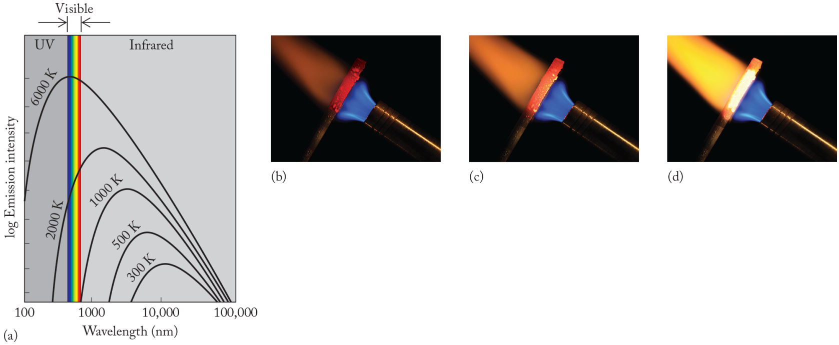

FIGURE 7.10 (a) Plots of emission intensity versus wavelength show that as the temperature of a solid increases, the intensity of the radiation that it emits increases and the wavelength of maximum intensity decreases. As a metal rod is heated, (b) it first glows red, (c) then turns orange, and (d) finally becomes white-hot as light of all colors is emitted.

$$E = h\nu \tag{7.2}$$

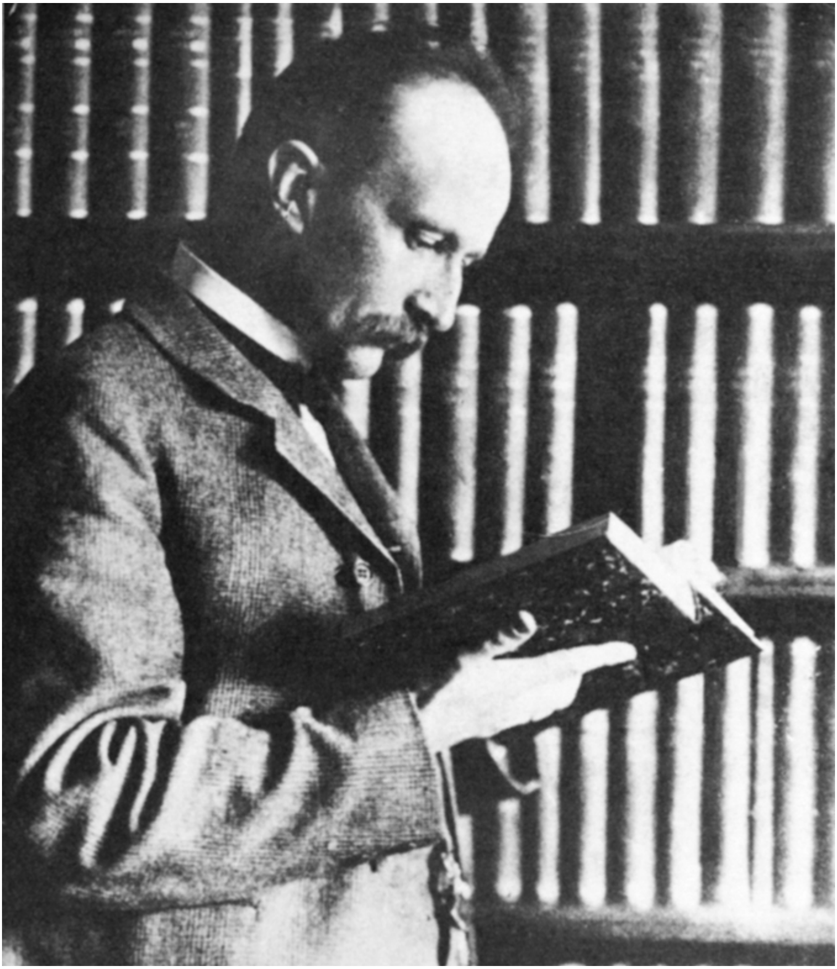

FIGURE 7.11 German scientist Max Planck is considered the father of quantum physics. He won the 1918 Nobel Prize in Physics for his pioneering work on the quantized nature of electromagnetic radiation. Planck was revered by his colleagues for his personal qualities as well as his scientific accomplishments.

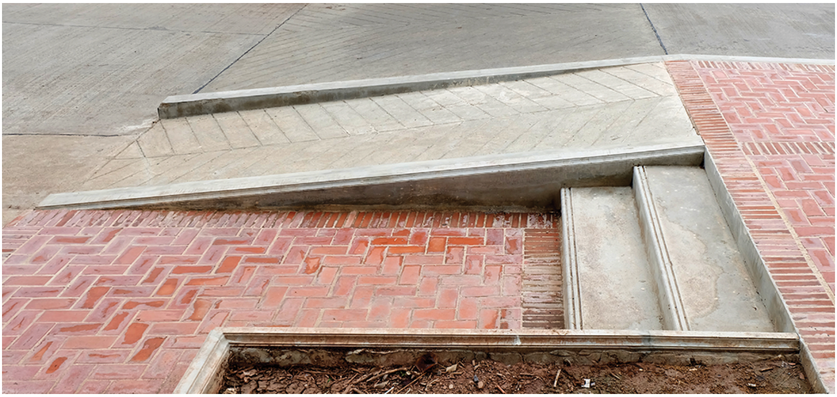

FIGURE 7.12 Quantized and unquantized heights. A flight of stairs exemplifies quantization because each step rises by a discrete height to the next step. The rise on a ramp, on the other hand, is continuous, not quantized.

$$E = \frac{hc}{\lambda} \tag{7.3}$$

$$E = \frac{hc}{\lambda} = \frac{(6.626 \times 10^{-34}\ \mathrm{J} \cdot \cancel{\mathrm{s}})\left(2.998 \times 10^{8}\ \frac{\cancel{\mathrm{m}}}{\cancel{\mathrm{s}}}\right)}{462\ \cancel{\mathrm{nm}} \times \frac{10^{-9}\ \cancel{\mathrm{m}}}{1\ \cancel{\mathrm{nm}}}}$$

$$= 4.30 \times 10^{-19}\ \mathrm{J}$$

$$E = \frac{hc}{\lambda} = \frac{(6.626 \times 10^{-34}\ \mathrm{J} \cdot \cancel{\mathrm{s}})\left(2.998 \times 10^{8}\ \frac{\cancel{\mathrm{m}}}{\cancel{\mathrm{s}}}\right)}{647\ \cancel{\mathrm{nm}} \times \frac{10^{-9}\ \cancel{\mathrm{m}}}{1\ \cancel{\mathrm{nm}}}}$$

$$= 3.07 \times 10^{-19}\ \mathrm{J}$$

$$\phi = h\nu_0 \tag{7.4}$$

FIGURE 7.13 A phototube includes a positive electrode and a negative metal electrode. (a) If radiation of high enough frequency and energy (violet light in this illustration) illuminates the negative electrode, electrons are dislodged from the surface and flow toward the positive electrode. This flow of electrons produces an electric current that is detected by the meter. The size of the current is proportional to the intensity of the radiation—to the number of photons per unit time striking the negative electrode. (b) The frequency of the red light is below the threshold frequency, so it cannot dislodge electrons and does not produce the photoelectric effect. (c) Even if many low-frequency photons bombard the surface of the metal, no electrons are emitted, and no electrical current flows.

$$\lambda\nu = c = 2.998 \times 10^{8}\ \text{m/s}$$

$$\nu = \frac{c}{\lambda} = \frac{2.998 \times 10^{8}\ \cancel{\text{m}}/\text{s}}{902\ \cancel{\text{nm}} \times \dfrac{10^{-9}\ \cancel{\text{m}}}{1\ \cancel{\text{nm}}}} = 3.33 \times 10^{14}\ \text{s}^{-1}$$

$$\phi = h\nu_0$$

$$\nu_0 = \frac{\phi}{h} = \frac{7.61 \times 10^{-19}\ \cancel{\text{J}}}{6.626 \times 10^{-34}\ \cancel{\text{J}} \cdot \text{s}} = 1.15 \times 10^{15}\ \text{s}^{-1}$$

7.3 Particles of Energy and

Quantum Theory

As studies of electromagnetic radiation progressed in the 19th century, scientists discovered limitations to Maxwell's wave model. One limitation was the inability to account for radiation given off by very hot objects. Consider what happens, for example, when a metal rod is heated in a flame. At first the rod gives off only heat in the form of infrared radiation, which we can feel but not see. As the temperature of the metal is increased from 500 to 1000 K (**Figure 7.10a**), the most intense radiation is still in the infrared region of the spectrum, but a small fraction of the emitted light is in the red region of the visible spectrum, as shown in **Figure 7.10b**. With still more heating, the intensity of the red glow increases, and the color of the rod begins to shift to red-orange, orange (**Figure 7.10c**), yellow, and eventually to white (**Figure 7.10d**) as the metal emits all wavelengths of visible light. Even white-hot metal emits little radiation in the ultraviolet region and none at even shorter wavelengths.

This phenomenon, which is called *blackbody* radiation, was well known at the end of the 19th century. However, none of Maxwell's equations for electromagnetic radiation could account for the emission spectrum of a heated metal filament. Another explanation—indeed, another model of radiation behavior—was required.

Quantum Theory

In 1900 the German scientist Max Planck (1858–1947; **Figure 7.11**) proposed such a model in which he discarded classical physics and made a bold assumption about radiant energy: no matter what its source, it can never be truly continuous. Instead, Planck proposed that radiant objects emit energy only in integral multiples of an elementary unit, or quantum, of energy defined by the equation

where ν is the frequency of the radiation that such an object emits and $\boldsymbol{h}$ is the Planck constant, $6.626 \times 10^{-34}\ \mathrm{J \cdot s}$.

To visualize the meaning of Planck’s quanta, consider two ways you might get from the sidewalk to the entrance of a building (**Figure 7.12**). If you walked up the steps, you would be able to stand at only discrete heights above the sidewalk—each height equal to the rise of a single step. You could not stand at a height between two adjacent steps because there would be nothing to stand on at that height. If you walked up the ramp, however, you could stop at any height between the sidewalk and the entrance. The discrete height changes represented by the steps are also a model of Planck’s hypothesis that energy is quantized; that is, it is released (analogous to walking down the steps) or absorbed (walking up the steps) in discrete packets, or quanta, of energy.

Combining Equations 7.1 and 7.2 yields an equation that relates the energy of a quantum of radiant energy to its wavelength:

Given the extremely tiny value of the Planck constant (h), the energy values we obtain using Equation 7.3 tend to be very small because E represents the number of joules in a single quantum of energy. Today we call the tiny packets of radiant energy photons. They represent elementary building blocks of electromagnetic radiation in much the same way that atoms represent the building blocks of matter. The observed brightness of a source of radiant energy is the sum of the energies of the enormous number of photons it produces per unit of time. Because Planck’s energy model is characterized by *quantum* building blocks, it has become known as quantum theory.

CONCEPT TEST

Which of these quantities vary by discrete values (are quantized) and which are continuous (not quantized)?

1. the volume of water that evaporates from a lake each day during a summer heat wave
2. the number of eggs remaining in a carton
3. the time it takes you to get ready for class in the morning

4. the number of red lights encountered when driving the length of Fifth Avenue in New York City

SAMPLE EXERCISE 7.2 Calculating the Energy of a Single Photon LO1

Chlorophyll *b*, a pigment found in plants, absorbs light with wavelengths of 462 nm and 647 nm. What are the energies of a photon associated with each of these wavelengths? What colors of light does chlorophyll *b* absorb at each wavelength?

Collect, Organize, and Analyze We are asked to calculate the energies of photons with two different wavelengths. To use Equation 7.3, which relates these quantities, we need to use the value of the Planck constant (h), which is 6.626×10^{-34} J · s, and the speed of light (c), 2.998×10^{8} m/s. The photons' wavelengths are given in nanometers, but this value of c has units of meters per second, so we need to convert nanometers to meters for the distance units to cancel. The value of h is extremely small, so the energy of one photon, even factoring in the speed of light, should be very low.

Solve

According to Figure 7.7, a wavelength of 462 nm is blue light, and a wavelength of 647 nm is orange light.

Think About It These quantities of energy are extremely small, as they should be, because a single photon is an atomic-level particle of radiant energy. The results of the calculations confirm that a photon of orange light has less energy than a photon of blue light.

Practice Exercise Leaves contain an array of different light-absorbing molecules to harvest the full spectrum of visible light. Some of these include β-carotene (the compound that makes carrots orange), which absorbs at $\lambda = 453$ nm and 482 nm. How much energy do single photons of 453 nm and 482 nm light have?

The Photoelectric Effect

Although Planck’s quantum model explained the emission spectra of hot objects, there was no experimental evidence in 1900 to support the existence of quanta of energy. In 1905 Albert Einstein (1879–1955) supplied that evidence. It came from his studies of a phenomenon called the photoelectric effect, in which electrons are emitted from metals when they are illuminated by and absorb electromagnetic radiation. Because light releases these electrons, they are called *photoelectrons.*

Photoelectrons are emitted by a material when the frequency of incident radiation is above a minimum threshold frequency (ν_0) characteristic of that material (**Figure 7.13**). Radiation at frequencies less than the threshold value produces no photoelectrons, no matter how intense the radiation is. On the other hand, even a dim source of radiant energy produces at least a few photoelectrons when the frequencies it emits are equal to, or greater than, the threshold frequency.

Einstein used Planck’s quantum theory to explain this behavior. He proposed that the threshold frequency is the frequency of the minimum quantum of absorbed energy needed to remove a single electron from the surface of a material. This minimum quantity of energy is related to the strength of the attraction between the nuclei of surface atoms and the electrons surrounding them, and it is called the material’s work function (ϕ):

If a photoelectric material is illuminated with radiation frequencies above the threshold frequency ($\nu > \nu_0$), any energy in excess of ϕ is imparted to each ejected electron as kinetic energy:

The higher the frequency of the incident light above the threshold frequency, the higher the kinetic energy, and hence the velocity, of the ejected electrons.

Wave–Particle Duality

Einstein's explanation of the photoelectric effect was of such profound significance that he was awarded the Nobel Prize in Physics for it in 1921. Why does the concept of photons have such far-reaching significance in science? Classical physics had identified the wave nature of light but could not account for light behaving as a particle. Only quantum physics recognizes the wave–particle duality of light: light behaves as both a wave *and* a particle.

SAMPLE EXERCISE 7.3 Applying the Photoelectric Effect LO2

Can germanium be used to detect infrared radiation ($\lambda = 902$ nm) emitted by a remote-control device? The work function of germanium is 7.61×10^{-19} J.

Collect, Organize, and Analyze We know the work function of germanium and a wavelength of infrared radiation, and we are asked to determine whether the radiation will dislodge photoelectrons from germanium. Equation 7.4 relates a material's work function (ϕ) to its threshold frequency (ν_0). To use Equation 7.4 to solve this problem, we need to convert wavelength to frequency, which we can do using Equation 7.1.

Solve Calculate the frequency of a 902 nm photon:

Rearrange Equation 7.4 to solve for the threshold frequency for germanium:

The frequency of the infrared radiation is lower than the threshold frequency for germanium. Therefore, the infrared radiation will *not* liberate photoelectrons, and germanium *cannot* be used to detect it.

Think About It Another way to solve this problem would have been to use Equation 7.3 (i.e., $E = hc/\lambda$) to determine the energy of a photon of 902 nm radiation. If this energy were equal to or greater than the work function, germanium could be used to detect the radiation. According to the results of the calculation above, the energy of a 902 nm photon is less than the work function of germanium.

Practice Exercise The work function of silver is 7.59×10^{-19} J. What is the longest wavelength (in nanometers) of electromagnetic radiation that can eject an electron from the surface of a piece of silver?

CONCEPT TEST

Use the electromagnetic spectrum in Figure 7.7 to answer this question without making a calculation. If a photon of orange light has sufficient energy to eject a photoelectron from the surface of a metal, does a photon of green light have enough energy to do so? If your answer is yes, what happens to the excess energy?

Glossary

quantum

(plural *quanta*) the smallest discrete quantity of a form of energy.

quantized

having values restricted to whole-number multiples of a specific base value.

photon

a quantum of electromagnetic radiation.

quantum theory

a model based on the idea that energy is absorbed and emitted in discrete quantities of energy called quanta.

photoelectric effect

the phenomenon of light striking a metal surface and producing an electric current (a flow of electrons).

threshold frequency (ν_0)
: the minimum frequency of light required to produce the photoelectric effect.

work function (ϕ)
: the amount of energy needed to remove an electron from the surface of a metal.

wave–particle duality
: the behavior of an object that exhibits the properties of both a wave and a particle.

Planck constant (h)
: the proportionality constant between the energy and frequency of electromagnetic radiation: $E = h\nu$; $h = 6.626 \times 10^{-34}\ \mathrm{J \cdot s}$.

7.4 The Hydrogen Spectrum and the Bohr Model

In formulating his quantum theory, Planck was influenced by the results of investigating the emission spectra produced by free (gas-phase) atoms, which led him to question whether any spectrum, even that of an incandescent light bulb, was truly continuous. Among these earlier results was a discovery made in 1885 by a Swiss mathematician and schoolteacher named Johann Balmer (1825–1898).

The Hydrogen Emission Spectrum

Balmer determined that the wavelengths of the four brightest lines in the visible region of the emission spectrum of hydrogen (Figure 7.4a) fit the simple equation

where n is 2 and m is a whole number greater than 2—specifically, 3 for the red line, 4 for the green, 5 for the blue, and 6 for the violet. Without having seen any other lines in hydrogen's visible emission spectrum, Balmer predicted there should be at least one more ($n = 7$) at the edge of the violet region, and indeed such a line was later discovered.

Balmer also predicted that a series of hydrogen emission lines should exist in regions outside the visible range, lines with wavelengths calculated by replacing $n = 2$ in Equation 7.6 with n

= 1, 3, 4, and so forth. He was right. In 1908 the German physicist Friedrich Paschen (1865–1947) discovered hydrogen emission lines in the infrared region, corresponding to $n = 3$ in Balmer's equation. A few years later, Theodore Lyman (1874–1954) at Harvard University discovered hydrogen emission lines in the UV region corresponding to $n = 1$. By the 1920s, the $n = 4$ and $n = 5$ series of emission lines also had been discovered. Like the $n = 3$ lines, they are in the infrared region.

In 1888 the Swedish physicist Johannes Robert Rydberg (1854–1919) revised Balmer's equation, changing wavelength to *wave number* ($1/\lambda$), which is the number of wavelengths per unit of distance. Rydberg's equation is

where n_1 is a positive whole number that remains fixed for a series of emission lines and n_2 is a whole number equal to $n_1 + 1$, $n_1 + 2$, . . . , for successive lines in the series. Values of n_1 in Rydberg's equation correspond to values of n in Balmer's equation, so setting $n_1 = 2$ and $n_2 = 3$, 4, 5, or 6 produces the wave numbers of the visible hydrogen emission lines.

SAMPLE EXERCISE 7.4 Calculating the Wavelength of a Line in the Hydrogen Emission Spectrum LO3

What is the wavelength of the visible hydrogen atomic emission line corresponding to $n_2 = 3$ in Equation 7.7?

Collect, Organize, and Analyze We are asked to calculate the wavelength of a line in the hydrogen emission spectrum given an n_2 value of 3. The n_1 value of all visible hydrogen emission lines is 2. Wavelengths of visible radiation are between 400 nm and 750 nm.

Solve

Think About It The calculated wavelength is in the visible region of the electromagnetic spectrum, so the answer is reasonable.

Practice Exercise What is the wavelength, in nanometers, of the line in the hydrogen spectrum corresponding to $n = 2$ and $m = 4$ in Equation 7.6?

When Balmer and Rydberg derived their equations describing the hydrogen spectrum, they did not know why the equations worked. The discrete frequencies of hydrogen's emission lines indicated that only certain levels of internal energy were available in hydrogen atoms. However, classical physics could not explain the existence of these internal energy levels. A new model that could explain these observations at the atomic level was needed.

The Bohr Model of Hydrogen

In the early 20th century, Ernest Rutherford established that atoms are mostly empty space occupied by negatively charged electrons surrounding a tiny nucleus containing most of the atom's mass and all its positive charge. What, then, keeps the electrons from falling into the nucleus? Rutherford suggested that the electrons might orbit the nucleus the way planets orbit the Sun. However, classical physics predicts that negative electrons orbiting a positive nucleus should emit energy in the form of electromagnetic radiation and eventually spiral into the nucleus. If this happened, no atom would be stable.

CONNECTION We discussed Rutherford's gold-foil experiment and the development of the idea of the nuclear atom in Section 2.2.

The Danish physicist Niels Bohr (1885–1962) was familiar with the challenge of trying to explain atom stability based on the Rutherford model because he had studied with Rutherford. Bohr proposed a theoretical model for the hydrogen atom that assumed its one electron travels around the nucleus in one of an array of concentric orbits. Each orbit represents an allowed energy level and is designated by the value of *n*:

where $n = 1, 2, 3, \ldots, \infty$. In the Bohr model, an electron in the orbit closest to the nucleus ($n = 1$) has the lowest energy:

The next-closest orbit has an n value of 2 and the energy of an electron in it is

This value is *less* negative than the value of the electron in the $n = 1$ orbit. Thus, as the value of n increases, the radius of the orbit increases and so, too, does the energy of an electron in the orbit—that is, its value becomes less negative. As n approaches ∞, E approaches zero:

Zero energy means that there is no longer any electrostatic attraction between the electron and the positively charged nucleus, in which case the electron is no longer part of the atom. The H atom has become two separate particles: an H^+ ion and a free electron.

CONNECTION We discussed the potential energy of attraction between charged particles in Section 6.2.

An important feature of the Bohr model is that it provides a theoretical framework for explaining the experimental observations and equations developed by Balmer and by Rydberg. To see how, consider what happens when an electron moves between two allowed energy levels in Bohr's model. If we label the initial energy level (the level where the electron starts) n_{initial}, and if we label the second level (the level where the electron ends up) n_{final}, then the change in energy of the electron is

If the electron moves to an orbit farther from the nucleus, then $n_{\text{final}} > n_{\text{initial}}$, and the value of the terms inside the parentheses in Equation 7.9 is negative because

This negative value multiplied by the negative coefficient would give us a positive ΔE and represent an increase in electron energy.

On the other hand, if the electron moves from an outer orbit to one closer to the nucleus, then $n_{\text{final}} < n_{\text{initial}}$, and the sign of ΔE is negative. This means the electron has lost energy. Equation 7.9 demonstrates that energy in the hydrogen atom is *quantized* because ΔE can have only certain values determined by n_{final} and n_{initial}.

When the electron in a hydrogen atom is in the lowest ($n = 1$) energy level, the atom is said to be in its ground state. If the electron in a hydrogen atom is in an energy level above $n = 1$, then the atom is said to be in an excited state. According to the Bohr model, a hydrogen atom's electron can move from the ground state ($n = 1$) energy level to an excited state (e.g., $n = 3$) by absorbing a quantity of energy (ΔE) that exactly matches the energy difference between the two states. Similarly, an electron in an excited state can move to an even higher energy level by absorbing a quantity of energy that exactly matches the energy difference between the two excited states. An electron in an excited state can also move to a lower-energy excited state, or to the ground state, by emitting a quantity of energy that exactly matches the energy difference between those two states. Any change in electron energy that occurs by absorption of energy (i.e., $\Delta E > 0$) or emission of energy (i.e., $\Delta E < 0$) is called an electron transition.

Energy-level diagrams, such as the one depicted in **Figure 7.14** for the hydrogen atom, show some of the transitions that electrons can make in these atoms from one energy level to another. Note how the differences in energy between levels decrease as the value of n increases. This means that transitions to and from the ground state ($n = 1$) involve the greatest losses and gains of energy, including the gain represented by the black arrow pointing upward, which depicts the absorption of enough energy to completely remove the electron from a hydrogen atom (ionization).

The downward-pointing arrows in Figure 7.14 represent decreases in a hydrogen atom's internal energy as it loses quanta of energy that exactly match the difference in energy (ΔE) between the initial and final states that define the length of the arrow. Often these quanta are the energies of photons that are emitted as the electron moves from a higher energy level to a lower one. Note how the longest of these arrows point to the ground state; these arrows represent the energies of ultraviolet radiation discovered by Theodore Lyman. The shorter arrows pointing to the $n = 2$ level represent the energies of the visible emission lines discovered by Johannes Balmer, and the even shorter ones pointing to the $n = 3$ level represent the even lower energies of the infrared radiation discovered by Friedrich Paschen. If the colored arrows had pointed up, they would represent absorption of quanta (including photons) leading to increases in the internal energy of the atom. Keep in mind that downward and upward arrows between the same two energy levels represent loss or gain of the same quantum of energy and emission or absorption of photons with same wavelength.

Equations 7.9 and 7.7 are very much alike. Their coefficients differ only because different units are used to express wave number and energy. In addition, Bohr was able to derive his coefficient from a combination of physical constants, including the Planck constant and the charge of an electron. It is not an arbitrary value that just happens to work; it is part of atomic structure. The key point is that Equation 7.7, which was developed to fit the absorption and emission spectra of hydrogen, has the same form as Equation 7.9, the theoretical equation developed by Bohr to explain the internal structure of the hydrogen atom. Thus, atomic emission and absorption spectra reveal the energies of electrons inside atoms.

CONCEPT TEST

Based on the lengths of the arrows in Figure 7.14, rank the following electron transitions in order of greatest change in energy to smallest change:

1. $n = 4 \rightarrow n = 2$
2. $n = 3 \rightarrow n = 2$
3. $n = 2 \rightarrow n = 1$
4. $n = 4 \rightarrow n = 3$

SAMPLE EXERCISE 7.5 Calculating the Energy Change of an Electron Transition in the Hydrogen Atom LO3

How much energy is required to ionize a ground-state hydrogen atom? Express your answer in energy per atom and energy per mole.

Collect and Organize We are asked to determine the energy required to remove an electron from a hydrogen atom in its ground state. Equation 7.9 enables us to calculate the energy change associated with any electron transition in a hydrogen atom. There are $N_A = 6.022 \times 10^{23}$ atoms per mole.

Analyze To use Equation 7.9, we need to identify the initial (n_{initial}) and final (n_{final}) energy levels. The ground state of a hydrogen atom corresponds to the $n = 1$ energy level. If the atom is ionized, $n = \infty$ and there is no longer any electrostatic attraction between the positively charged nucleus and the electron.

Solve

Dividing by ∞^2 yields zero, so the difference in parentheses simplifies to -1. Therefore:

$$\Delta E = 2.178 \times 10^{-18}\ \text{J}$$

This value represents the energy needed to ionize one H atom. To ionize 1 mole of them requires

Think About It The sign of ΔE is positive because energy must be added to overcome the electrostatic attraction between the negatively charged electron and the proton in the nucleus of an H atom.

Practice Exercise Calculate the energy required to ionize an excited-state hydrogen atom with an electron initially in the $n = 3$ energy level. Before doing the calculation, predict whether this energy is greater than or less than the 2.178×10^{-18} J needed to ionize a ground-state hydrogen atom.

One of the strengths of the Bohr model of the hydrogen atom is that it accurately predicts the energy needed to remove the electron. This energy is called the ionization energy of the hydrogen atom. We examine the ionization energies of other elements in Section 7.11. However, the Bohr model applies only to hydrogen atoms and to ions that have only a single electron. The model does not agree with the observed spectra of multielectron atoms and ions because it does not account for the way electrons interact with each other. Thus, the picture of the atom provided by Bohr's model is extremely limited. Nevertheless, it enabled scientists to begin using quantum theory to explain the behavior of matter at the atomic level.

CONCEPT TEST

Can the Bohr model be used to explain the emission spectrum of He atoms? Why or why not?

Glossary

ground state	the most stable, lowest-energy state available to an atom, ion, or molecule.
excited state	any energy state above the ground state in an atom, ion, or molecule.
electron transition	the movement of an electron between energy levels.

7.5 Electron Waves

A decade after Bohr published his model of the hydrogen atom, a French graduate student named Louis de Broglie (1892–1987) provided a theoretical basis for the stability of electron orbits. His approach incorporated yet another significant advance in the way early-20th-century scientists conceived of atoms and subatomic particles—namely, to think of them not only as particles of matter but also as waves. His work provided an answer to the question of why an electron in the hydrogen atom does not spiral into the nucleus.

de Broglie Wavelengths

de Broglie proposed that if light, which we normally think of as a wave, has particle properties, then perhaps the electron, which we normally think of as a particle, has wave properties. If that were true, an electron moving around in an atom should have a characteristic wavelength. de Broglie calculated electron wavelengths from Einstein's equations relating energy and mass, $E = mc^2$, and the energy and wavelength of a photon, $E = hc/\lambda$:

To apply Equation 7.10 to electrons, de Broglie replaced c (the speed of light) with u, the speed of an orbiting electron in an atom:

where h is the Planck constant, m is the mass of the electron in kilograms, and u is its velocity in meters per second. The wavelength of an electron calculated in this way is often called the *de Broglie wavelength* of the electron.

de Broglie's equation is not restricted to electrons—any moving particle has wavelike properties. In other words, the particle behaves as a matter wave. de Broglie predicted that moving particles much bigger than electrons, such as atomic nuclei, molecules, and even macroscopic objects such as tennis balls and airplanes, should have characteristic wavelengths described by Equation 7.11. The wavelengths of such large objects are extremely small, though, given the tiny size of the Planck constant in the numerator and the large size of the mass in the denominator of Equation 7.11. As a result, we never notice the wave nature of large objects in motion.

SAMPLE EXERCISE 7.6 Calculating the Wavelength of a Particle in Motion LO4

(a) Compare the wavelength of a 142-g baseball thrown at 44 m/s (98 mi/h) with the size of the ball, which has a diameter of 7.5 cm. (b) Compare the wavelength of an electron ($m_e = 9.109 \times 10^{-31}$ kg) moving at one-tenth the speed of light in a hydrogen atom with the size of the atom (diameter $= 1.06 \times 10^{-10}$ m).

Collect, Organize, and Analyze Given the masses and velocities of these two moving objects, Equation 7.11 may be used to calculate their wavelengths. Given the small value of *h*, it is likely that the wavelength of a pitched baseball is only a tiny fraction of the size of the baseball. However, the wavelength of an electron moving at one-tenth the speed of light may be a much greater fraction of the size of the atom that it orbits. The fraction on the right side of Equation 7.11 has units of joule-seconds in the numerator and mass and velocity in the denominator. To combine these units in a way that gives us a unit of length, we need to use the following conversion factor:

$$1\ \text{J} = 1\ \text{kg} \cdot \text{m}^2/\text{s}^2$$

To use this equality, we must express the mass of the baseball in kilograms:

$$142\ \text{g} = 0.142\ \text{kg}$$

Solve

1. For the baseball:

$$\lambda = \frac{h}{mu} = \frac{6.626 \times 10^{-34}\ \cancel{\text{J}} \cdot \cancel{\text{s}}}{(0.142\ \cancel{\text{kg}})(44\ \cancel{\text{m}/\text{s}})} \times \frac{1\ \cancel{\text{kg}} \cdot \text{m}^{\cancel{2}}/\cancel{\text{s}^2}}{1\ \cancel{\text{J}}}$$
$$= 1.06 \times 10^{-34}\ \text{m}$$

The wavelength of the baseball is

$$\frac{1.06 \times 10^{-34}\ \cancel{\text{m}}}{0.075\ \cancel{\text{m}}} \times 100\% = 1.4 \times 10^{-31}\%$$

of the ball's diameter.

2. The wavelength of an electron moving at one-tenth the speed of light is

$$\lambda = \frac{h}{mu} = \frac{6.626 \times 10^{-34}\ \cancel{\text{J}} \cdot \text{s}}{(9.109 \times 10^{-31}\ \cancel{\text{kg}})(2.998 \times 10^{7}\ \cancel{\text{m/s}})} \times \frac{1\ \cancel{\text{kg}} \cdot \text{m}^{\cancel{2}}/\cancel{\text{s}}^{2}}{1\ \cancel{\text{J}}}$$
$$= 2.43 \times 10^{-11}\ \text{m}$$

and

$$\frac{2.43 \times 10^{-11}\ \cancel{\text{m}}}{1.06 \times 10^{-10}\ \cancel{\text{m}}} \times 100\% = 23\%$$

of the diameter of a hydrogen atom.

Think About It The matter wave of the baseball is much too small to be observed, so its wavelike character contributes nothing to the behavior of the baseball. We expected that. Our experience with objects in the world is that they behave like particles, not like waves. For the electron, however, the wavelength is a significant percentage of the size of the hydrogen atom. This is *not* a familiar experience to us—a particle that also has properties of waves such as frequency and wavelength. The implications of this for our understanding of the structure of the atom are discussed in the rest of this section.

Practice Exercise The velocity of the electron in the ground state of a hydrogen atom is 2.2×10^{6} m/s. What is the wavelength of this electron in meters?

de Broglie explained the stability of the electron levels in Bohr's model of the hydrogen atom by proposing that the electron in a hydrogen atom behaves like a circular wave oscillating around the nucleus. To understand the implications of this statement, we need to examine what is required to make a stable, circular wave. Consider the motion of a vibrating violin string of length L (**Figure 7.15a**). Because the string is fixed at both ends, there is no vibration at the ends and the vibration is at maximum in the middle. The wave created by this combination of fixed ends and maximum vibration in the middle is a standing wave: a wave that oscillates back and forth within a fixed space rather than moving through space the way waves of light travel through space. On a standing wave, any points that have zero displacement, such as the two ends of the string, are called nodes. The sound wave produced in this way on a violin string is called the *fundamental* of the string. The wavelength of the fundamental is $2L$. It has the lowest frequency and longest wavelength possible for that string. The length of the string is one-half the wavelength of the fundamental ($L = \lambda/2$).

If the string is held down in the middle (creating a third node) and plucked halfway between the middle and one end, a new, higher-frequency wave called the *first harmonic* is produced. The wavelength of this harmonic is equal to L because $L = 2(\lambda/2) = \lambda$. We can continue generating higher frequencies with wavelengths that are related to the length of the string by the equation

where n is a whole number such that $L = 3(\lambda/2)$, $4(\lambda/2)$, $5(\lambda/2)$, and so on.

The standing-wave pattern for a circular wave generated by an electron differs slightly from that of a vibrating violin string in that the circular wave has no defined stationary ends. Instead, the electron vibrates in an endless series of waves. However, standing waves are only produced if, as shown in **Figure 7.15b**, the circumference of the circle equals a whole-number multiple of the electron's wavelength:

Equation 7.12 offers a new interpretation of Bohr's number n: it represents the number of matter waves in a given energy level. de

Broglie's work also solved the problem of a negatively charged electron spiraling into the positively charged nucleus. Because $n = 1$ represents the minimum circumference of the circular wave of a moving electron, the electron must be a minimum distance from the nucleus. Furthermore, the lowest energy possible for an electron in a hydrogen atom occurs for a standing wave with circumference λ, so the electron cannot get any closer to the nucleus than that.

de Broglie's research created a quandary for the graduate faculty at the University of Paris, where he studied. Bohr's model of electrons moving between allowed energy levels had been widely criticized as an arbitrary suspension of well-tested physical laws. de Broglie's rationalization of Bohr's model seemed even more outrageous to many scientists. Before the faculty would accept his thesis, they wanted another opinion, so they sent it to Albert Einstein for review. Einstein wrote back that he found the young man's work "quite interesting." That endorsement was good enough for the faculty: de Broglie's thesis was accepted in 1924 and immediately submitted for publication. Five years later, he was awarded the Nobel Prize in Physics.

The Heisenberg Uncertainty Principle

If electrons exhibit both particle-like and wavelike behavior, then what impact does the wave behavior have on our ability to locate the electron? A wave, by its very nature, is spread out in space. The question "Where is the electron?" has one answer if we treat the electron as a particle and a very different answer if we treat it as a wave. This issue was addressed by the German physicist Werner Heisenberg (1901–1976), who proposed the following thought experiment: Watch an electron with a microscope to "see" the electron's path around an atom. The microscope (if it existed) would need to use gamma rays for illumination (rather than visible light) because gamma rays are the only part of the electromagnetic spectrum with wavelengths short enough to match the diminutive size of electrons. According to Equations 7.2 and 7.3, however, the short wavelengths and high frequencies of gamma rays mean that they have enormous energies—so large that any gamma ray striking an electron would knock the electron off course. The only way to *not* affect the electron's motion would be to use a much lower-energy, longer-wavelength source of radiation to illuminate it—but then we would be unable to see the tiny electron clearly.

This situation presents a quantum mechanical dilemma. The only means for clearly observing an electron make it impossible to know the electron's motion or, more precisely, its momentum, which is defined as an object's velocity times its mass. Therefore, we can never know exactly both the position and the momentum of the electron simultaneously. This conclusion is known as the Heisenberg uncertainty principle, and it is expressed mathematically by Equation 7.13:

where Δx is the uncertainty in the position of the electron, m is its mass, Δu is the uncertainty in its velocity, and h is the Planck constant. To Heisenberg, this uncertainty was the essence of quantum mechanics. Its message for us is that there are limits to what we can observe, measure, and therefore know.

SAMPLE EXERCISE 7.7 Calculating (Heisenberg) Uncertainty LO4

Use the data in Sample Exercise 7.6 to compare the uncertainty in the velocity of the baseball with the uncertainty in the velocity of the electron. Assume that the position of the baseball is known to within one wavelength of red light ($\Delta x_{\text{baseball}} = 680$ nm) and that the position of the electron is known to within the radius of the hydrogen atom ($\Delta x_{\text{electron}} = 5.29 \times 10^{-11}$ m).

Collect and Organize We are asked to calculate the uncertainty in the velocities of two particles given the uncertainties in their positions. From Sample Exercise 7.6 we know that the mass of a baseball is 0.142 kg and the mass of an electron is 9.109×10^{-31} kg.

Analyze Equation 7.13 provides a mathematical connection between these variables. According to Equation 7.13, the uncertainty in the velocity and position of a particle is inversely proportional to its mass. Therefore, we can expect little uncertainty in the velocity of the baseball, but much greater uncertainty in the velocity of the electron. We need to rearrange the terms in the equation to solve for the uncertainty in velocity (Δu):

Solve For the baseball:

For the electron:

Comparing the two values, we see that the uncertainty in the velocity of the baseball is extremely small (about 10^{-28} m/s), whereas that of the electron is huge (greater than 1 million m/s).

Think About It The uncertainty in the measurement of the baseball's velocity is so minuscule that it is insignificant. This result is expected for objects in the macroscopic world. However, the uncertainty in the measurement of the velocity of the electron is huge, which is what we must expect at the atomic level, where “particles” such as the electron also behave like waves.

Practice Exercise What is the uncertainty, in meters, in the position of an electron moving near a nucleus at a speed of 8×10^7 m/s? Assume the uncertainty in the velocity of the electron is 1% of its value—that is, $\Delta u = (0.01)(8 \times 10^7 \text{ m/s})$.

When Heisenberg proposed his uncertainty principle, he was working with Bohr at the University of Copenhagen. The two scientists had widely different views about the significance of the uncertainty principle and the idea that particles could behave like waves. To Heisenberg, uncertainty was a fundamental characteristic of nature. To Bohr, it was merely a mathematical consequence of the wave–particle duality of electrons; there was no physical meaning to an electron's position and path. The debate between these two gifted scientists was heated at times. Heisenberg later wrote about one particularly emotional debate:

> [A]t the end of the discussion I went alone for a

> walk in the neighboring park [and] repeated to myself again and again the question: “Can nature possibly be as absurd as it seems?”[1]

The Heisenberg uncertainty principle is fundamental to our present understanding of the atom. If we cannot know both the position and momentum of an electron in a hydrogen atom, then the electron cannot be moving in circular orbits as implied by Bohr’s original model. As we see in Section 7.6, the Heisenberg uncertainty principle limits us to knowing only the *probability* of finding an electron at a location in an atom.

Glossary

matter wave	the wave associated with any particle.
standing wave	a wave confined to a given space, with a wavelength (λ) related to the length L of the space by $L = n(\lambda/2)$, where n is a whole number.
node	a location in a standing wave that experiences no displacement; in the context of orbitals, nodes are locations at which electron density goes to zero.
Heisenberg uncertainty principle	the principle that we cannot determine both the position and the momentum of a particle in an atom at the same time.

FIGURE 7.21 During the first three decades of the 20th century, quantum theory evolved from classical 19th-century theories of the nature of matter and energy. The arrows trace the development of modern quantum theory, which incorporates the assumption that radiant energy has both wavelike and particle-like properties and that mass (matter) also has both wavelike and particle-like properties.

7.6 Quantum Numbers and Electron Spin

Many of the leading scientists of the 1920s were unwilling to accept the dual wave–particle nature of electrons proposed by de Broglie unless the model could be used to predict the features of the hydrogen emission spectrum. This kind of application required the development of equations describing the behavior of electron waves. During his Christmas vacation in 1925, the Austrian physicist Erwin Schrödinger (1887–1961) did just that, developing in a few weeks the mathematical foundation for what came to be called wave mechanics or quantum mechanics.

Schrödinger's mathematical description of electron waves is called the Schrödinger wave equation. It is not discussed in detail in this book, but you should know that solutions to the wave equation are called wave functions (ψ): mathematical expressions that describe how the matter wave of an electron in an atom varies both with time and with the location of the electron in the atom. Wave functions define the energy levels in the hydrogen atom. They can be simple trigonometric functions, such as sine or cosine waves, or they can be very complex.

What is the physical significance of a wave function? Actually, there is none. However, the *square of a wave function* (ψ^2) does have physical meaning. Initially, Schrödinger believed that a wave function depicted the "smearing" of an electron through three-dimensional space. This notion of subdividing a discrete particle was later rejected in favor of the model developed by German physicist Max Born (1882–1970), who proposed that ψ^2 defines an orbital: the space around the nucleus of an atom where the probability of finding an electron is high. Born later showed that his interpretation could be used to calculate the probability of a transition between two orbitals, as happens when an atom absorbs or emits a photon.

To help visualize the probabilistic meaning of ψ^2, consider what happens when we spray ink onto a flat surface (**Figure 7.16**). If we then draw a circle encompassing most of the ink spots, we are identifying the region of maximum probability for finding the spots.

Quantum mechanical orbitals in an atom are not two-dimensional concentric orbits, as in Bohr's model of the hydrogen atom, or even two-dimensional circles, as in Figure 7.16. Instead, as we see in detail in Section 7.7, orbitals are three-dimensional regions of space with distinctive shapes, orientations, and average distances from the nucleus. Each orbital is a solution to Schrödinger's wave equation and is identified by a unique combination of three integers, or quantum numbers, whose values flow directly from the mathematical solutions to the wave equation. The quantum numbers are n, ℓ, and m_ℓ:

- The principal quantum number n is like Bohr's number n for the hydrogen atom in that it is a positive integer that indicates the relative size and energy of an orbital or group of orbitals in an atom. Orbitals with the same value of n are in the same *shell*. Orbitals with larger values of n are farther from the nucleus and, in the hydrogen atom, represent higher energy levels, consistent with Bohr's model of the hydrogen atom. In multielectron atoms, the relationship between energy levels and orbitals is more complex but increasing values of n generally represent higher energy levels.
- The angular momentum quantum number ℓ is an integer with a value ranging from zero to $n - 1$ that defines the shape of an orbital. Orbitals with the same value of n and ℓ are in the same *subshell* and represent equal energy levels. Orbitals with a given value of ℓ are identified with a letter according to the following scheme:

Value of ℓ				
Type of Orbital				

- The choice of letters to designate the values of ℓ (i.e., *s*, *p*, *d*, and *f*) may seem a bit odd. Before quantum mechanics was developed, scientists recording line spectra of the elements described the lines they observed as ***s**harp*, ***p**rincipal*, ***d**iffuse*, and ***f**undamental*. Designating orbitals with the letters *s*, *p*, *d*, and *f* recognizes this historical convention.
- The magnetic quantum number m_ℓ is an integer with a value

from $-\ell$ to $+\ell$. It defines the orientation of an orbital in the space around the nucleus of an atom.

Each subshell in an atom has a two-part designation containing the appropriate value of n and a letter designation for ℓ. For example, orbitals with $n = 3$ and $\ell = 1$ are called 3*p* orbitals, and electrons in 3*p* orbitals are called 3*p* electrons.

TABLE 7.1 Quantum Numbers of the Orbitals in the First Four Shells

m_ℓ	NUMBER OF ORBITALS In Subshell	In Shell
		0
1, 0, +1		4
1, 0, +1 2, −1, 0, +1, +2		9
1, 0, +1 2, −1, 0, +1, +2 3, −2, −1, 0, +1, +2, +3		16

How many 3*p* orbitals are there? The number depends on how many m_ℓ values can an $\ell = 1$ (*p*) subshell have, and the answer is three: −1, 0, and +1. These three m_ℓ values mean that there are three 3*p* orbitals, each with a unique combination of n, ℓ, and m_ℓ values. **Table 7.1** lists all the possible combinations of these three quantum numbers for the orbitals of the first four shells.

SAMPLE EXERCISE 7.8 Identifying the Subshells and Orbitals in an Energy Level LO5

(a) What are the designations of all the subshells in the $n = 3$ shell?
(b) How many orbitals are in these subshells?

Collect and Organize We are asked to describe the subshells in the third shell and to determine how many orbitals are in all these subshells. Table 7.1 lists all the subshells in the first four shells.

Analyze The designations of subshells are based on the possible values of the quantum numbers n and ℓ. The allowed values of ℓ depend on the value of n, because ℓ is an integer from 0 up to $n - 1$. The number of orbitals in a subshell depends on the number of possible values of m_ℓ (i.e., integers that range from $-\ell$ to $+\ell$).

Solve

1. The allowed values of ℓ for $n = 3$ range from 0 through $(n - 1)$, so they are 0, 1, and 2. These ℓ values correspond to the subshell designations *s, p,* and *d*, respectively. The appropriate subshell names are thus 3*s*, 3*p*, and 3*d*.
2. The possible values of m_ℓ from $-\ell$ to $+\ell$ are as follows:

   $\ell = 0$; $m_\ell = 0$: This combination of ℓ and m_ℓ values for the $n = 3$ shell represents a single 3*s* orbital.

   $\ell = 1$; $m_\ell = -1, 0,$ or $+1$: These three combinations of ℓ and m_ℓ values for the $n = 3$ shell represent the three 3*p* orbitals.

   $\ell = 2$; $m_\ell = -2, -1, 0, +1,$ or $+2$: These five combinations of ℓ and m_ℓ values represent the five 3*d* orbitals.

Think About It There are a total of $1 + 3 + 5 = 9$ orbitals in the $n = 3$ shell. The total number of orbitals in a shell increases with increasing values of n because as n increases the allowed values ℓ and m_ℓ also increase. Thus, there is only 1 orbital in the $n = 1$ shell, there are 4 in $n = 2$, and 16 in $n = 4$.

Practice Exercise How many orbitals are there in the $n = 5$ shell?

Figure 7.17 visually summarizes the quantum number rules. This system of quantum numbers provides a useful “shorthand” to refer to the orbitals that are solutions to Schrödinger’s wave equation. Even so, the Schrödinger wave equation could account for most, but not all, aspects of atomic spectra. The emission spectrum of hydrogen, for example, has a pair of red lines at 656 nm where Balmer thought there was only one line (**Figure 7.18**). There are also pairs of lines in the spectra of multielectron atoms that have a single electron in their outermost shells (see Figure 7.3). The Schrödinger equation cannot explain these pairs of lines.

In 1925, two students at the University of Leiden in the Netherlands, Samuel Goudsmit (1902–1978) and George Uhlenbeck (1900–1988), proposed that the pairs of lines, called *doublets*, were caused by a property they called electron spin. In their model, electrons spin in one of two directions, designated “spin up” and “spin down.” A moving electron (or any charged particle) creates a magnetic field by its motion. The spinning motion produces a second magnetic field oriented up or down. To account for these two spin orientations, Goudsmit and Uhlenbeck proposed a fourth quantum number, the spin magnetic quantum number (m_s). The values of m_s are $+\frac{1}{2}$ for spin up and $-\frac{1}{2}$ for spin down.

Even before Goudsmit and Uhlenbeck proposed the electron-spin hypothesis, two other scientists, Otto Stern (1888–1969) and Walther Gerlach (1889–1979), had observed the effect of electron spin when they shot a beam of silver ($Z = 47$) atoms through a magnetic field (**Figure 7.19**). Those atoms in which the net electron spin was “up” were deflected in one direction by the field, whereas those in which the net electron spin was “down” were deflected in the opposite direction.

In 1925 Austrian physicist Wolfgang Pauli (1900–1958; **Figure 7.20**) proposed that no two electrons in a multielectron atom have the same set of four quantum numbers. This idea is known as the Pauli exclusion principle. The three quantum numbers from Schrödinger’s wave equation define the orbitals where an atom’s electrons are likely to be. The two allowed values of the spin magnetic quantum number indicate that each orbital can hold two electrons—one with $m_s = +\frac{1}{2}$ and the other with $m_s = -\frac{1}{2}$. Thus, each electron in an atom has a unique combination of n, ℓ, m_ℓ, and m_s values.

SAMPLE EXERCISE 7.9 Identifying Valid Quantum Number Sets LO5

Which of these combinations of quantum numbers are valid?

	n	ℓ	m_ℓ	m_s
(a)	[illegible]	[illegible]	[illegible]	$+\frac{1}{2}$
(b)	[illegible]	[illegible]	[illegible]	$+\frac{1}{2}$
(c)	[illegible]	[illegible]	[illegible]	[illegible]
(d)	[illegible]	[illegible]	[illegible]	$-\frac{1}{2}$
(e)	[illegible]	[illegible]	[illegible]	$-\frac{1}{2}$

Collect, Organize, and Analyze We are asked to validate five sets of quantum numbers. These rules apply: A principal quantum number (n) can be any positive integer. The values of ℓ in a given shell are integers from 0 to $(n - 1)$; the values of m_ℓ in a given subshell are all integers from $-\ell$ to $+\ell$, including 0. The only two options for m_s are $+\frac{1}{2}$ or are $-\frac{1}{2}$.

Solve

1. Because $n = 1$, the maximum (and only) value of ℓ is $(n - 1) = 1 - 1 = 0$. Therefore, the values of n and ℓ are valid. However, if $\ell = 0$, then m_ℓ must be 0; it cannot be -1. Therefore, this set is not valid. The spin quantum number is a possible value.
2. Because $n = 3$, ℓ can be 2 and m_ℓ can be -2. Also, $m_s = +\frac{1}{2}$ is a valid choice for the spin magnetic quantum number. This set is valid.
3. Because $n = 2$, ℓ cannot be 2, making this set invalid. In addition, m_s has an invalid value (0).
4. d. Because $n = 2$, ℓ can be 0, and for that value of ℓ, m_ℓ must be 0. The value of m_s is also valid, and so is the set.
5. This set contains two impossible values, $n = -3$ and $\ell = -2$, so it is invalid.

Think About It The values of n, ℓ, and m_ℓ are related mathematically, and m_s can be either $+\frac{1}{2}$ or $-\frac{1}{2}$. Every electron has its own unique set of four quantum numbers.

Practice Exercise Write all the possible sets of quantum numbers for an electron in the $n = 3$ shell that has an angular momentum quantum number $\ell = 1$ and a spin quantum number $m_s = +\frac{1}{2}$.

Momentous advances in chemistry and physics were made in the first three decades of the 20th century because of the brilliant minds of Einstein, Planck, Rutherford, Bohr, de Broglie, Schrödinger, and others, who have forever changed scientists' view of the fundamental structure of matter and the universe. **Figure 7.21** summarizes and connects some of these advances.

How different is the view of the interaction of matter and energy provided by quantum mechanics from the laws governing the behavior of large objects? A pebble picked up and dropped immediately falls to the ground. Electrons, however, remain in excited states for indeterminate (though usually short) times before falling to their ground states. This lack of determinacy bothered Einstein and many of his colleagues. Had they discovered an underlying theme of nature—that some processes cannot be described or known with certainty? Are there fundamental limits to how well we can know and understand our world and the events that change it?

The variable lifetimes of excited states are the basis for the lasers used in bar-code scanners at grocery stores, laser pointers, DVD players, and in surgery (**Figure 7.22**). The word *laser* is an acronym for **L**ight **A**mplification by **S**timulated **E**mission of **R**adiation. The phrase *stimulated emission* is linked to the fact that the atoms in lasers remain in excited states for unusually long times, which increases the populations of these excited states. Then, if a photon with just the right energy encounters one of these excited-state atoms, it stimulates the decay of the excited state, producing a second photon that matches the first: same wavelength, same phase, and going in the same direction. When these two photons encounter two more excited-state atoms, they could produce four in-phase photons, which could produce four more, and so on. In this way, one incident photon is rapidly amplified into an intense pulse of monochromatic light. To produce a steady beam of this light, electrical energy continuously pumps up the lasing material, repopulating the excited state. By manipulating the composition of lasers, scientists can adjust the electronic energy levels inside them and the color of the light they produce.

Glossary

wave mechanics (also called quantum mechanics)

a mathematical description of the wavelike behavior of particles on the atomic level.

Schrödinger wave equation

a description of how the electron matter wave varies with location and time around the nucleus of a hydrogen atom.

orbital

a region around the nucleus of an atom where the probability of finding an electron is high; each orbital is defined by the square of the wave function (ψ^2) and is identified by a unique combination of three quantum numbers.

quantum number

a number that specifies the energy, the probable location or orientation of an orbital, or the spin of an electron within an orbital.

angular momentum quantum number (ℓ)

an integer having any value from 0 to $n - 1$ that defines the shape of an orbital.

spin magnetic quantum number (m_s)

either $+\frac{1}{2}$ or $-\frac{1}{2}$, indicating that the spin orientation of an electron is either up or down, respectively.

Pauli exclusion principle

the principle that no two electrons in an atom can have the same set of four quantum numbers.

wave function (ψ)

a solution to the Schrödinger wave equation.

principal quantum number (n)

a positive integer describing the relative size and energy of an atomic orbital or group of orbitals in an atom.

magnetic quantum number (m_ℓ)

an integer that may have any value from $-\ell$ to $+\ell$, where ℓ is the angular momentum quantum number; it defines the orientation of an orbital in space.

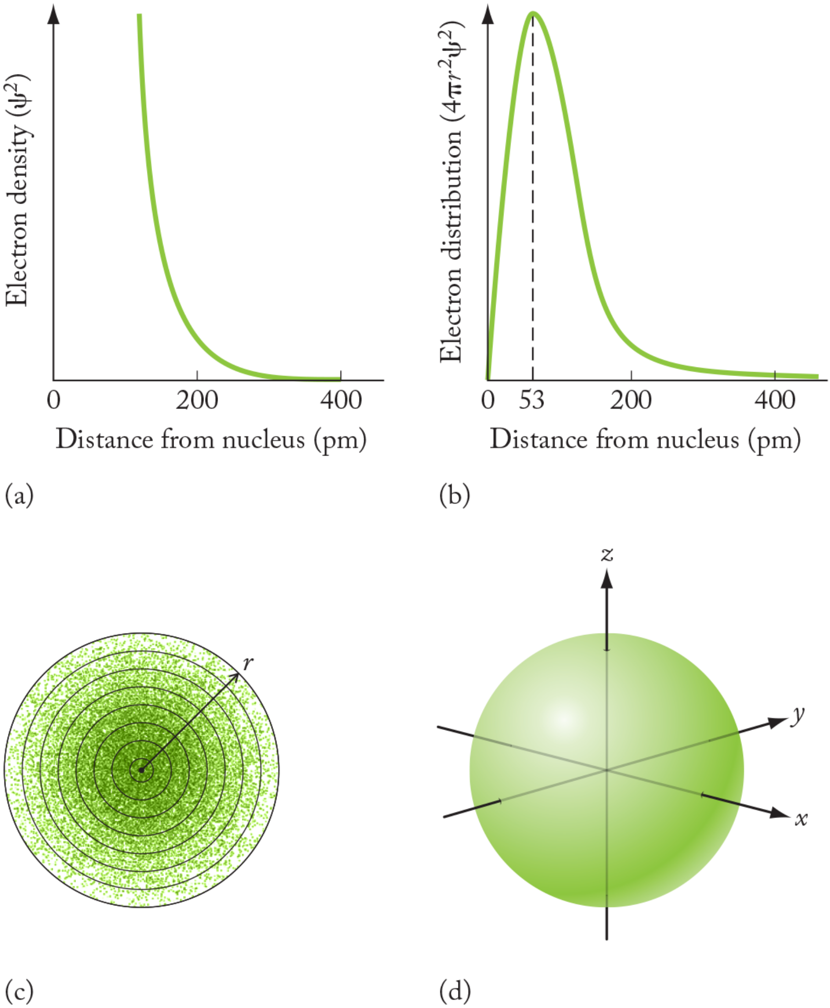

FIGURE 7.23 (a) Probable electron density in the 1*s* orbital of the hydrogen atom represented by a plot of electron density (ψ^2) versus distance from the nucleus. (b) Electron distribution in the 1*s* orbital versus distance from the nucleus. The distribution is essentially zero for both very short distances from the nucleus and very long distances from the nucleus. The maximum probability occurs at r = 53 pm. (c) Cross section through the hydrogen atom, with the space surrounding the nucleus divided into an arbitrary number of thin, concentric, hollow layers. Each layer has a unique value for radius *r*. The probability of finding an electron in a layer of radius *r* depends on the volume of the layer and the density of electrons in

the layer. (d) Boundary–surface representation of a sphere within which the probability of finding a 1*s* electron is 90%.

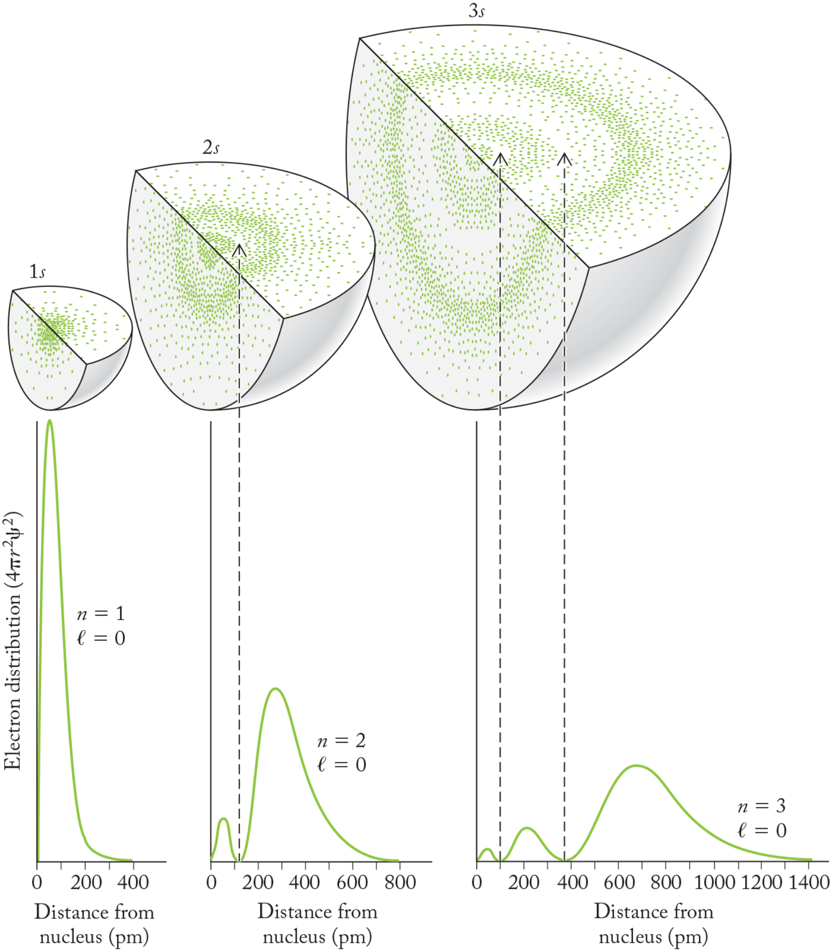

FIGURE 7.24 These radial distribution profiles of 1*s*, 2*s*, and 3*s* orbitals have 0, 1, and 2 nodes, respectively, identifying (with dashed arrows) locations of zero electron density. Electrons in all these *s* orbitals have some probability of being close to the nucleus, but 3*s* electrons are more likely to be farther away from the nucleus than 2*s* electrons, which are more likely to be farther away than 1*s* electrons.

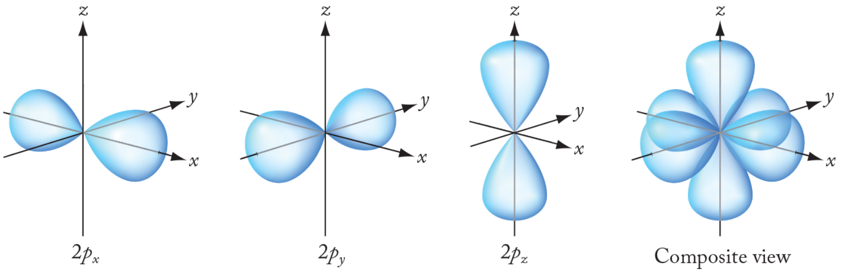

FIGURE 7.25 Boundary–surface views of the three *p* orbitals, showing their orientation along the *x*-, *y*-, and *z*-axes. The nucleus of the atom containing these orbitals is located at the origin. These shapes are an elongated version of the theoretical shapes of the orbitals. We use this version throughout the book to make it easier to see the orientation of the lobes.

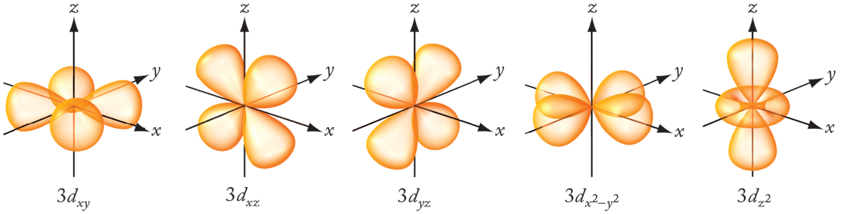

FIGURE 7.26 Boundary–surface views of the five *d* orbitals, showing their orientation relative to the *x*-, *y*-, and *z*-axes. The d_{xy}, d_{xz}, and d_{yz} orbitals are *not* aligned along any axis; the $d_{x^2-y^2}$ orbital lies along the *x*- and *y*-axes; the d_{z^2} orbital consists of two teardrop-shaped lobes along the *z*-axis with a donut-shaped torus ringing the point where the two lobes meet.

7.7 The Sizes and Shapes of Atomic Orbitals

As noted in Section 7.6, the orbitals that are solutions to Schrödinger's wave equation have three-dimensional shapes that are graphical representations of ψ^2. In this section, we examine the shapes of atomic orbitals and explain how those shapes affect the energies of the electrons in them.

s Orbitals

Figure 7.23 shows several representations of the 1*s* orbital of the hydrogen atom. In Figure 7.23a, electron density is plotted against distance from the nucleus and shows that density decreases with increasing distance. However, Figure 7.23b provides a more useful profile of electron distribution. To understand why, imagine if the hydrogen atom were like an onion, made of many concentric spherical layers, all the same thickness. A cross section of this image of the atom is shown in Figure 7.23c. What would be the probability of finding the electron in one of these spherical layers? A layer very close to the nucleus has a very small radius, so it accounts for only a small fraction of the total volume of the atom. A layer with a larger radius makes up a much larger fraction of the volume of the atom because the volume of the layers increases as a function of r^2. (The volume of a sphere depends on r^3, but here we are discussing a spherical shell, the volume of which depends on r^2.) Even though electron densities are higher closer to the nucleus (as Figure 7.23a shows), the volumes of the spherical layers closest to the nucleus are so small that the chances of the electron being near the center of an atom are extremely low; this is shown in Figure 7.23b, where the curve starts off at essentially zero for electron distribution values at distances very close to the nucleus. Farther from the nucleus, electron densities are lower, but the volumes of the layers are much larger, so the probability of the electron being in one of these layers is relatively high, represented by the peak in the curve of Figure 7.23b. At greater distances, volumes of the layers are very large but ψ^2 drops to nearly zero (see Figure 7.23a), so the chances of finding an electron in layers far from the nucleus are very small.

Figure 7.23b, then, represents a combination of two competing factors: increasing layer volume and decreasing probability of finding an electron in a given layer. This combination produces a *radial distribution profile* for the electron. Figure 7.23b is not a plot of ψ^2 versus distance from the nucleus as in Figure 7.23a, but rather a plot of $4\pi r^2\psi^2$ versus distance from the nucleus. In geometry, $4\pi r^2$ is the formula for the surface area of a sphere, but here it represents the volume of one of the thin spherical layers in Figure 7.23c.

A significant feature of the curve in Figure 7.23b is that its maximum value corresponds to the most likely radial distance of the electron from the nucleus. The value of r corresponding to this maximum for the 1*s* orbital of hydrogen is 53 picometers (pm).

Figure 7.23d provides a view of the spherical shape of this (or any other) *s* orbital. The surface of the sphere encloses the volume within which the probability of finding a 1*s* electron is 90%. This type of depiction, called a *boundary–surface representation*, is one of the most useful ways to view the relative sizes, shapes, and orientations of orbitals. All *s* orbitals are spheres, which have only one orientation and in which electron density depends only on distance from the nucleus. Boundary surfaces are a useful way to depict the shape and relative size of an orbital.

The relative sizes of 1*s*, 2*s*, and 3*s* orbitals are shown in **Figure 7.24**. Note that orbital size increases with increasing values of the principal quantum number n. Note also that the sections of the spheres above the profile curves show bands in which the density of dots is high. The dots represent the probability of an electron being in these regions of three-dimensional space, and each band is called a *local maximum* of electron density. In all three profiles, a local maximum occurs close to the nucleus. This means that electrons in *s* orbitals—even *s* orbitals with high values of n—have some probability of being close to the nucleus.

The local maxima in any *s* orbital are separated from other local maxima by nodes. The number of nodes in any *s* orbital is equal to $n - 1$. Nodes have the same meaning here as they do in one-dimensional standing waves (recall Figure 7.15a): they are places where the wave has zero amplitude. In the context of electrons as three-dimensional matter waves, nodes are locations at which electron density goes to zero.

CONCEPT TEST

How many nodes are there in the electron distribution profile of the 6*s* orbital?

p and *d* Orbitals

All shells with $n \geq 2$ have a subshell containing three *p* orbitals ($\ell = 1$; $m_\ell = -1, 0, +1$). Each of these orbitals has two teardrop-shaped lobes, oriented opposite each other, along one of the three perpendicular Cartesian axes *x*, *y*, and *z* (**Figure 7.25**). These orbitals are designated p_x, p_y, and p_z, depending on the axis along which the lobes are situated. The two lobes of a *p* orbital may be labeled with plus and minus signs (not in this text, but in other sources), indicating that the sign of the wave function defining them is either $+\psi$ or $-\psi$. (These signs are not in any way connected with electric charges.) An electron in a *p* orbital occupies *both* lobes. Because a node of zero probability separates the two lobes, you may wonder how an electron gets from one lobe to the other. One way to think about how this happens is to remember that an electron behaves as a three-dimensional standing wave, and waves have no difficulty passing through nodes. In Figure 7.15a, for example, there is a node right in the middle of the $n = 2$ standing wave that separates the positive and negative displacement regions in the vibrating string.

The five *d* orbitals ($\ell = 2$; $m_\ell = -2, -1, 0, +1, +2$) found in shells of *n*$ 3 all have different orientations (**Figure 7.26**). Four of them consist of four teardrop-shaped lobes oriented like the leaves in a four-leaf clover. In three of these orbitals, the lobes are not situated along the *x*-, *y*-, and *z*-axes, but rather in the quadrants formed by the axes. These orbitals are designated d_{xy}, d_{xz}, and d_{yz}. In the fourth orbital in this set, designated $d_{x^2-y^2}$, the four lobes lie along the *x*- and *y*-axes. The fifth *d* orbital, designated d_{z^2}, is mathematically equivalent to the other four but has a much different shape, with two teardrop-shaped lobes oriented along the *z*-axis and a donut shape called a *torus* in the *x*–*y* plane that surrounds the middle of the two lobes. We do not address the shapes and geometries of *f* orbitals in this chapter because only *s*, *p*, and *d* orbitals are involved in discussions of chemical bonding in the chapters to come.

FIGURE 7.34 (a) This diagram shows the sequence in which atomic orbitals fill. (b) The same color coding in this version of the periodic table highlights the four “blocks” of elements in which valence-shell *s* (green), *p* (blue), *d* (orange), and *f* (purple) orbitals are filled as atomic number increases across a row of the table.

FIGURE 7.35 Strontium nitrate is a common ingredient in road flares that give off red light.

7.8 The Periodic Table and Filling the Orbitals of Multielectron Atoms

Now that we have developed a model to describe the atomic orbitals, we can use that model to describe atoms containing more than one electron. To explore the orbital-filling sequence, let's start at the beginning of the periodic table with hydrogen and put each successive electron into the lowest-energy orbital available as we move through the table element by element. This method is based on the aufbau principle (German *aufbauen*, "to build up"), which states that the most stable atomic structures are those in which the electrons are in the lowest-energy orbitals available.

CONNECTION We described in Section 2.5 how Mendeleev developed the first useful periodic table of the elements, not only decades before de Broglie gave us electron waves and Schrödinger pioneered quantum mechanics, but even before atoms were known to consist of electrons, protons, and neutrons.

To decide which orbitals contain electrons, we start with two rules:

1. Electrons always go into the lowest-energy orbital available.
2. Each orbital can hold up to two electrons.

Using these rules, let's assign the single electron in a hydrogen ($Z = 1$) atom to the appropriate orbital. We have already discussed how the single electron in a ground-state atom of hydrogen is in the $1s$ orbital. We represent this arrangement with the electron configuration $1s^1$, where the first "1" indicates the principal quantum number (n) of the orbital, "s" indicates the type of orbital, and the superscript "1" indicates that there is *one* electron in this $1s$ orbital. Because the hydrogen atom has only one electron, $1s^1$ is the complete electron configuration for a hydrogen atom in its ground state.

To be unambiguous about the electron configuration, we use orbital diagrams to show how electrons, represented by single-headed arrows, are distributed among orbitals, represented by boxes. A single-headed arrow pointing upward represents an electron with spin up ($m_s = +\frac{1}{2}$), and a downward-pointing single-headed arrow represents an electron with spin down ($m_s = -\frac{1}{2}$). Because hydrogen has only one electron, its orbital diagram contains one single-headed arrow in a box labeled $1s$ (**Figure 7.27a**).

The atomic number of helium is 2, which tells us there are two protons and two electrons in the neutral atom. Using the aufbau principle, we simply add another electron to the 1*s* orbital. We know that each orbital can contain two electrons, but the spin quantum numbers for the two electrons cannot be the same. One must be $+\frac{1}{2}$ and the other must be $-\frac{1}{2}$. These two electrons are said to be *spin-paired.* Their presence gives helium a ground-state electron configuration of $1s^2$. With two electrons, the 1*s* orbital is now full and so is the $n = 1$ shell (**Figure 7.27b**).

The concept of a *filled shell* is key to understanding chemical properties: elements composed of atoms that have filled *s* and *p* subshells in their outermost shells are chemically stable and generally unreactive. Helium is such an element, as are all the other elements in group 18.

The location of lithium ($Z = 3$) in the periodic table—the first element in the second period—is a signal that lithium has one electron in its $n = 2$ shell. The row numbers in the periodic table correspond to the *n* values of the outermost shells of the elements in the rows. The second shell has four orbitals (one 2*s* and three 2*p*), so it can hold up to eight electrons. Lithium's third electron occupies the lowest-energy orbital in the second shell, which is the 2*s* orbital, making its electron configuration $1s^22s^1$.

Now that we've begun to place electrons in the second shell, let's consider the forces that an electron in the second shell experiences. An electron in a 2*s* or 2*p* orbital has an electrostatic attraction to the positively charged nucleus, but that electron is also partially shielded from the nucleus by the two negative charges on the 1*s* electrons (**Figure 7.28**). This shielding essentially reduces the nuclear charge experienced by a lithium atom's 2*s* electron, that is, its effective nuclear charge (Z_{eff}), from +3 to about +1.

Returning to the ground-state lithium atom, we saw that its third electron occupies the 2*s* orbital. Why is the 2*s* orbital lower in energy than any of the 2*p* orbitals? We can best explain this difference in energies by comparing the radial distribution profiles of these orbitals (**Figure 7.29**). The small peak on the 2*s* curve near the nucleus indicates that an electron in the 2*s* orbital is closer to the nucleus more of the time than an electron in a 2*p* orbital, which has no such secondary peak. This closer proximity means that a 2*s* electron experiences a greater Z_{eff} than an electron in a 2*p* orbital, even though both are shielded by the 1*s* electrons. Therefore, a 2*s* electron is lower in energy than a 2*p* electron, which is why the 2*s* orbital fills first.

We can simplify the electron configuration of Li and all the elements that follow it in the periodic table by using a *condensed electron configuration*. For Li, this is $[\text{He}]2s^1$. In this form, the symbols representing all the electrons in orbitals that were filled in the rows above the element of interest are replaced by the symbol of the group 18 element at the end of the row above the element. For Li, this is [He]. Condensed electron configurations are useful because they replace the orbital notation for the core electrons in filled shells and subshells with the symbol of a single noble gas. Only the orbital notation for the electrons in the outermost shell is written out. These outermost electrons are called valence electrons. The distinction between core and valence electrons is used in later chapters to explain reactions and bond formation.

In any atom, the shell containing the valence electrons is referred to as the valence shell. Lithium has a single electron in its valence-shell *s* orbital, as does hydrogen, the element directly above it in the periodic table; therefore, both atoms have the valence-shell configuration ns^1. Here *n* represents both the number of the row in which the atom is located on the table and the principal quantum number of the valence shell in the atom.

Beryllium ($Z = 4$) is the fourth element in the periodic table and the first in group 2. The configuration for its four electrons is $1s^22s^2$ or $[\text{He}]2s^2$. The other elements in group 2 also have two spin-paired electrons in the *s* orbital of their valence shell. The second shell is not filled at this point because it also has three empty *p* orbitals that will fill as we move to the next elements in the periodic table.

Boron ($Z = 5$) is the next element and the first element in group 13.

Its fifth electron is in one of its three 2*p* orbitals, resulting in the condensed electron configuration $[\mathrm{He}]2s^2 2p^1$. Designating the 2*p* orbital that contains the fifth electron as $2p_x$, $2p_y$, or $2p_z$ is not important because these three orbitals all have the same energy; we say they are degenerate orbitals.

The next element is carbon ($Z = 6$). It has four electrons in its valence shell (the $n = 2$ shell), so its condensed electron configuration is $[\mathrm{He}]2s^2 2p^2$. Are the two electrons in the 2*p* orbitals both in the same orbital? All electrons have a negative charge and repel one another. Thus, they occupy orbitals that are as far away from each other as possible, which means the two 2*p* electrons in carbon occupy separate 2*p* orbitals. This distribution pattern follows Hund's rule, named after the German physicist Friedrich Hund (1896–1997), which states that the lowest-energy electron configuration for degenerate orbitals (such as the $2p_x$, $2p_y$, and $2p_z$ orbitals in the 2*p* subshell) is the one with the maximum number of unpaired parallel valence electrons (i.e., all their spins have the same direction).

Hund's rule is the third rule we apply when determining electron configurations. By convention, the first electron placed in an orbital has a positive spin. When electrons fill a degenerate set of orbitals, Hund's rule requires that an electron with a positive spin occupy each valence orbital before any electron with a negative spin enters any orbital. Electrons do not pair in degenerate orbitals until each orbital is occupied by a single electron. To obey Hund's rule, the orbital diagram for carbon must be

which shows that the two 2*p* electrons are unpaired and have the same spin.

The next element is nitrogen ($Z = 7$), represented by either $1s^2 2s2p^3$ or $[\mathrm{He}]2s^2 2p^3$. According to Hund's rule, the third 2*p* electron is assigned to the third 2*p* orbital, so that the electron distribution is

As we proceed across the second row to neon ($Z = 10$), we fill the 2*p* orbitals as shown in **Figure 7.30**. The last three 2*p* electrons added (in oxygen, fluorine, and neon) spin pair with the first three, so that in neon, the three 2*p* orbitals are all filled. At this point the $n = 2$ shell is full. Helium, neon, and all the other noble gases in group 18 have filled *s* and *p* orbitals in their valence shells. This same trend is seen throughout the periodic table: *main group elements in the same column of the periodic table have the same valence-shell electron configuration*. Argon, krypton, xenon, and radon also have filled *s* and *p* orbitals in their outermost occupied shells, and they also are chemically inert gases at room temperature.

Sodium ($Z = 11$) follows neon in the periodic table. It is the third element in group 1 and the first element in the third period. Ten of its electrons are distributed as in neon. The 11th electron is in the lowest-energy orbital available after 2*p* has been filled, which is 3*s*. The condensed electron configuration of Na is $[\mathrm{Ne}]3s^1$. Just as we write condensed electron configurations that provide orbital notation for only the outermost occupied shell, we can also condense orbital diagrams in this same way, so that the condensed orbital diagram for sodium is

This diagram reinforces the message that the electron configuration of a sodium atom consists of a neon core plus a single electron in the 3*s* orbital of the valence shell. The sodium atom has the same generic valence-shell configuration as lithium and hydrogen—namely, ns^1, where *n* is the period number. This pattern for main group elements in the same group continues throughout the periodic table. The electron configuration of magnesium ($Z = 12$), for instance, is $[\mathrm{Ne}]3s^2$, and the electron configuration of every other element in group 2 consists of the immediately preceding noble gas core followed by ns^2.

The next six elements in the periodic table—aluminum, $[\mathrm{Ne}]3s^2 3p^1$, to argon, $[\mathrm{Ne}]3s^2 3p^6$—show a pattern of increasing numbers of 3*p* electrons, a trend that continues until all three 3*p* orbitals are filled (six electrons), which means the *s* and *p* orbitals of the $n = 3$ shell are filled (eight electrons). Thus, argon is chemically inert, as predicted by its position in group 18.

Before leaving the third row, let's revisit the condensed electron configuration of sodium, [Ne]$3s^1$. This configuration represents a ground-state sodium atom because all the electrons, and most importantly its valence electron, occupy the lowest-energy orbitals available. Now think back to the discussion about atomic emission spectra in Section 7.1 and the distinctive yellow-orange glow that sodium makes in the flames of Bunsen burners, as shown back in Figure 7.3 and here in **Figure 7.31a**. Each sodium atom absorbs a quantum of energy from the Bunsen burner that raises the valence electron from the ground state to an excited state (a transition represented by the orange arrow pointing to the right in **Figure 7.32**). The easiest excited state to populate is the one with the smallest energy above the ground state. We have seen that the 3*p* orbitals fill after the 3*s* orbital because they have the next lowest energy. Therefore, the lowest-energy (or *first*) excited state of sodium is one in which its 3*s* electron has moved up to a 3*p* orbital. This excited state has the electron configuration [Ne]$3p^1$ (see Figure 7.32) and a very short lifetime. The electron typically takes less than a nanosecond to fall back to the ground state in a transition represented by the yellow-orange arrow pointing to the left in Figure 7.32. This transition releases a quantum of energy ($h\nu$) equal to the difference in energy between the 3*p* and 3*s* orbitals in a Na atom—the energy of a photon of yellow-orange light.

After argon comes potassium ($Z = 19$) in the fourth row of group 1 ([Ar]$4s^1$). Potassium atoms, like those of sodium, produce a distinctive emission spectrum when heated in a Bunsen burner flame (**Figure 7.31b**). Potassium is followed by calcium ($Z = 20$) in group 2 ([Ar]$4s^2$), at which point the 4*s* orbital is filled but the 3*d* orbitals are still empty. (Review Table 7.1 if you need help in recalling that the $n = 3$ shell contains a *d* subshell.) Why were the 3*d* orbitals not filled before 4*s*?

Applying the first aufbau principle—in building atoms, each electron goes in the lowest-energy orbital available—would be straightforward were it not for the fac that the differences in energy between shells get smaller as *n* gets larger (**Figure 7.33**). These smaller differences result in orbitals with large ℓ values in one shell having energies similar to those of orbitals with small ℓ values in the next higher shell. Note in Figure 7.33 that the energy of the 4*s* orbital is slightly lower than that of the 3*d* orbitals. The 4*s* orbitals in potassium and calcium are the lowest-energy orbitals available and are filled before any electrons go into a 3*d* orbital.

The element after calcium is scandium ($Z = 21$). It is the first element in the central region of the periodic table, the region populated by transition metals. Scandium has the condensed electron configuration [Ar] $3d^{1}4s^{2}$. Note that the orbitals are listed in order of increasing principal quantum number, not necessarily in the order in which they were filled. The advantage of writing configurations based on n is that it helps us predict the order in which elements lose valence electrons when they form monatomic cations (as discussed in next section). The 3*d* orbitals are filled in the transition metals from scandium to zinc ($Z = 30$). This pattern of filling the *d* orbitals of the shell whose principal quantum number is 1 less than the period number, $(n - 1)d$, is followed throughout the periodic table: the 4*d* orbitals are filled in the transition metals of the fifth period, and so on (**Figure 7.34**).

The element after scandium is titanium ($Z = 22$), which has one more *d* electron than scandium, so its condensed electron configuration is [Ar] $3d^{2}4s^{2}$. Vanadium ($Z = 23$) has the configuration [Ar] $3d^{3}4s^{2}$. At this point, you may feel you can accurately predict the electron configurations of the remaining transition metals in the fourth period. However, because the energies of the 3*d* and 4*s* orbitals are similar, the sequence of *d*-orbital filling deviates in two spots from the pattern you might expect. The next element, chromium ($Z = 24$), has the configuration [Ar] $3d^{5}4s^{1}$:

This half-filled set of *d* orbitals is an energetically favored configuration. Apparently, the stability of having five half-filled 3*d* orbitals compensates for the energy needed to raise a 4*s* electron to a 3*d* orbital. As a result, [Ar] $3d\,^{4}4s^{2}$is a lower-energy electron configuration than [Ar] $3d^{4}4s^{2}$.

Another deviation from the expected filling pattern is observed near the end of a row of transition metals. Copper ($Z = 29$) has the electron configuration [Ar] $3d^{9}4s^{2}$ instead of the expected [Ar] $3d^{10}4s^{1}$ because a filled set of *d* orbitals also represents a lower-energy electron configuration.

Figure 7.34 illustrates the overall orbital-filling pattern described above. It also shows how the periodic table can be used to predict the electron configurations of the elements. The color patterns and labels in Figure 7.34a indicate which type of orbital is filled going across each row from left to right. For example, groups 1 and 2 are called *s* block elements because their outermost electrons are in *s* orbitals. Similarly, groups 13 through 18 (except for helium) are called the *p* block elements because their outermost electrons are in *p* orbitals. Note how the principal quantum numbers (*n*) of the outermost orbitals in the *s* and *p* blocks match their row numbers: 2*s* and 2*p* in row 2, 3*s* and 3*p* in row 3, and so on. This means that the periodic table is a very useful reference for writing the electron configurations of the ground states of atoms. For example, barium is the group 2 element in the sixth row. This location means that a ground-state Ba atom has 2 electrons in its 6*s* orbital, so its condensed electron configuration is

Ba: $[\mathrm{Xe}]6s^{2}$

Between the *s* and *p* blocks are the transition metals in groups 3 through 12, which make up the *d* block, and the two rows of elements at the bottom of the periodic table, called the lanthanides and actinides, which make up the *f* block. Both of the *f* block series are 14 elements long. The *n* value of the *d* orbitals being filled in a row is always one less than the row number, and the *n* value of the *f* orbitals being filled is two less than the row number.

Several relationships are worth noting between the quantum numbering system (Figure 7.17) and the organization of the periodic table into rows and *s*, *p*, *d*, and *f* blocks (Figure 7.34b):

- Each row number corresponds to a value of *n*. The first row begins the $n = 1$ shell, the second row begins the $n = 2$ shell, and so on.
- There are *n* subshells in the *n*th shell. There is one subshell (1*s*) in the $n = 1$ shell, there are two subshells (2*s* and 2*p*) in

the $n = 3$ shell, and so on.

- There are n^2 orbitals in the nth shell and a maximum of $2n^2$ electrons. The first row has $n = 1$, so $1^2 = 1$ orbital (1*s*). The second row has $n = 2$, so $2^2 = 4$ orbitals (2*s*, $2p_x$, $2p_y$, and $2p_z$), and so on.
- Each block represents a subshell and there are $(2\ell + 1)$ orbitals in each subshell. The *s* block (subshell) consists of $(2 \times 0 + 1 = 1)$ one *s* orbital in each row. The *p* block consists of $(2 \times 1 + 1 = 3)$ three *p* orbitals in each row. The *d* block consists of $(2 \times 2 + 1 = 5)$ five *d* orbitals in each row. Lastly, the *f* block consists of $(2 \times 3 + 1 = 7)$ seven *f* orbitals in each row.
- Because the *s*, *p*, *d*, and *f* subshells always contain 1, 3, 5, and 7 orbitals, respectively, and each orbital contains 2 electrons, the *s* block consists of 2 elements in one row of the periodic table, the *p* block consists of 6 elements, the *d* block consists of 10 elements, and the *f* block consists of 14 elements. In the $n = 4$ shell, for example, there are 2 elements in the *s* block (K and Ca), 6 elements in the *p* block (Ga through Kr), 10 elements in the *d* block (Y through Cd), and 14 elements in the *f* block (Ce through Lu).

With these patterns in mind, let's write the condensed electron configuration of lead ($Z = 82$), which is the group 14 element in the sixth row. The noble gas that most closely precedes it is Xe ($Z = 54$). The difference in atomic numbers means that we need to account for $82 - 54 = 28$ electrons in the electron configuration symbols. The location of Pb and the block labels in Figure 7.34b indicates that these 28 electrons are distributed as follows:

- 2 electrons in 6*s*
- 14 electrons in 4*f*
- 10 electrons in 5*d*
- 2 electrons in 6*p*

Therefore, the condensed electron configuration of ground-state lead atoms reflects this distribution:

Pb: $[\mathrm{Xe}]\ 4f^{14}5d^{10}6_s{}^{2}6p^{2}$

SAMPLE EXERCISE 7.10 Writing Electron Configurations LO6

Strontium salts give off a bright red light at the high temperature of fireworks, explosions, and signal flares (**Figure 7.35**). What is the ground-state electron configuration of strontium atoms?

Collect, Organize, and Analyze Strontium is in the fifth row of group 2 of the periodic table. This means that the last orbital to be filled in an atom of Sr is 5*s* (see Figure 7.34b). The sequence of filling the atom's inner-shell orbitals (Figure 7.34a) is 1*s*, 2*s*, 2*p*, 3*s*, 3*p*, 4*s*, 3*d*, 4*p*, and then 5*s*. The atomic number of strontium, Z = 38, means that each strontium atom has 38 electrons.

Solve An *s* orbital can hold up to 2 electrons, a set of three *p* orbitals can hold 6 electrons, and a set of five *d* orbitals can hold 10. Therefore, the distribution of the 38 electrons in an atom of Sr is $1_s{}^2 2_s{}^2 2p^6 3_s{}^2 3p^6 3d^{10} 4_s{}^2 4p^6 5_s{}^2$.

Think About It The location of Sr in Figure 7.34 also indicates that the condensed electron configuration of Sr is [Kr] $5_s{}^2$.

Practice Exercise Gallium arsenide (GaAs) is used in the red lasers in bar-code readers. Write the electron configuration of a ground-state atom of gallium ($Z = 31$) and a ground-state arsenic atom ($Z = 33$).

SAMPLE EXERCISE 7.11 Writing Condensed Electron Configurations of Transition Metal Atoms LO6

Write the condensed electron configuration of an atom of silver.

Collect and Organize We need to write an element's condensed electron configuration, in which filled inner-shell orbitals are represented by the atomic symbol of the noble gas immediately preceding the element of interest in the periodic table. Silver ($Z =$

47) is the group 11 element in the fifth row of the periodic table.

Analyze Krypton ($Z = 36$) is the noble gas at the end of the fourth row. The difference between their atomic numbers ($47 - 36$) means that we need to assign 11 electrons to the orbitals after [Kr] in the condensed electron configuration of silver.

Solve According to the orbital-filling pattern in Figure 7.34a, 2 of the 11 electrons would be in the 5*s* orbital and the other 9 would be in 4*d* orbitals. However, a filled set of *d* orbitals is more stable than a partially filled set. Therefore silver, like copper just above it in the periodic table, has 10 electrons in its outermost *d* orbital and only 1 electron in its outermost *s* orbital. The condensed electron configuration of an Ag atom is [Kr] $4d^{10}5_s^1$.

Think About It We can generate a tentative electron configuration by simply moving across a row in Figure 7.34b until we come to the element of interest. However, we may need to move an *s* electron to a *d* orbital to take into account the stability of half-filled and filled *d* orbitals.

Practice Exercise Write the condensed electron configuration of a ground-state atom of cobalt ($Z = 27$).

Glossary

aufbau principle

the method of building electron configurations of atoms by adding one electron at a time as atomic number increases across the rows of the periodic table; each electron goes into the lowest-energy orbital available.

electron configuration

the distribution of electrons among the orbitals of an atom or ion.

orbital diagram

depiction of the arrangement of electrons in an atom or ion, using boxes to represent orbitals.

effective nuclear charge (Z_{eff})

the attraction toward the nucleus experienced by a valence-shell electron, which is approximately equal to the sum of the positive charge on the nucleus and the total negative charge of all inner-shell electrons.

core electrons

electrons in the filled, inner shells of an atom or ion that are not involved in chemical reactions.

valence electrons

electrons in the outermost occupied shell of an atom; the electrons that are transferred or shared in chemical reactions.

valence shell

the outermost occupied shell of an atom.

degenerate orbitals

describes orbitals of the same energy.

Hund's rule

the lowest-energy electron configuration of an atom has the maximum number of unpaired electrons, all of which have the same spin, in degenerate orbitals.

7.9 Electron Configurations of Ions

In Section 2.6 we learned that metals and nonmetals can form cations or anions (Figure 2.20) by losing or gaining one or more electrons. How does the electron configuration of an ion compare with that of the neutral parent atom? To write the electron configuration of an ion, we begin with the electron configuration of its neutral parent atom. For a cation, we remove the appropriate number of electrons from the orbital(s) with the highest principal quantum number. For an anion, we add the appropriate number of electrons to one or more partially filled outer-shell orbitals.

Ions of the Main Group Elements

The *s* block elements (see Figure 7.34) form monatomic cations by losing all the outer-shell electrons, producing ions with the electron configurations of the noble gases immediately preceding them in the periodic table. For example, an atom of sodium forms a Na^+ ion by losing the single 3*s* electron:

The nonmetal elements of the *p* block that form monatomic anions do so by gaining enough electrons to fill the outer-shell *p* orbitals, producing ions with the electron configurations of the noble gases at the right ends of the corresponding rows in the periodic table. For example, an atom of fluorine forms a F^- ion by gaining one electron, which fills the set of three 2*p* orbitals and gives it the electron configuration of neon:

A Na^+ ion and a F^- ion both have the same electron configuration as the neutral atom of Ne. We say that Na^+, F^-, and Ne are isoelectronic, meaning they have the same electron configuration.

CONNECTION In previous chapters we learned the charges on the ions of common elements. Electron configurations help us understand why these ions have the charges they do.

SAMPLE EXERCISE 7.12 Determining Isoelectronic Species LO6

(a) Write the condensed electron configurations of the ions in CsF, $MgCl_2$, CaO, and KBr. (b) Which ions in part (a) are isoelectronic?

Collect and Organize In part (a), we must determine the electron configuration of each ion in four binary ionic compounds. In part (b), we must identify the configurations from part (a) that are equivalent. Figure 7.34a provides information on the order in which orbitals are filled.

Analyze The elements in the compounds include

- two from group 1, Cs and K, which are present as 1+ cations
- two from group 2, Mg and Ca, which are present as 2+ cations
- one from group 16, O, which is present as a 2− anion
- three from group 17, F, Cl, and Br, which are present as 1− anions

Solve

1. Let's arrange these atoms and ions in a table in which we list the condensed electron configurations of the parent atoms, the formulas of the ions (derived from the parent elements' positions in the periodic table—see Figure 2.20), followed by the number of electrons lost or gained to form each ion, and finally the condensed electron configuration of the ion that is produced.

Element	Configuration	Ion	Number of Electrons Lost/Gained	Configuration
Cs	[Xe]$6s^1$	Cs^+	1	[Xe]
K	[Ar]$4s^1$	K^+	1	[Ar]
Mg	[Ne]$3s^2$	Mg^{2+}	2	[Ne]
Ca	[Ar]$4s^2$	Ca^{2+}	2	[Ar]
O	[He]$2s^22p^4$	O^{2-}	2	[He]$2s^22p^6$ = [Ne]
F	[He]$2s^22p^5$	F^-	1	[He]$2s^22p^6$ = [Ne]
Cl	[Ne]$3s^23p^5$	Cl^-	1	[Ne]$3s^23p^6$ = [Ar]
Br	[Ar]$3d^{10}4s^24p^5$	Br^-	1	[Ar]$3d^{10}4s^24p^6$ = [Kr]

2. Based on the ion electron configurations in the last column, we have three ions that are isoelectronic with Ne (Mg^{2+}, O^{2-}, and F^-) and three that are isoelectronic with Ar (K^+, Ca^{2+}, and Cl^-).

Think About It The electron configurations of all the ions make sense because each cation has the stable electron configuration of the noble gas in the preceding row of the periodic table, and each anion is isoelectronic with the noble gas element at the end of its row.

Practice Exercise Write the electron configurations of the ions in KI, BaO, Rb_2O, and $Al(NO_3)_3$. Which of these ions are isoelectronic with Ar?

CONCEPT TEST

Potassium has one valence electron in the 4*s* orbital. Figure 7.31b shows the color produced from excited-state potassium atoms. Write a condensed electron configuration for an excited-state potassium atom. How does that electron configuration differ from that of a potassium ion?

Transition Metal Cations

As with the main group elements, writing the electron configurations of transition metal cations begins by considering the metal atoms from which the cations form. Zinc atoms, like those of many transition metals, form ions with $2+$ charges by losing both electrons from the *s* orbital in the outermost shell:

A few transition metals, including silver, have only one outer-shell *s* electron and may form singly charged ions:

We might have expected Zn and Ag atoms to lose the 3*d* and 4*d* electrons, respectively, reasoning that the last orbitals to be filled should be the first to lose electrons when an atom forms a positive ion. Instead, the rule that the electrons in orbitals with the highest *n* value ionize first applies to all atoms, including transition metals. Preferential loss of outer-shell *s* electrons explains why the most frequently encountered charge on transition metal ions is $2+$.

Transition metal atoms may also lose one or more *d* electrons in addition to the two valence *s* electrons when forming ions with charges $>2+$. For example, an atom of scandium, [Ar] $3d^{1}4_{s}^{2}$, loses both 4*s* electrons *and* the 3*d* electron when it forms a Sc^{3+} ion. The chemistry of titanium, [Ar] $3d^{2}4_{s}^{2}$, is dominated by its atoms losing all four of the 4*s* and 3*d* electrons to form Ti^{4+} ions. In other cases, some—but not all—of the outermost *d* electrons are lost when a transition metal atom forms an ion. For example, when an atom of copper, [Ar] $3d^{10}4_{s}^{1}$, forms a Cu^{2+} ion, it loses its 4*s* electron and one 3*d* electron, giving it a [Ar] $3d^{9}$ electron configuration.

SAMPLE EXERCISE 7.13 Writing Condensed Electron Configurations of Transition Metal Ions LO6

What are the condensed electron configurations of Fe^{3+} and Ni^{2+}?

Collect and Organize We are asked to write the electron configurations of ions formed by two transition metals: iron ($Z = 26$) and nickel ($Z = 28$). We can use Figure 7.34a, which shows the order in which orbitals are filled, to determine the electron configurations of the neutral atoms. Then, electrons in orbitals with the highest *n* value ionize first. For transition metal atoms that means their outermost *s* electrons, not their outermost *d* electrons.

Analyze The location of iron in group 8 of the periodic table indicates that its atoms have two 4*s* electrons and six 3*d* electrons built on an argon core. Nickel is in group 10, so its atoms have two more 3*d* electrons than iron. As a result, the electron configurations of Fe and Ni *atoms* are

$$\text{Fe} = [\text{Ar}]3d^{6}\ 4_{s}^{2}\text{and Ni} = [\text{Ar}]3d^{8}4_{s}^{2}$$

Solve Fe atoms lose their 4*s* electrons *and* one 3*d* electron when forming Fe^{3+} ions, whereas Ni atoms lose two 4*s* electrons to form Ni^{2+} ions, producing these condensed electron configurations:

Think About It Both atoms lose both of their valence-shell *s* electrons, which is what usually happens when transition metals form monatomic cations. By also losing one of its 3*d* electrons, each Fe atom forms an Fe^{3+} ion with a stable, half-filled set of 3*d* orbitals.

Practice Exercise Write the electron configurations for the manganese atom and the ions Mn^{3+} and Mn^{4+}.

We have yet to consider the lanthanides (elements 58 through 71) and actinides (elements 90 through 103), represented by the two purple rows in Figure 7.34b. The lanthanides have partly filled 4*f* orbitals, whereas the actinides have partly filled 5*f* orbitals. There are 14 elements in each group, reflecting the capacity of the seven orbitals in each *f* subshell ($\ell = 3$; $m_\ell = -3, -2, -1, 0, +1, +2,$ and $+3$). According to Figure 7.34a, the 4*f* orbitals are not filled until after the 6*s* orbital has been filled. This order of filling occurs because 6*s* and 4*f* orbitals have similar energies (Figure 7.33). Similarly, the 5*f* orbitals are filled after the 7*s* orbital is filled.

The periodic table is a useful reference for predicting the physical and chemical properties of elements. Our quantum mechanical perspectives on atomic structure provide us with a theoretical basis for explaining why particular families of elements behave similarly. The original table was based on periodic trends in observable chemical properties. Now we know that the chemical properties of an element are closely linked to the electron configurations of the atoms of the element.

CONCEPT TEST

The electron configuration of Eu ($Z = 63$) is $[\mathrm{Xe}]4f^76s^2$, but the electron configuration of Gd ($Z = 64$) is $[\mathrm{Xe}]4f^75d^16s^2$. Suggest a reason why the additional electron in Gd goes into a 5*d* orbital instead of a 4*f* orbital, which would result in the electron configuration [Xe]$4f^8 6s^2$.

7.10 The Sizes of Atoms and Ions

The sizes of atoms are usually expressed in terms of their radii. The atomic radius of an element that occurs in nature as a diatomic molecule, such as N_2 and O_2, is simply half the distance between the nuclear centers in the molecule (**Figure 7.36a**). The atomic radius of a metal, also called its *metallic* radius, is half the distance between the nuclear centers in the solid metal (**Figure 7.36b**). The values of ionic radii are derived from the distances between nuclear centers in solid ionic compounds (**Figure 7.36c**). The periodic trends in the relative sizes of atoms are shown in **Figure 7.37**. Several factors contribute to these trends.

Trends in Atom and Ion Sizes

The radial distribution profiles in Figure 7.24 show how the distance from the nucleus to the *s* orbitals increases as the principal quantum number *n* increases. This same trend is observed for *p, d,* and *f* orbitals as well. Therefore, we expect the atomic radii of elements in the same group of the periodic table to increase with increasing atomic number. For example, the atomic radii of the halogens increase as we move from the top to the bottom of group 17 of the periodic table:

Element									
Atomic Number									
***n* Value of Valence Shell**									
Atomic Radius (pm)									

This pattern holds for other groups of elements, as shown in Figure 7.37.

As we move across a row (period) in the periodic table, each successive element has one additional electron. We might expect that the addition of electrons across a row would mean a corresponding increase in the size of the atom. Surprisingly, however, experimental data do not support this prediction. Atomic radii tend to *decrease* as the atomic number increases across a row of the periodic table. This pattern is particularly evident as we move from left to right across the main group elements (Figure 7.37). To explain these data, we need to consider two competing interactions:

1. *Increasing effective nuclear charge.* Each time the atomic number increases, so does the positive charge of the nucleus. Consider, for example, an atom of sodium-23, which has 11 protons, 12 neutrons, and 11 electrons, and an atom of magnesium-24, which has 12 protons, 12 neutrons, and 12 electrons. The one valence electron of Na and the two valence electrons of Mg are both in the 3*s* orbital, meaning that the valence electron in Na is probably at the same distance from the Na nucleus as the two valence electrons in Mg are from the Mg nucleus. The two valence electrons in Mg experience a larger effective nuclear charge than the valence electron in Na: the electrostatic attraction of electrons (regardless of whether it is one or two) in a 3*s* orbital to 12 protons is

stronger than the attraction to 11 protons because the distance is unchanged. As Z_{eff} increases, the size of atoms decreases.

2. *Increasing repulsion between valence electrons.* As atomic number increases, so does the number of valence electrons. More electrons mean more electron–electron repulsions (because two negatively charged particles repel one another), which tends to increase the size of the atoms.

The experimental data tabulated in Figure 7.37 show that atomic size decreases with increasing Z across each row of main group elements. This means that interaction 1, effective nuclear charge, more than offsets interaction 2, repulsions between the increasing number of valence electrons.

The cations of the main group elements are much smaller than their parent atoms, whereas the anions are much larger (**Figure 7.38**). To understand these trends, let's revisit what happens when a Na atom forms a Na^+ ion. The atom loses its only valence-shell (3*s*) electron, forming an ion with a much smaller neonlike core of 1*s*, 2*s,* and 2*p* electrons. On the other hand, when a Cl atom gains an electron and forms a Cl^- ion, it contains one more electron (18) than a Cl atom (17). The additional electron means more electron–electron repulsion, which increases the size of the valence shell and results in a Cl^- ion that is bigger than a Cl atom. This phenomenon causes all monatomic anions to be larger than the atoms from which they form.

CONCEPT TEST

Rank the following orbitals in an atom of silver in order of decreasing effective nuclear charge experienced by the electrons in them: 1*s*, 2*s*, 3*s*, 4*s*, 2*p*, 3*p*, 4*p*.

SAMPLE EXERCISE 7.14 Ordering Atoms and Ions by Size LO7

Arrange each set by size, largest to smallest: (a) O, P, S; (b) Na^+, Na, K.

Collect and Organize We are asked to rank a set of three atoms according to their size and a set of two atoms and one cation of one of the atoms according to their size. The location of elements in the periodic table can be used to determine the relative sizes of the atoms.

Analyze Sizes decrease as we move from left to right across a period and increase as we move down a column. In addition, a cation is always smaller than the atom from which it is made.

Solve

1. S is below O in group 16, so in terms of atomic size, $\mathrm{S} > \mathrm{O}$. S is to the right of P, so $\mathrm{P} > \mathrm{S}$. The size order is thus $\mathrm{P} > \mathrm{S} > \mathrm{O}$.
2. Cations are smaller than their atoms, so $\mathrm{Na} > \mathrm{Na}^+$. K is below Na in the alkali metals group, and size increases down a group, so $\mathrm{K} > \mathrm{Na}$. Therefore, the size order is $\mathrm{K} > \mathrm{Na} > \mathrm{Na}^+$.

Think About It The trend in the sizes of the atoms in set (a) reflects decreasing atomic size with increasing effective nuclear charge within a row of elements in the periodic table and increasing atomic size with increasing atomic number down a group. The relative sizes of the particles in set (b) are linked (1) to increasing atomic size as one goes down a column of elements in the periodic table and (2) to the smaller size of a cation than its parent atom.

Practice Exercise Arrange each set in order of increasing size (smallest to largest): (a) Cl^-, F^-, Li^+; (b) P^{3-}, Al^{3+}, Mg^{2+}.

Learning Objectives

- Use atomic orbitals and the concept of effective nuclear charge to explain the ionization energies and relative sizes of atoms and monatomic ions **Return to Sample Exercises 7.14, 7.15**

$$\mathrm{Mg}(g) \rightarrow \mathrm{Mg}^{+}(g) + 1\ \mathrm{e}^{-} \qquad (\mathrm{IE}_1 = 738\ \mathrm{kJ/mol})$$

$$\mathrm{Mg}^{+}(g) \rightarrow \mathrm{Mg}^{2+}(g) + 1\ \mathrm{e}^{-} \qquad (\mathrm{IE}_2 = 1451\ \mathrm{kJ/mol})$$

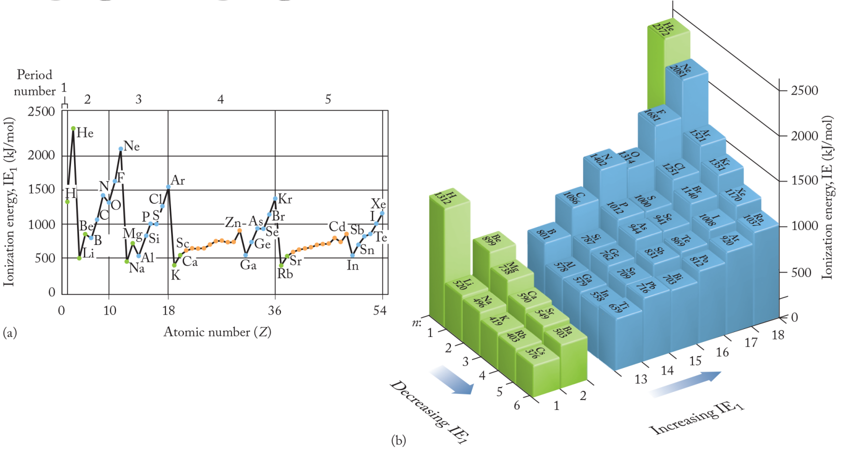

FIGURE 7.39 The first ionization energies (IE_1) of the elements generally increase from left to right in a period and decrease from top to bottom in a group: (a) IE_1 values for the elements in the first five periods; (b) IE_1 values for all the main group elements.

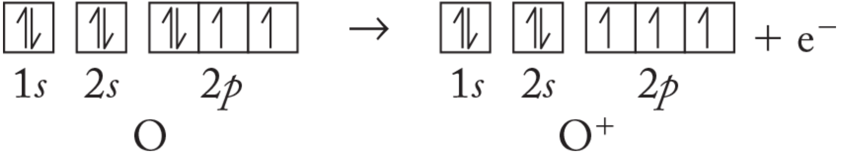

7.11 Ionization Energies

In developing electron configurations, we followed a theoretical framework for the arrangement of electrons in orbitals that was developed in the early years of the 20th century. Is there actual experimental evidence for the existence of orbitals representing different energy levels inside atoms? Yes, there is. The evidence includes the measurement of the energies needed to remove electrons from atoms and ions.

Ionization energy (IE) is the energy needed to remove 1 mole of electrons from 1 mole of gas-phase atoms or ions in their ground state. Removing these electrons always requires an addition of energy to the system because a negatively charged electron is attracted to a positively charged nucleus, and overcoming that attractive force requires energy. The amount of energy needed to remove 1 mole of electrons from 1 mole of atoms to make 1 mole of cations with a 1+ charge is called the *first ionization energy* (IE_1); the energy needed to remove 1 mole of electrons from 1 mole of 1+ cations to make 1 mole of cations with a 2+ charge is the *second ionization energy* (IE_2); and so forth. For example,

The total energy required to make 1 mole of $Mg^{2+}(g)$ cations from 1 mole of $Mg(g)$ atoms is the sum of these two ionization energies:

$$Mg(g) \rightarrow Mg^{2+}(g) + 2\ e^-$$

$$\text{Total IE} = (738 + 1451)\ \text{kJ/mol} = 2189\ \text{kJ/mol}$$

Figure 7.39 shows how the first ionization energies of the main group elements vary. The IE_1 of hydrogen is 1312 kJ/mol, whereas the IE_1 of helium is nearly twice as big: 2372 kJ/mol. This difference is reasonable because He atoms have two protons per nucleus, whereas H atoms have only one. Twice the nuclear charge increases Z_{eff}, so nearly twice the ionization energy is needed to pull an electron away from the nucleus. In general, first ionization energies increase from left to right across a period. Thus, the easiest element to ionize in a period is the group 1 element, and the hardest is the group 18 element. This pattern makes sense because as the charge of the nucleus increases across a row, so do Z_{eff} and the attractions between the nucleus and the valence electrons.

Two anomalies occur in the general trend of increasing IE_1 with increasing Z across a row. One shows up in the decrease in IE_1 values between the group 2 and group 13 elements in the second and third rows. Note that B and Al lose a *p* electron when they ionize, whereas Be and Mg lose an *s* electron. It is easier to remove a *p* electron because it experiences a smaller effective nuclear charge than an *s* electron in the same shell. A second anomaly occurs between the group 15 and 16 elements in each row in which there is a decrease in IE_1 values because ionization of group 16 atoms involves removal of an electron from a filled *p* orbital (see the orbital diagram below). This takes slightly less energy because removal of the electron reduces electron–electron repulsion.

Figure 7.39 also shows how IE_1 values decrease with increasing atomic number down in each group. There are two reasons for this. First, the increasing size of the atoms (see Figure 7.37) means that the valence-shell electrons in atoms of elements farther down each group are farther from the nucleus, and so they experience less electrostatic attraction to the positive charge of the nucleus. In addition, the greater number of protons and greater nuclear charges of atoms farther down each group are offset by more inner shells of electrons that effectively shield valence-shell electrons from the greater nuclear charge. As a result, the effective nuclear charge experienced by, for example, the outer-shell *s* electron in an atom of any group 1 element is essentially the same: $+1$.

Another perspective on energy levels in atoms is provided by *successive* ionization energies. Consider the trend in the energies needed to remove all the electrons in the atoms of the first 10 elements (**Table 7.2**). For multielectron atoms, the second ionization energy (IE_2) is always greater than IE_1 because the second electron is being removed from an ion that already has a positive charge. Because electrons carry a negative charge, they are held more strongly in a cation (have stronger electrostatic attractions to the nucleus) than in the atom from which the cation was formed.

The energy needed to remove a third electron is greater still because it is being removed from a $2+$ ion. Superimposed on this trend are much more dramatic increases in ionization energy (separated by the red line in Table 7.2) when all the valence electrons in an ionizing atom have been removed and the next electron comes from an inner shell. Core electrons experience less shielding and a greater effective nuclear charge than valence electrons, which means that much more energy is needed to ionize them.

SAMPLE EXERCISE 7.15 Ranking Ionization Energies LO7

Arrange argon, magnesium, and phosphorus in order of increasing first ionization energy.

Collect, Organize, and Analyze We are asked to order three elements based on their IE_1 values. All three are in the third row of the periodic table. First ionization energies generally increase from left to right across a row because of increasing effective nuclear charge.

Solve Ranking the elements in order of increasing first ionization energies, according to their increasing group numbers:

$$Mg < P < Ar$$

Think About It Magnesium forms stable 2+ cations, so we expect its ionization energy to be smaller than the values for phosphorus and argon, which do not form cations. Argon is a noble gas with a stable valence electron configuration, so its first ionization energy should be the highest of the three. We can check our prediction against Figure 7.39b: Mg, 738 kJ/mol; P, 1012 kJ/mol; Ar, 1521 kJ/mol.

Practice Exercise Arrange cesium, calcium, and neon in order of decreasing first ionization energy.

CONCEPT TEST

Why does ionization energy decrease with increasing atomic number from helium to neon to argon?

Glossary

ionization energy (IE)

the quantity of energy needed to remove 1 mole of electrons from 1 mole of ground-state atoms or ions in the gas phase.

Endnotes

- All values in kilojoules per mole of atoms.Return to reference a

Learning Objectives

- Use atomic orbitals and the concept of effective nuclear charge to explain the ionization energies and relative sizes of atoms and monatomic ions **Return to Sample Exercises 7.14, 7.15**

FIGURE 7.40 Electron affinity (EA) values of main group elements are expressed in kilojoules per mole. The more negative the value, the more energy is released when 1 mole of atoms combines with 1 mole of electrons to form 1 mole of anions with a 1– charge. A greater release of energy reflects stronger electrostatic attractions between the nuclei of the elements and free electrons.

FIGURE 7.41 Lithium carbonate is sometimes used to produce vivid red colors in fireworks. $E = \frac{hc}{\lambda}$

7.12 Electron Affinities

In Section 7.11 we examined the periodic nature of the energy required to ionize atoms. Now we look at a complementary process, called electron affinity (EA), which is the change in energy when 1 mole of electrons is added to 1 mole of gas-phase atoms or monatomic cations.

The energy associated with adding 1 mole of electrons to 1 mole of chlorine atoms in the gas phase is

$$Cl(g) + e^- \rightarrow Cl^-(g) \qquad EA_1 = -349 \text{ kJ/mol}$$

The electron affinities of many elements are negative, meaning the formation of anions with a 1− charge releases energy (**Figure 7.40**). The values in Figure 7.40, however, reveal that the trends in

EA are not as regular as the trends in size and IE. Electron affinity increases down a column only for the group 1 metals, whereas other groups do not display a clear trend. In general, electron affinity becomes more negative with increasing atomic number across a row, but there are exceptions to that trend, too. The halogens (group 17) have the most negative EA values, which seems logical given that each halogen atom becomes isoelectronic with a noble gas electron configuration upon gaining one more electron.

The addition of an electron to an atom of a noble gas consumes energy, which makes sense because these atoms already have stable electron configurations. Beryllium and magnesium have very small, but positive, electron affinities because an additional electron occupies a valence-shell *p* orbital, which is significantly higher in energy than a valence-shell *s* orbital.

CONCEPT TEST

Describe at least one similarity and one difference in the periodic trends for first ionization energies and electron affinities among the main group elements.

SAMPLE EXERCISE 7.16 Integrating Concepts: Red Fireworks

The brilliant red color of some fireworks (**Figure 7.41**) is produced by the presence of lithium carbonate (Li_2CO_3) in the shells that are launched into the night sky and explode at just the right time. The explosions produce enough energy to vaporize the lithium compound and produce excited-state lithium atoms. These atoms quickly lose energy as they transition from their excited states to their ground states, emitting photons of red light that have a wavelength of 670.8 nm.

1. How much energy is in each photon of red light emitted by an excited-state lithium atom?
2. What is the frequency of the red light?
3. Lithium atoms in the lowest-energy state above the ground

state emit these red photons. What is the difference in energy between the ground state of a Li atom and its lowest-energy excited state?
4. What is the electron configuration of a ground-state lithium atom?
5. What is the electron configuration of a lithium atom in its lowest-energy excited state?

Collect and Organize We are asked to calculate the energy of photons of red light from their wavelength. We are also asked to relate this energy to the difference in energies between a lithium atom's lowest-energy excited state and its ground state and to write the electron configurations of these states. The energy of a photon is related to its wavelength (λ) by Equation 7.3:

Lithium is the group 1 element in the second row of the periodic table.

Analyze The energy of a photon (E) emitted by an excited-state atom is the same as the difference in energies (ΔE) between the excited state and the lower-energy state (in this case, the ground state) of the transition that produced the photon. All the group 1 elements have one electron in their valence-shell *s* orbital. In lithium this electron is in the 2*s* orbital, which is occupied after the 1*s* has filled. The next higher energy orbitals are the 2*p* orbitals.

Solve

1. The energy of a photon with a wavelength of 670.8 nm is

$$E = \frac{hc}{\lambda} = \frac{(6.626 \times 10^{-34}\ \text{J}\cdot\cancel{\text{s}})\left(2.998 \times 10^{8}\ \frac{\cancel{\text{m}}}{\cancel{\text{s}}}\right)}{670.8\ \cancel{\text{nm}}\left(\frac{10^{-9}\ \cancel{\text{m}}}{\cancel{\text{nm}}}\right)} = 2.961 \times 10^{-19}\ \text{J}$$

2. Frequency and wavelength are related:

$$c = \nu\lambda \qquad \text{so} \qquad \nu = \frac{c}{\lambda}$$

The frequency of red light with a wavelength of 670.8 nm is

$$\nu = \frac{2.998 \times 10^{8}\ \frac{\cancel{\text{m}}}{\text{s}}}{670.8\ \cancel{\text{nm}}\left(\frac{10^{-9}\ \cancel{\text{m}}}{\cancel{\text{nm}}}\right)} = 4.469 \times 10^{14}\ \text{s}^{-1}$$

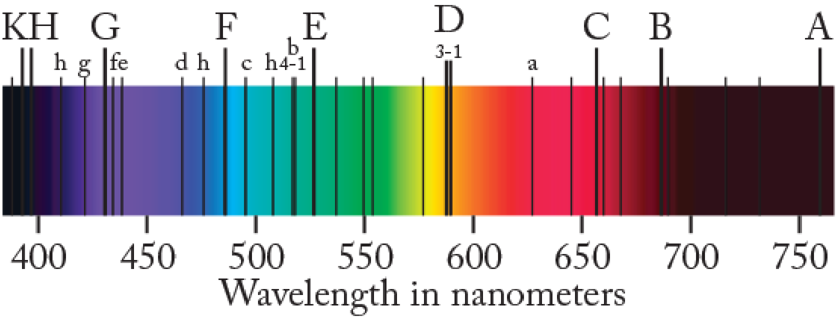
3. The difference in energies between the ground state of a Li atom and its lowest-energy excited state must match exactly the energy of the photon emitted; therefore, $\Delta E = 2.961 \times 10^{-19}$ J.
4. The electron configuration of a ground-state Li atom is $1_s^2 2_s^1$.
5. In the lowest-energy excited state, the valence electron has moved to the next higher energy orbital above the 2*s* orbital, which is one of the three 2*p* orbitals. Therefore, the electron configuration of the excited state is $1_s 2p^1$.

Think About It You might expect that the colors that lithium and other elements make in fireworks explosions are the same colors they produce in Bunsen burner flames. You would be right. Many of the colors are produced by transitions from lowest-energy excited states to ground states because the lowest-energy excited state is the one most easily populated by the thermal energy available in a gas flame or exploding firework shell.

Glossary

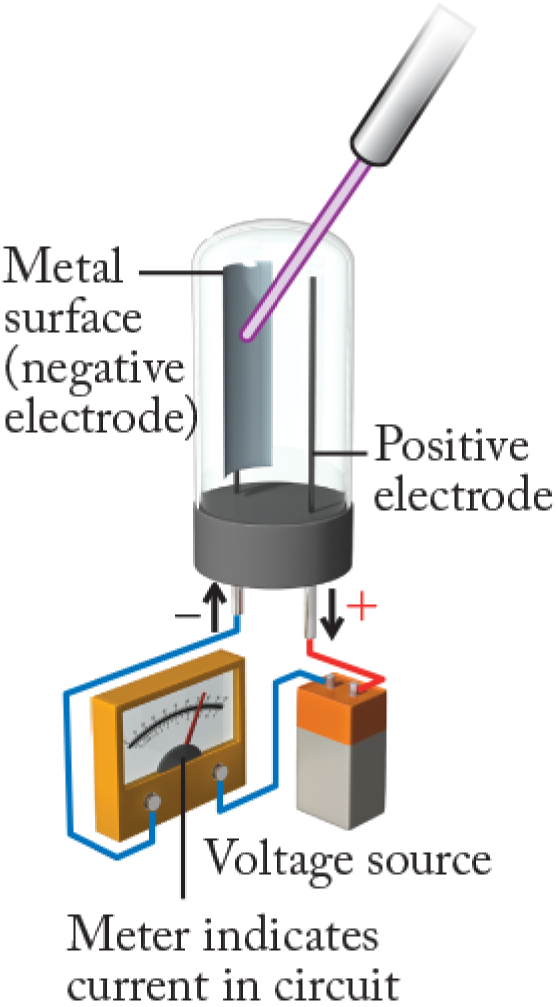
electron affinity (EA)

the energy change that occurs when 1 mole of electrons combines with 1 mole of atoms or monatomic cations in the gas phase.



SUMMARY

LO1 Visible light and other forms of electromagnetic radiation have wavelike properties described by characteristic wavelengths and frequencies. The speed of light is a constant in a vacuum, $c = 2.998 \times 10^8$ m/s, but slows as it passes through liquids and solids. (Sections 7.1 and 7.2)

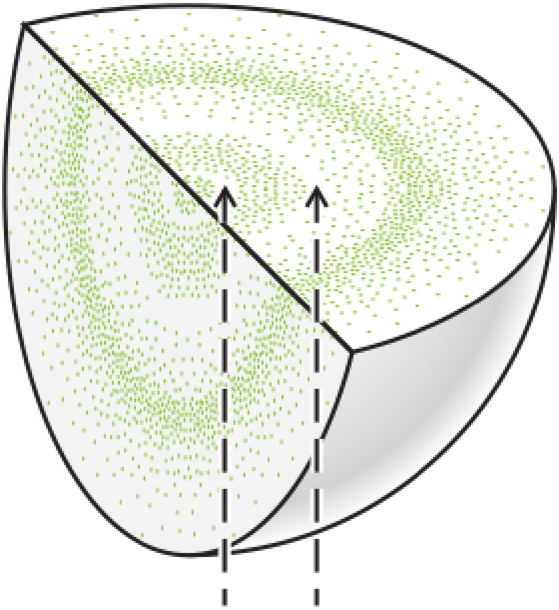


Metal surface (negative electrode)
Positive electrode
−
+
Voltage source
Meter indicates current in circuit

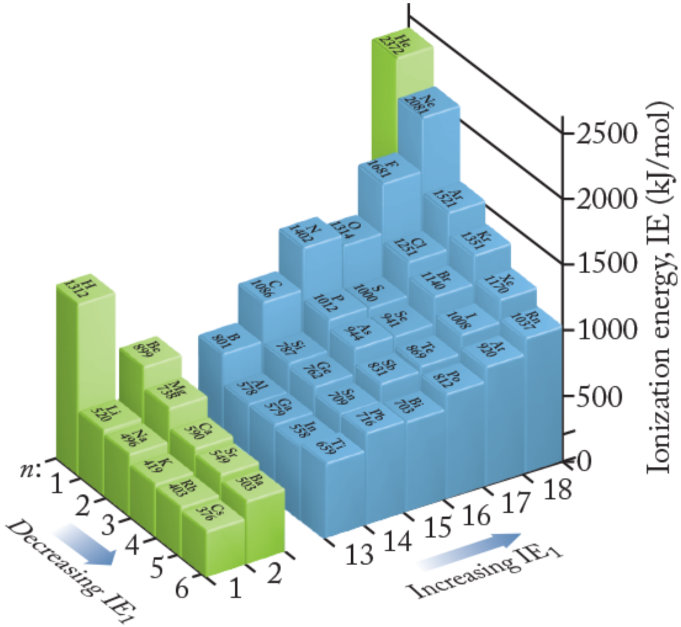
- LO2 Max Planck used quantum theory, which incorporates the assumption that all electromagnetic radiation consists of discrete particles of energy called quanta, to explain blackbody radiation. The Planck constant relates the energy of a quantum of light, called a photon, to its frequency. Einstein also used quantum theory to explain the photoelectric effect: a process in which a metal surface emits electrons when illuminated by electromagnetic radiation that is at or above a threshold frequency. (Section 7.3)
- LO3 Free atoms in flames and in gas-discharge tubes produce atomic emission spectra consisting of narrow bright lines at

characteristic wavelengths. When continuous radiation passes through atomic gases, absorption produces the dark lines of atomic absorption spectra. The bright lines of an element's emission spectrum and the dark lines of its absorption spectrum are at the same wavelengths. A ground-state atom or ion has all its electrons in the lowest possible energy levels. Other arrangements are called excited states. Electron transitions from higher to lower energy levels in an atom cause the atom to emit particular frequencies of radiation; absorption of radiation of the same frequencies accompanies electron transitions from the same lower to higher energy levels. (Sections 7.1 and 7.4)

- LO4 de Broglie proposed that electrons in atoms, as well as all other moving particles, have wave properties and can be treated as matter waves. He explained the stability of the electron orbits in the Bohr hydrogen atom in terms of standing waves: the circumferences of the allowed orbits had to be whole-number multiples of the hydrogen electron's characteristic wavelength. The Heisenberg uncertainty principle states that both the position and momentum of an electron cannot be precisely known at the same time. (Section 7.5)



- LO5 The solutions to Schrödinger's wave equation are mathematical expressions called wave functions (ψ), where ψ^2 defines the regions within an atom, called orbitals, that describe the probability of finding an electron at a given distance from the nucleus. Orbitals have characteristic three-dimensional sizes, shapes, and orientations that are depicted by boundary–surface representations. Each orbital has a unique set of three quantum numbers that come directly from the solution to the Schrödinger wave equation: the principal quantum number n, which defines orbital size and energy level; the angular momentum quantum number (ℓ), which defines orbital shape; and the magnetic quantum number m_ℓ, which defines orbital orientation in space. A fourth quantum number, the spin magnetic quantum number m_s, is necessary to explain certain characteristics of emission spectra. (Sections 7.6 and 7.7)
- LO6 According to the aufbau principle, electrons fill the lowest-energy atomic orbitals of a ground-state atom first. Two electrons in the same orbital have opposite-spin quantum numbers m_s: $+\frac{1}{2}$ and $-\frac{1}{2}$. The Pauli exclusion principle states that no two electrons in an atom can have the same four values of n, ℓ, m_ℓ, and m_s. An electron configuration is a set of numbers and letters expressing the number of electrons that occupy each orbital in an atom or ion. The electrons in the outermost occupied shell of an atom are valence electrons. All the orbitals of a given subshell are degenerate; they all have the same energy. Hund's rule states that in any set of degenerate orbitals, one electron must occupy each orbital before a second electron occupies any orbital in the set. We use orbital diagrams to show in detail how electrons are distributed among orbitals, which are represented by boxes. (Sections 7.8 and 7.9)



- LO7 Effective nuclear charge (Z_{eff}) is the net nuclear charge experienced by outer-shell electrons when they are shielded from the full nuclear charge by inner-shell electrons. Greater Z_{eff} means lower energy. The sizes of atoms increase with increasing atomic number in a group of elements because valence-shell electrons with higher *n* values are, on average, farther from the nucleus. However, the sizes of atoms decrease with increasing atomic number across a row of elements because the valence electrons experience higher effective nuclear charges. Anions are larger than their parent atoms because of additional electron–electron repulsion, but cations are smaller than their parent atoms—sometimes much smaller when all the electrons in the valence shell are lost. Ionization energy (IE) is the amount of energy needed to remove 1 mole of electrons from 1 mole of atoms or ions in the gas phase. IE values generally increase with increasing effective nuclear charge across a row and decrease with increasing atomic number down a group in the periodic table. The energy differences between the different shells and subshells of atoms are reflected in the values of successive ionization energies (IE_1, IE_2, IE_3, . . .). (Sections 7.8, 7.10, 7.11)

- LO8 Electron affinity (EA) is the energy change that occurs when 1 mole of electrons combines with 1 mole of atoms or ions in the gas phase. Electron affinity values of many main group elements are negative (energy is released when they acquire electrons) but positive for nitrogen and the noble gases. (Section 7.12)

PARTICULATE PREVIEW WRAP-UP

Each process forms an ion from a neutral parent atom. Because cations are positively charged and smaller than their neutral parent atoms, an electron is lost in the first process. Because anions are negatively charged and larger than their neutral parent atoms, an electron is gained in the second process. Ionizing an electron from a neutral atom to form a cation requires the absorption of energy. For most elements, the second process emits energy.

PROBLEM-SOLVING SUMMARY

Type of Problem	Concepts and Equations	Sample Exercises
Calculating frequency from wavelength	$\lambda\nu = c \quad \text{where } c = 2.998 \times 10^8\ \text{m/s}$ (7.1)	7.1
Calculating the energy of a photon	$E = \frac{hc}{\lambda}$ (7.3)	7.2
Applying the photoelectric effect	$\phi = h\nu_0$ (7.4) $KE_{\text{electron}} = h\nu - \phi$ (7.5)	7.3
Calculating the wavelength of a line in the hydrogen spectrum	$\frac{1}{\lambda} = [1.097 \times 10^{-2}\ \text{nm}^{-1}]\left(\frac{1}{n_1^2} - \frac{1}{n_2^2}\right)$ (7.7)	7.4
Calculating the energy needed for an electron transition	$\Delta E = -2.178 \times 10^{-18}\ \text{J}\left(\frac{1}{n_{\text{final}}^2} - \frac{1}{n_{\text{initial}}^2}\right)$ (7.9)	7.5
Calculating the wavelength of particles in motion	$\lambda = \frac{h}{mu}$ (7.11)	7.6
Calculating uncertainty	$\Delta x \cdot m\Delta u \geq \frac{h}{4\pi}$ (7.13)	7.7
Identifying the subshells and orbitals in an energy level and valid quantum number sets	n defines the shell, ℓ defines the subshell type of orbital, and [illegible] has a unique combination of allowed n, ℓ, and m_ℓ values. ℓ is any integer from 0 to $n - 1$; m_ℓ is any integer from $-\ell$ to $+\ell$, including zero.	7.8, 7.9
Writing electron configurations of atoms and ions; determining isoelectronic species	Orbitals fill in the following sequence: $1s^2$, $2s^2$, $2p^6$, $3s^2$, $3p^6$, $4s^2$, $3d^{10}$, $4p^6$, $5s^2$, $4d^{10}$, $5p^6$, $6s^2$, $4f^{14}$, $5d^{10}$, $6p^6$	7.10, 7.11, 7.12, 7.13

(superscripts represent maximum numbers of electrons). Arrange orbitals in electron configuration based on the increasing value of *n*. In forming transition metal ions, electrons are removed to maximize the number of *d* electrons; there is enhanced stability in half-filled and filled *d* subshells.

7.14 Ordering atoms and ions by size Effective nuclear charge and shielding explain observable periodic trends. In general, sizes decrease from left to right across a row and increase down a column of the periodic table. Cations are smaller, and anions are larger, than their parent atoms.

7.15 Ranking ionization energies First ionization energies generally increase across a row and decrease down a column.

VISUAL PROBLEMS

(Answers to boldface end-of-chapter questions and problems are in the back of the book.)

Which of the elements highlighted in Figure P7.1 consist of ground-state atoms with:

1. a single *s* electron in the valence shell? (More than one answer is possible.)
2. filled sets of *s* and *p* orbitals in the valence shell?
3. filled sets of *d* orbitals?
4. half-filled sets of *d* orbitals?
5. two *s* electrons in the valence shell?

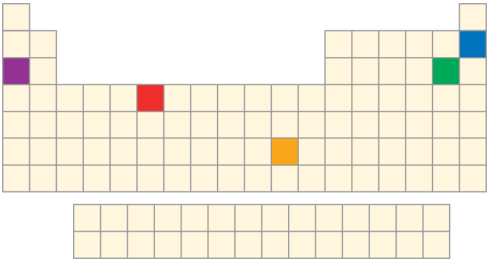


FIGURE P7.1

Which of the highlighted elements in Figure P7.1:

1. forms a common monatomic ion that is larger than its parent

atom?

2. has the most unpaired electrons per ground-state atom?
3. has a complete octet of valence electrons?
4. forms a common monatomic ion that is isoelectronic with another highlighted element?

Which of the elements highlighted in Figure P7.3 forms monatomic ions by

1. losing an *s* electron?
2. losing two *s* electrons?
3. losing two *s* electrons and a *d* electron?
4. adding an electron to a *p* orbital?
5. adding electrons to two *p* orbitals?

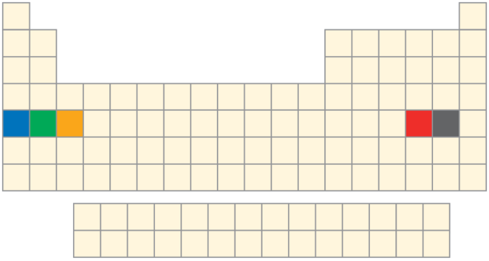

FIGURE P7.3

Which of the highlighted elements in Figure P7.3:

1. forms common monatomic ions smaller than the parent atoms? (More than one answer is possible.)
2. has the largest first ionization energy, IE_1?
3. has the largest second ionization energy, IE_2?

Rank the elements highlighted in Figure P7.3 by:

1. increasing atomic size.
2. increasing size of the most common monatomic ions.

Which arrow in Figure P7.6 represents:

1. emission of light with the longest wavelength?
2. absorption of light of an atom in an excited state?
3. a transition requiring absorption of the most energy?

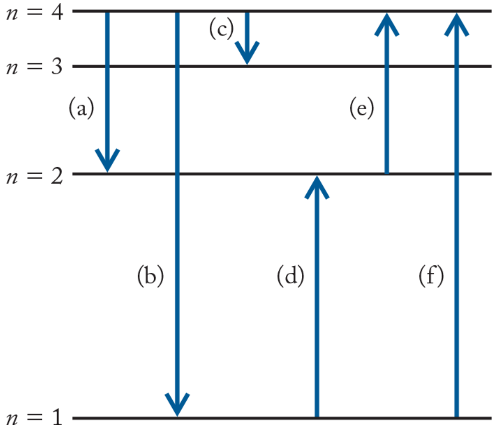

FIGURE P7.6

In Figure P7.7, which sphere represents a Na atom, a Na^+ ion, and a K atom?

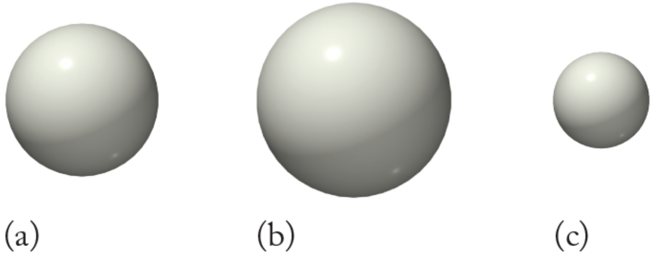

FIGURE P7.7

Which orbital diagram in Figure P7.8 represents:

1. the ground state of an oxygen cation, O^+?
2. an excited state of a nitrogen atom?
3. a violation of Hund’s rule?
4. a violation of the Pauli exclusion principle?

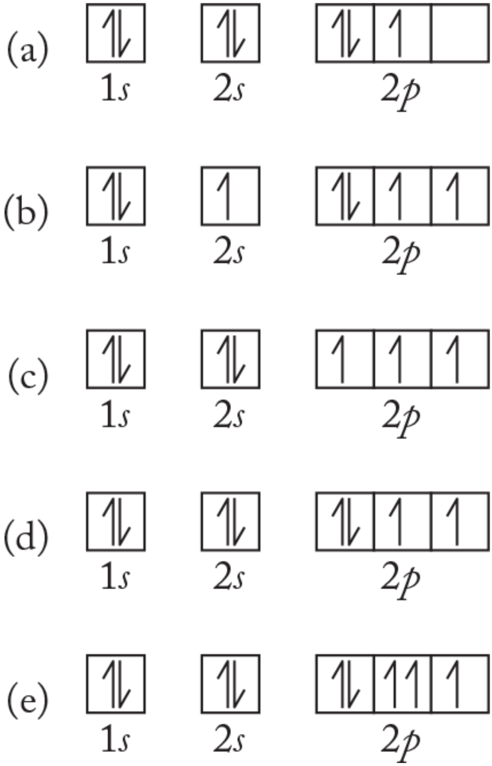

FIGURE P7.8

Which light represented by the waves in Figure P7.9 has:

1. the highest frequency?
2. the lowest energy?
3. the highest energy?

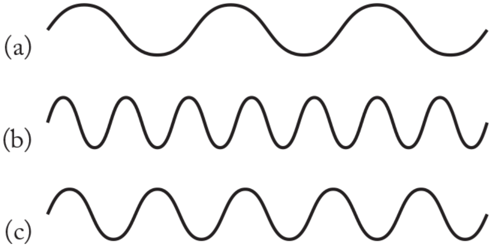

FIGURE P7.9

Use representations [A] through [I] in Figure P7.10 to answer questions (a)–(f).

1. Compare [A] and [H]. Which valence electron experiences the larger Z_{eff}? Which is more shielded from the positive charge of the nucleus? Which has the lower IE_1?
2. Which representation depicts the loss of an electron?
3. Which representations can be discussed using only a quantized model of light?
4. Which representations are consistent with the model of an atom that uses probability to locate electrons?
5. What do the arrows represent in [E] and [I]?
6. Which representation conveys that the probability of finding an electron at the nucleus is zero?

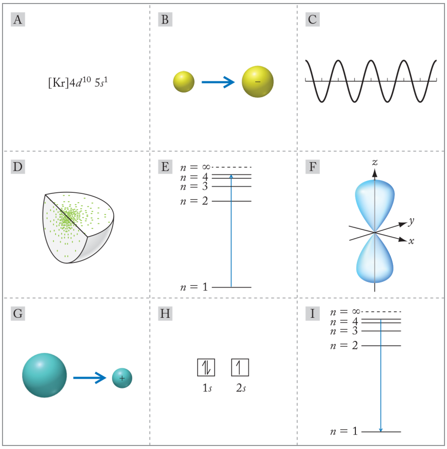

FIGURE P7.10

QUESTIONS AND PROBLEMS

Rainbows of Light; Waves of Energy

Concept Review

Describe the similarities and differences between the atomic emission and absorption spectra of hydrogen.

Are Fraunhofer lines the result of atomic emission or atomic absorption?

How did the study of the atomic emission spectra of elements lead to the identification of the Fraunhofer lines in sunlight?

What would happen to the appearance of the Fraunhofer lines in the solar spectrum if sunlight were passed through a flame containing high-temperature calcium atoms and then analyzed?

Why are the various forms of radiant energy called *electromagnetic* radiation?

Explain with a sketch why the frequencies of long-wavelength waves of electromagnetic radiation are lower than those of short-wavelength waves.

Dental X-rays When X-ray images are taken of your teeth and gums in the dentist's office, your body is covered with a lead shield (Figure P7.17). Explain the need for this precaution.

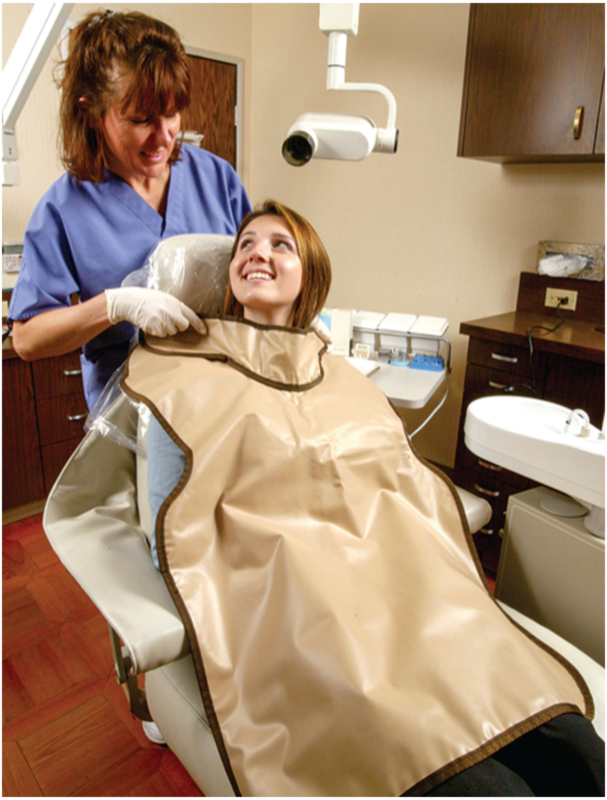

FIGURE P7.17

UV Radiation and Skin Cancer Ultraviolet radiation causes skin damage that may lead to cancer, but exposure to infrared radiation does not seem to cause skin cancer. Why do you think this is so?

Gamma rays are an example of "ionizing" radiation because they have the energy to break apart molecules into molecular ions and free electrons. What other forms of electromagnetic radiation could also be ionizing radiation?

If light consists of waves, why don't things look "wavy" to us?

Problems

In each pair, which radiation has higher frequency? (a) ultraviolet or infrared radiation; (b) visible light or gamma rays; (c) microwaves or radio waves

In each pair, which radiation has longer wavelength? (a) visible light or microwaves; (b) radio waves or gamma rays; (c) infrared or ultraviolet radiation

If the wavelength of a photon of red light is twice that of a photon of ultraviolet radiation, how much more energy does the UV photon have?

If the frequency of a photon of red light is twice that of a photon of infrared radiation, how much more energy does the photon of red light have?

Digital Screens Tablets and cell phones emit blue light (Figure P7.25) that is known to disrupt sleep patterns when viewed before going to bed. The longest wavelength that corresponds to blue light is 495 nm. What is the frequency of this radiation?

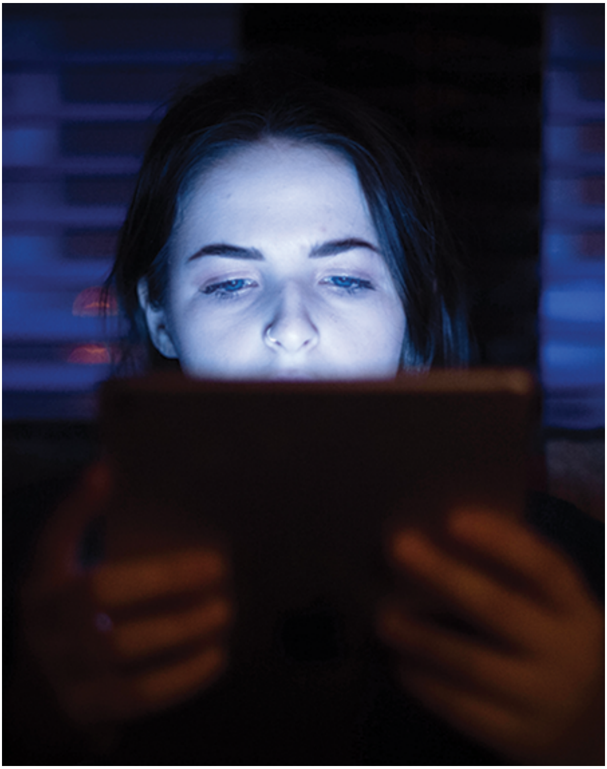

FIGURE P7.25

Submarine Communications In the 1990s the Russian and American navies developed extremely low-frequency communications networks to send messages to submerged submarines. The frequency of the carrier wave of the Russian network was 82 Hz, whereas the Americans used 76 Hz.

1. What was the ratio of the wavelengths of the Russian network to the American network?
2. To calculate the actual underwater wavelength of the transmissions in either network, what additional information would you need?

Drones and Phones Remote control aerial vehicles such as the drone in Figure P7.27 typically operate at gigahertz (GHz) frequencies, whereas cell phones operate using megahertz (MHz) frequencies. Calculate the wavelengths corresponding to the following frequencies:

1. quadcopter drone, 2.4 GHz
2. Apple iPhone, 848 MHz

FIGURE P7.27

Which radiation has the longer wavelength: (a) radio waves from an AM radio station broadcasting at 680 kHz or (b) infrared radiation emitted by the surface of Earth ($\lambda = 15\ \mu\text{m}$)?

Which radiation has the lower frequency: (a) radio waves from an AM radio station broadcasting at 1030 kHz or (b) the red light ($\lambda = 633$ nm) from a helium–neon laser?

Which radiation has the higher frequency: (a) the red light on a barcode reader at a grocery store or (b) the green light on the battery charger for a laptop computer?

Speed of Light How long does it take moonlight to reach Earth when the distance to the moon is 384,000 km?

Exploration of the Solar System How long would it take an instruction to a Martian rover to travel to Mars from a NASA site on Earth when Earth and Mars are 68.4 million km apart?

Particles of Energy and Quantum Theory

Concept Review

What is the difference between a quantum and a photon?

A variable power supply is connected to an incandescent light bulb. At the lowest power setting, the bulb feels warm to the touch but produces no light. At medium power, the light bulb filament emits a red glow. At the highest power, the light bulb emits white light. Explain this emission pattern.

What effect does the intensity (amplitude) of a wave have on the emission of electrons from a surface, if we assume that the frequency of incident radiation is above the threshold frequency?

Is the kinetic energy of a photoelectron quantized?

Which of the following have quantized values? Explain your selections.

1. the elevation of the treads of a moving escalator
2. the elevations at which the doors of an elevator open
3. the speed of an automobile

Which of the following have quantized values? Explain your selections.

1. the pitch of a note played on a slide trombone
2. the pitch of a note played on a flute
3. the wavelengths of light produced by the heating elements in a toaster
4. the wind speed at the top of Mt. Everest

Problems

Tanning Booths Prolonged exposure to ultraviolet radiation in tanning booths significantly increases the risk of skin cancer. What is the energy of a photon of UV light with a wavelength of 305 nm? Is this enough energy to break a C − C bond with a bond energy of 345 kJ/mol?

Remote Controls Most remote controllers for AV equipment emit radiation with the wavelength profile shown in Figure P7.40. What type of radiation is shown and what is the energy of a photon at the peak wavelength?

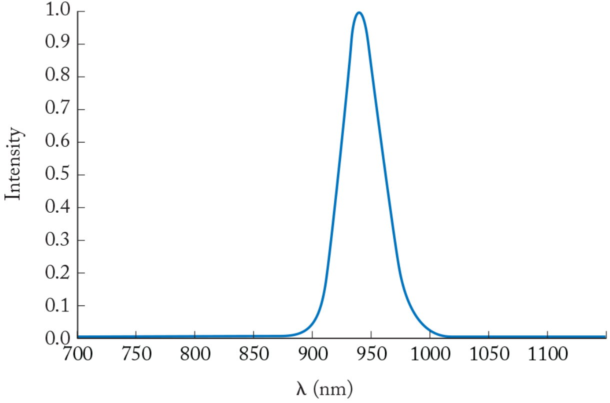

FIGURE P7.40

Thin layers of potassium ($\phi = 3.68 \times 10^{-19}$ J) and sodium ($\phi = 4.41 \times 10^{-19}$ J) are exposed to radiation of wavelength 300 nm. Which metal emits electrons with the greater velocity? What is the velocity of these electrons?

Titanium ($\phi = 6.94 \times 10^{-19}$ J) and silicon ($\phi = 7.24 \times 10^{-19}$ J) surfaces are irradiated with UV radiation with a wavelength of 250 nm. Which surface emits electrons with the longer wavelength? What is the wavelength of the electrons emitted by the titanium surface?

Solar Power Photovoltaic cells convert solar energy into electricity. Could tantalum ($\phi = 6.81 \times 10^{-19}$ J) be used to convert visible light to electricity? Assume that most of the electromagnetic energy from the Sun is in the visible region near 500 nm.

With reference to Problem 7.43, could tungsten ($\phi = 7.20 \times 10^{-19}$ J) be used to construct solar cells?

The power of a red laser ($\lambda = 630$ nm) is 1.00 watt (abbreviated W, where 1 W = 1 J/s). How many photons per second does the laser emit?

The energy density of starlight in interstellar space is 10^{-15} J/m^3. If the average wavelength of starlight is 500 nm, what is the corresponding density of photons per cubic meter of space?

The Hydrogen Spectrum and the Bohr Model

Concept Review

Why should hydrogen have the simplest atomic spectrum of all the elements?

For an electron in a hydrogen atom, how is the value of n of its orbit related to its energy?

Does the electromagnetic energy emitted by an excited-state H atom depend on the individual values of n_1 and n_2, or only on the difference between them ($n_1 - n_2$)?

Explain the difference between a ground-state H atom and an excited-state H atom.

Without calculating any wavelength values, identify which of the four electron transitions listed below for the hydrogen atom would be associated with emitting a photon of the shortest wavelength.

from n1.= 1 to n =
from n2.= 2 to n = 3
from n3.= 3 to n =
from n4.= 4 to n = 5

Without calculating any frequency values, identify which of the four electron transitions listed below for the hydrogen atom would be associated with absorbing a photon of the highest frequency.

1. from $n = 4$ to $n =$
2. from $n = 6$ to $n = 8$
3. from $n = 9$ to $n = 11$
4. from $n = 11$ to $n = 13$

Electron transitions from $n = 2$ to $n = 3$, 4, 5, or 6 in hydrogen atoms are responsible for some of the Fraunhofer lines in the Sun's spectrum. Are there any Fraunhofer lines caused by transitions that start from $n = 3$ in hydrogen atoms?

In the visible portion of the atomic emission spectrum of hydrogen (Figure 7.4), are there any bright lines caused by electron transitions to the $n = 1$ state?

Balmer observed a hydrogen emission line for the transition from $n = 6$ to $n = 2$, but not for the transition from $n = 7$ to $n = 2$. Why?

In what ways should the emission spectra of H and He^+ be alike, and in what ways should they be different?

Problems

Calculate the wavelength of the photons emitted by hydrogen atoms when they undergo transitions from $n = 4$ to $n = 3$. In which region of the electromagnetic spectrum does this radiation occur?

Calculate the frequency of the photons emitted by hydrogen atoms when they undergo transitions from $n = 5$ to $n = 3$. In which region of the electromagnetic spectrum does this radiation occur?

The energies of the photons emitted by one-electron atoms and ions fit the equation

$$E = (2.178 \times 10^{-18}\ \mathrm{J})Z^2\left(\frac{1}{n_1^{\,2}} - \frac{1}{n_2^{\,2}}\right)$$

where Z is the atomic number, n_2 and n_1 are positive integers, and $n_2 > n_1$.

1. As the value of Z increases, does the wavelength of the photon associated with the transition from $n = 2$ to $n = 1$ increase or decrease?
2. Can the wavelength associated with the transition from $n = 2$ to $n = 1$ ever be observed in the visible region of the spectrum?

Can transitions from higher energy states to the $n = 2$ level in He^+ ever produce visible light? If so, for what values of n_2? (*Hint*: The equation in Problem 7.59 may be useful.)

The transition from $n = 3$ to $n = 2$ in a hydrogen atom produces a photon with a wavelength of 656 nm. What is the wavelength of the transition from $n = 3$ to $n = 2$ in a Li^{2+} ion? (Use the equation in Problem 7.59.)

The hydrogen atomic emission spectrum includes a UV line with a wavelength of 92.3 nm.

1. Is this line associated with a transition between different excited states or between an excited state and the ground state?
2. What is the value of n_1 of this transition?
3. What is the energy of the longest wavelength photon that a ground-state hydrogen atom can absorb?

Electron Waves

Concept Review

Identify the symbols in the de Broglie equation $\lambda = h/mu$, and explain how the relation links the properties of a particle to those of a wave.

How does de Broglie’s hypothesis that electrons behave like waves explain the stability of the electron orbits in the Bohr model of the hydrogen atom?

Would the density of an object influence its de Broglie wavelength?

Would the shape of an object influence its de Broglie wavelength?

Problems

Calculate the wavelengths of the following objects:

1. a muon (a subatomic particle with a mass of 1.884×10^{-25} g) traveling at 325 m/s
2. electrons ($m_e = 9.10938 \times 10^{-28}$ g) moving at 4.05×10^6 m/s in an electron microscope
3. a 75-kg athlete running a 4-minute mile
4. Earth (mass $= 6.0 \times 10^{27}$ g) moving through space at 3.0×10^4 m/s

Two objects are moving at the same velocity. Which (if any) of the following statements about them is true?

1. The de Broglie wavelength of the heavier object is longer than that of the lighter one.
2. If one object has twice as much mass as the other, its wavelength is one-half the wavelength of the other.
3. Doubling the velocity of one of the objects will have the same effect on its wavelength as doubling its mass.

Which (if any) of the following statements about the frequency of a particle is true?

1. Heavy, fast-moving objects have lower frequencies than those

of lighter, faster-moving objects.

2. Only very light particles can have high frequencies.
3. Doubling the mass of an object and halving its velocity results in no change in its frequency.

How rapidly would each of the following particles be moving if they all had the same wavelength as a photon of red light ($\lambda = 750$ nm)?

1. an electron of mass 9.10938×10^{-28} g
2. a proton of mass 1.67262×10^{-24} g
3. a neutron of mass 1.67493×10^{-24} g
4. an α particle of mass 6.64×10^{-24} g

Kinetic molecular theory tells us that helium atoms at 500 K are in constant random motion.

1. Calculate the root-mean-square speed of helium atoms at 500 K.
2. What is the wavelength of a helium atom at 500 K?

Neon atoms are expected to move more slowly than helium atoms at the same temperature.

1. Using Graham’s law of effusion and your answer from Problem 7.71, calculate the root-mean-square speed of neon atoms at 500 K.
2. What is the wavelength of a neon atom at 500 K?

Particles in a Cyclotron The first cyclotron was built in 1930 at the University of California, Berkeley, and was used to accelerate molecular ions of hydrogen, $H_2{}^+$, to a velocity of 4×10^6 m/s. (Modern cyclotrons can accelerate particles to nearly the speed of light.) If the uncertainty in the velocity of the $H_2{}^+$ ion was 3%, what was the uncertainty of its position?

Radiation Therapy An effective treatment for some cancerous tumors involves irradiation with “fast” neutrons. The neutrons from one treatment source have an average velocity of 3.1×10^7 m/s. If the velocities of individual neutrons are known to within 2% of this value, what is the uncertainty in the position of one of them?

Quantum Numbers and Electron Spin; The Sizes and Shapes of Atomic Orbitals

Concept Review

How does the concept of an orbit in the Bohr model of the hydrogen atom differ from the concept of an orbital in quantum theory?

What properties of an orbital are defined by each of the three quantum numbers n, ℓ, and m_ℓ?

Why does the size of an *s* orbital increase as the value of quantum number n increases?

Why do we need two quantum numbers to define a type of orbital when four are needed to describe an electron in an orbital?

Problems

How many orbitals are there in an atom with each of the following principal quantum numbers? (a) 1; (b) 2; (c) 3; (d) 4; (e) 5

How many orbitals are there in an atom with the following combinations of quantum numbers?

$n = 3{,}1\ell = 2$
$n = 3{,}2\ell = 1$
$n = 4{,}3\ell = 2, m_\ell = 2$

What is the maximum number of electrons in the $n = 2$ shell of an atom?

What is the maximum number of electrons in an atom for which $n = 3$ and $\ell = 2$?

What set of orbitals corresponds to each of the following sets of quantum numbers? How many electrons could occupy these orbitals?

$n = 2,1\ell = 0$
$n = 3,2\ell = 1$
$n = 4,3\ell = 2$
$n = 1,4\ell = 0$

What set of orbitals corresponds to each of the following sets of quantum numbers? How many electrons could occupy these orbitals?

$n = 2,1\ell = 0$
$n = 5,2\ell = 3$
$n = 3,3\ell = 2$
$n = 4,4\ell = 3$

Which of the following combinations of quantum numbers are allowed?

a. $n = 1, \ell = 1, m_\ell = 0, m_s = +\frac{1}{2}$
b. $n = 3, \ell = 0, m_\ell = 0, m_s = -\frac{1}{2}$
c. $n = 1, \ell = 0, m_\ell = 1, m_s = -\frac{1}{2}$
d. $n = 2, \ell = 1, m_\ell = 2, m_s = +\frac{1}{2}$

Which of the following combinations of quantum numbers are allowed?

a. $n = 3, \ell = 2, m_\ell = 0, m_s = -\frac{1}{2}$

b. $n = 5, \ell = 4, m_\ell = 4, m_s = +\frac{1}{2}$

c. $n = 3, \ell = 0, m_\ell = 1, m_s = +\frac{1}{2}$

d. $n = 4, \ell = 4, m_\ell = 1, m_s = -\frac{1}{2}$

The Periodic Table and Filling the Orbitals of Multielectron Atoms; Electron Configurations of Ions

Concept Review

What is meant when two or more orbitals are said to be degenerate?

Explain how the electron configurations of the group 2 elements are linked to their location in the periodic table developed by Mendeleev (see Figure 2.11).

How do we know from examining the structure of the periodic table that the 4*s* orbital is filled before the 3*d* orbital?

Explain why so many transition metals form ions with a 2+ charge.

Why is there only one ground-state electron configuration for an atom but many excited-state electron configurations?

Can the ground-state electron configuration for an atom ever be an excited-state electron configuration for a different atom?

Problems

List the following orbitals in order of increasing energy in a multielectron atom:

$n = 3,1\ell = 2$ b. $n = 5, \ell = 1$

$n = 3,2\ell = 0$ d. $n = 4, \ell = 1$

Place the following orbitals in order of increasing energy in a multielectron atom:

$n = 2,1\ell = 1$ b. $n = 5, \ell = 3$
$n = 3,2\ell = 2$ d. $n = 4, \ell = 3$

What are the electron configurations of Li, Li^{+}, Ca, F^{-}, Na^{+}, Mg^{2+}, and Al^{3+}?

Which species listed in Problem 7.95 are isoelectronic with Ne?

In what way are the electron configurations of H, Li, Na, K, Rb, and Cs similar?

In what way are the electron configurations of C, Si, and Ge similar?

What are the condensed electron configurations of the following ground-state atoms and ions? How many unpaired electrons are there in each? (a) K; (b) K^{+}; (c) S^{2-}; (d) N; (e) Ba; (f) Ti^{4+}; (g) Al

What are the condensed electron configurations of the following ground-state atoms and ions? How many unpaired electrons are there in each? (a) O; (b) P^{3+}; (c) Na^{+}; (d) Sc; (e) Ag^{+}; (f) Cd^{2+}; (g) Zr^{2+}

Identify the element and the number of unpaired electrons in each of the following ground-state, condensed electron configurations of gas-phase atoms:

[Ar]$3d^{2}$1.$4s^{2}$
[Ar]$3d^{5}$2.$4s^{1}$
[Ar]$3d^{10}$3.$4s^{1}$
*d. [Kr]4.$4d^{10}$

Identify the ion and the number of unpaired electrons in each of the following ground-state, condensed electron configurations of monatomic cations:

1. [Ne]
2. $[\text{Kr}]\,4d^{10}5s^{2}$
3. $[\text{Ar}]33d^{10}$
4. $1s^{2}2s^{2}2p^{6}$

Identify the element with the lowest atomic number that has two unpaired electrons in its ground state.

Identify the first-row transition metal that has no unpaired electrons in its ground state.

Does the ground-state electron configuration of Na^{+} represent an excited-state electron configuration of Ne?

Which excited state of the hydrogen atom is likely to be of higher energy, $1s^{1}2s^{1}$ or $1s^{1}3s^{1}$?

Predict the charge of the monatomic ions formed by Al, N, Mg, and Cs.

Predict the charge of the monatomic ions formed by S, P, Zn, and I.

Which of the following electron configurations represent an excited state?

1. $[\text{He}]2s^{1}2p^{5}$
b. 2. $[\text{Kr}]4d^{10}5s^{2}5p^{1}$
3. $[\text{Ar}]3d^{10}4s^{2}4p^{5}$
d. 4. $[\text{Ne}]3s^{2}3p^{2}4s^{1}$

Which of the following electron configurations represent an excited state?

1. $[\text{Ne}]3s^{2}3p^{1}$

b. $[Ar]3d^{10}4s^{1}4p^{2}$

c. $[Kr]4d^{10}5s^{1}5p^{1}$

d. $[Ne]3s^{2}3p^{6}4s^{1}$

Boric acid, H_3BO_3, gives off a green color (Figure P7.111) when ignited.

1. Write ground-state electron configurations for B and O.
2. Assign oxidation numbers to each of the elements in boric acid. If the oxidation number reflects the ionic charge on the element, write ground-state electron configurations for each ion.

FIGURE P7.111

Introducing calcium chloride into a flame imparts an intense orange color (Figure P7.112).

1. Write ground-state electron configurations for Ca and Cl.
2. Calcium chloride contains calcium and chloride ions. Write ground-state electron configurations for each ion.

FIGURE P7.112

Magnesium metal burns in air forming solid magnesium oxide.

1. Write a balanced chemical equation describing this reaction.
2. Write the electron configurations of the atoms in magnesium metal and the ions in magnesium oxide.
3. Which element is oxidized, and which is reduced in this reaction?

Sodium metal reacts (sometimes explosively) with chlorine gas, forming solid sodium chloride.

1. Write a balanced chemical equation describing this reaction.
2. Write the electron configurations of the atoms in sodium metal and the ions in sodium chloride.
3. Which element is oxidized, and which is reduced in this reaction?

Appendix 3 lists the ground state of gas-phase palladium atoms as [Kr] $4d^{10}$. Which of the following is the *best* explanation for this observation?

1. The aufbau principle only applies to transition metal atoms in period 4.
2. Gas-phase palladium atoms are always in an excited state.
3. The energy of the 5*s* orbital must be higher than that of the 4*d* orbital for Pd.
4. Palladium is always present as a Pd^{2+} cation because of the photoelectric effect.

The ground-state electron configuration in Appendix 3 for gas-phase silver ions is [Kr] $4d^{10}5_{s}^{1}$. Which of the following statements best explains the electron configuration of silver *and* is consistent with the answer to Problem 7.115?

1. *nd* orbitals always fill before $(n + 1)s$ orbitals.
2. The energy of the 4*d* orbital is still lower in energy than the 5*s* orbital in Ag atoms.
3. The repulsion between electrons in the 4*d* orbital are greater than in the 5*s* orbital.
4. Gas-phase silver atoms are always in an excited state.

Removing a 1*s* electron from beryllium requires X-rays with wavelength 110.7 nm. Table 7.2 lists the first ionization energy of Be as 900 kJ/mol.

1. Why don't these data represent the same process?
2. Does the energy to remove the 1*s* electron correspond to the second ionization energy of Be, which is 1758 kJ/mol?

The first ionization energies of group 1 elements decrease from top to bottom in the group. The energies to move an electron from $n = 1$ to $n = \infty$, however, increase from Li to Cs. Why are the trends opposite?

The Sizes of Atoms and Ions

Concept Review

Sodium atoms are much larger than chlorine atoms, but in NaCl sodium ions are much smaller than chloride ions. Why?

Why does atomic size tend to decrease with increasing atomic number across a row of the periodic table?

Which of the following group 1 elements has the largest atoms: Li, Na, K, or Rb? Explain your selection.

Which of the following group 17 elements has the largest monatomic ions: F, Cl, Br, or I? Explain your selection.

Problems

Using only the periodic table as a guide, arrange each set of particles by size, from largest to smallest:

1. Al, P, Cl, Ar
2. C, Si, Ge, Sn
3. Li^+, Li, Na, K
4. F, Ne, Cl, Cl^-

Using only the periodic table, arrange each set of particles by size, from largest to smallest:

1. Li, B, N, Ne b. Mg, K, Ca, Sr
2. Rb^+, Sr^{2+}, Cs, Fr d. S^{2-}, Cl^-, Ar, K^+

Ionization Energies

Concept Review

How do ionization energies change with increasing atomic number (a) down a group of elements in the periodic table and (b) from left to right across a period of elements?

The first ionization energies of the main group elements are given in Figure 7.39. Explain the differences in the first ionization energy between (a) He and Li; (b) Li and Be; (c) Be and B; (d) N and O.

Explain why it is more difficult to ionize a fluorine atom than a boron atom.

Do you expect the ionization energies of anions of group 17 elements to be lower or higher than for neutral atoms of the same group?

Problems

Which of the following elements should have the smallest *second* ionization energy? Br, Kr, Rb, Sr, Y

Why is the first ionization energy (IE_1) of Al ($Z = 13$) less than the IE_1 of Mg ($Z = 12$) *and* less than the IE_1 of Si ($Z = 14$)?

Without referring to Figure 7.39, arrange the following groups of elements in order of increasing first ionization energy.

1. F, Cl, Br, I
2. Li, Be, Na, Mg
3. N, O, F, Ne

Without referring to Figure 7.39, arrange the following groups of elements in order of increasing first ionization energy.

1. Mg, Ca, Sr, Ba
2. He, Ne, Ar, Kr
3. P, S, Cl, Ar

Electron Affinities

Concept Review

An electron affinity (EA) value that is negative indicates that the free atoms of an element are less stable than the $1-$

anions they form by acquiring electrons. Does this mean that all the elements with negative EA values exist in nature as anions? Give some examples to support your answer.

The electron affinities of the group 17 elements are all negative values, but the EA values of the group 18 noble gases are all positive. Explain this difference.

The electron affinities of the group 17 elements increase with increasing atomic number. Suggest a reason for this trend.

Ionization energies generally increase with increasing atomic number across the second row of the periodic table, but electron affinities generally decrease. Explain the opposing trends.

Additional Problems

Searching for Extraterrestrial Life Project Ozma was an early attempt to find any advanced civilizations elsewhere in our universe. Launched in 1959, scientists involved with the project decided to search space for a signal emitted by H atoms at 1240 MHz. They reasoned that other intelligent life might come to the same conclusion about a "universal" communication frequency.

1. Calculate the wavelength and energy of this light.
2. Does this frequency correspond to Balmer, Lyman, or Paschen lines in the emission spectrum of H?

X-ray Absorption Spectroscopy Electrons in multielectron atoms absorb X-rays at characteristic energies, leading to ionization. The characteristic energies for each element allow scientists to identify the element. For magnesium, X-rays with $\lambda = 952$ pm are required to selectively eject an electron from $n = 1$, but $\lambda = 197$ nm removes an electron from $n = 2$.

1. Calculate the frequency and energy of these X-rays.
2. Why are the wavelengths and energies different for the two electrons?
3. In terms of Bohr's values of n, what transitions do these represent?

Satellite Radio and Weather Radio Sirius XM radio transmits at 2.3 GHz using a network of satellites. The National Oceanic and Atmospheric Administration (NOAA) transmits warnings for tornados over weather radios at 162 MHz. Which of these signals uses photons of higher energy? Of shorter wavelength? Of higher frequency?

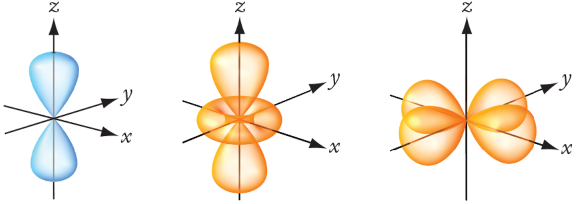
Interstellar Hydrogen Astronomers have detected hydrogen atoms in interstellar space in the $n = 732$ excited state. Suppose an atom in this excited state undergoes a transition from $n = 732$ to $n = 731$.

1. How much energy does the atom lose because of this transition?
2. What is the wavelength of radiation corresponding to this transition?
3. What kind of telescope would astronomers need to detect radiation of this wavelength? (*Hint*: It would not be one designed to capture visible light.)

When an atom absorbs an X-ray of sufficient energy, one of its 2*s* electrons may be emitted, creating a hole that can be spontaneously filled when an electron in a higher-energy orbital—a 2*p*, for example—falls into it. A photon of electromagnetic radiation with an energy that matches the energy lost in the 2*p*→ 2*s* transition is emitted. Predict how the wavelengths of 2*p*→ 2*s* photons would differ between (a) different elements in the fourth row of the periodic table and (b) different elements in the same column (e.g., between the noble gases from Ne to Rn).

Compare the orbital representations labeled (i), (ii), and (iii) in

Figure P7.142.



(i) (ii) (iii) **FIGURE P7.142**

---

1. Which orbital has the lowest energy?
2. Which two orbitals have the same value for the quantum number ℓ?
3. What is the maximum number of electrons that can occupy (i)? (ii)? (iii)?

The spin quantum number, m_s, was first detected by passing a beam of silver atoms through a magnetic field. Why doesn’t this experiment allow scientists to distinguish between the two most likely ground-state electron configurations for silver: [Kr] $4d^{10}5s^{1}$ and [Kr] $4d^{9}5_{s}^{2}$?

A green flame is observed when copper(II) chloride is heated in a flame (Figure P7.144).

1. Write the ground-state electron configuration for copper atoms.
2. There are two common forms of copper chloride, copper(I) chloride and copper(II) chloride. What is the difference in the ground-state electron configurations of copper in these two compounds?

FIGURE P7.144

Two helium ions (He^+) in the $n = 3$ excited state emit photons of radiation as they return to the ground state. One ion does so in a single transition from $n = 3$ to $n = 1$. The other does so in two steps: $n = 3$ to $n = 2$ and then $n = 2$ to $n = 1$. Which of the following statements about these two pathways is true?

1. The sum of the energies lost in the two-step process is the same as the energy lost in the single transition from $n = 3$ to $n = 1$.
2. The sum of the wavelengths of the two photons emitted in the two-step process is equal to the wavelength of the single photon emitted in the transition from $n = 3$ to $n = 1$.
3. The sum of the frequencies of the two photons emitted in the two-step process is equal to the frequency of the single photon emitted in the transition from $n = 3$ to $n = 1$.
4. The wavelength of the photon emitted by the He^+ ion in the $n = 3$ to $n = 1$ transition is shorter than the wavelength of a photon emitted by an H atom in an $n = 3$ to $n = 1$ transition.

Use your knowledge of electron configurations to explain the following observations:

1. Silver tends to form ions with a charge of 1+, but the element to the right of silver in the periodic table tends to form ions with 2+ charges.
2. The heavier group 13 elements (Ga, In, Tl) tend to form ions with charges of 1+ or 3+ but not 2+.
3. The heavier elements of group 14 (Sn, Pb) and group 4 (Ti, Zr, Hf) tend to form ions with charges of 2+ or 4+.

Trends in ionization energies of the elements as a function of the position of the elements in the periodic table are a useful test of our understanding of electronic structure.

1. Should the same trend in the first ionization energies for elements with atomic numbers $Z = 31$ through $Z = 36$ be observed for the second ionization energies of the same elements? Explain why or why not.
2. Which element should have the greater second ionization energy: Rb ($Z = 37$) or Kr ($Z = 36$)? Why?

Chemistry of Photo-Gray Glasses “Photo-gray” lenses for eyeglasses darken in bright sunshine because the lenses contain tiny, transparent AgCl crystals. Exposure to light removes electrons from Cl^- ions, forming a chlorine atom in an excited state (indicated below by the asterisk):

$$Cl^- + h\nu \rightarrow Cl^* + e^-$$

The electrons are transferred to Ag^+ ions, forming silver metal:

$$Ag^+ + e^- \rightarrow Ag$$

Silver metal is reflective, giving rise to the photo-gray color.

1. Write a balanced chemical equation describing the overall chemical reaction.
2. Which elements are oxidized, and which are reduced?

3. Write condensed electron configurations of Cl^-, Cl, Ag, and Ag^+.
4. Would more energy be needed to remove an electron from a Br^- ion or from a Cl^- ion? Explain your answer.
5. How might substitution of AgBr for AgCl affect the light sensitivity of photo-gray lenses?

The first ionization energy of a gas-phase atom of a particular element is 6.24×10^{-19} J. What is the maximum wavelength of electromagnetic radiation that could ionize this atom?

Tin (in group 14) forms both Sn^{2+} and Sn^{4+} ions, but magnesium (in group 2) forms only Mg^{2+} ions.

1. Write condensed ground-state electron configurations for the ions Sn^{2+}, Sn^{4+}, and Mg^{2+}.
2. Which neutral atoms have ground-state electron configurations identical to Sn^{2+} and Mg^{2+}?
3. Which 2+ ion is isoelectronic with Sn^{4+}?

Rare Earth Magnets The rare earth elements, $Z = 57–71$, are used in the strong magnets found in many automobiles.

1. Predict the ground-state electron configurations for these 15 elements.
2. Using Table A3.1 in the appendix, which of these elements have electron configurations different from those predicted in part (a)?
3. How might one rationalize the differences between the observed and predicted electron configurations for the elements identified in part (b)?
4. Can we distinguish between the observed and predicted electron configurations for the elements in part (b) by determining the number of unpaired electrons?

Oxygen Ions in Space Between 1999 and 2007 the Far Ultraviolet Spectroscopic Explorer satellite analyzed the spectra of emission sources within the Milky Way. Among the satellite's findings were interplanetary clouds containing oxygen atoms that have lost five electrons.

1. Write an electron configuration for these highly ionized oxygen atoms.
2. Which electrons have been removed from the neutral atoms?
3. The ionization energies corresponding to removal of the third, fourth, and fifth electrons are 4581 kJ/mol, 7465 kJ/mol, and 9391 kJ/mol, respectively. Explain why removal of each additional electron requires more energy than removal of the previous one.
4. What is the maximum wavelength of radiation that will remove the fifth electron from an O atom?

Effective nuclear charge (Z_{eff}) is related to atomic number (Z) by the shielding parameter (σ) according to the equation $Z_{\text{eff}} = Z - \sigma$.

1. Calculate Z_{eff} for the outermost *s* electrons of Ne and Ar given $\sigma = 4.24$ (for Ne) and 11.24 (for Ar).
2. Explain why the shielding parameter is much greater for Ar than for Ne.

Fog Lamp Technology Sodium fog lamps and street lamps contain gas-phase sodium atoms and sodium ions. Sodium atoms emit yellow-orange light at 589 nm. Do sodium ions emit the same yellow-orange light? Explain why or why not.

How can an electron get from the (+) lobe of a *p* orbital to the (−) lobe without going through the node between the lobes?

Einstein did not fully accept the uncertainty principle, remarking that "He [God] does not play dice." What do you think Einstein meant? Niels Bohr allegedly responded by saying, "Albert, stop telling God what to do." What do you think Bohr meant?

The wavelengths of Fraunhofer lines in galactic spectra are not the same as those in sunlight: they tend to be shifted to longer wavelengths (*redshifted*), in part because of the Doppler effect. The Doppler effect is described by the equation

$$\frac{(\nu - \nu')}{\nu} = \frac{u}{c}$$

where ν is the unshifted frequency, ν' is the perceived frequency, c is the speed of light, and u is the speed at which the object is moving. If hydrogen in a galaxy that is receding from Earth at half the speed of light emits radiation with a wavelength of 656 nm, will the radiation still be in the visible part of the electromagnetic spectrum when it reaches Earth?

The work function of mercury is 7.22×10^{-19} J.

1. What is the minimum frequency of radiation required to eject photoelectrons from a mercury surface?
2. Could visible light produce the photoelectric effect in mercury?

Glossary

electromagnetic radiation
any form of radiant energy in the electromagnetic spectrum.

frequency
(ν) the number of crests of a wave that pass a stationary point of reference per second.

quantum theory
a model based on the idea that energy is absorbed and emitted in discrete quantities of energy called quanta.

photon
a quantum of electromagnetic radiation.

photoelectric effect
the phenomenon of light striking a metal surface and

producing an electric current (a flow of electrons).

atomic emission spectrum

a characteristic series of bright lines produced by high-temperature atoms.

atomic absorption spectrum

a characteristic series of dark lines produced when free, gaseous atoms are illuminated by a continuous source of radiation.

ground state

the most stable, lowest-energy state available to an atom, ion, or molecule.

excited state

any energy state above the ground state in an atom, ion, or molecule.

electron transition

the movement of an electron between energy levels.

matter wave

the wave associated with any particle.

standing wave

a wave confined to a given space, with a wavelength (λ) related to the length L of the space by $L = n(\lambda/2)$, where n is a whole number.

Heisenberg uncertainty principle

the principle that we cannot determine both the position and the momentum of a particle in an atom at the same time.

Schrödinger’s wave equation

a description of how the electron matter wave varies with location and time around the nucleus of a hydrogen atom.

orbital

a region around the nucleus of an atom where the probability of finding an electron is high; each orbital is defined by the square of the wave function (ψ^2) and is identified by a unique combination of three quantum numbers.

quantum number

a number that specifies the energy, the probable location or orientation of an orbital, or the spin of an electron within an orbital.

angular momentum quantum number (ℓ)

an integer having any value from 0 to $n - 1$ that defines the shape of an orbital.

aufbau principle

the method of building electron configurations of atoms by adding one electron at a time as atomic number increases across the rows of the periodic table; each electron goes into the lowest-energy orbital available.

Pauli exclusion principle

the principle that no two electrons in an atom can have the same set of four quantum numbers.

electron configuration

the distribution of electrons among the orbitals of an atom or ion.

valence electrons

electrons in the outermost occupied shell of an atom; the electrons that are transferred or shared in chemical reactions.

degenerate orbitals

describes orbitals of the same energy.

Hund’s rule

the lowest-energy electron configuration of an atom has the maximum number of unpaired electrons, all of which have the same spin, in degenerate orbitals.

orbital diagram

depiction of the arrangement of electrons in an atom or ion, using boxes to represent orbitals.

effective nuclear charge (Z_{eff})

the attraction toward the nucleus experienced by a valence-shell electron, which is approximately equal to the sum of the positive charge on the nucleus and the total negative charge of all inner-shell electrons.

ionization energy (IE)

the quantity of energy needed to remove 1 mole of electrons from 1 mole of ground-state atoms or ions in the gas phase.

electron affinity (EA)

the energy change that occurs when 1 mole of electrons combines with 1 mole of atoms or monatomic cations in the gas phase.

wavelength (λ)

the distance from crest to crest or trough to trough on a wave.

quantum (plural *quanta*)

the smallest discrete quantity of a form of energy.

Planck constant (h)

the proportionality constant between the energy and frequency of electromagnetic radiation: $E = h\nu$; $h = 6.626 \times 10^{234}\ \mathrm{J \cdot s}$.

threshold frequency (ν_0)

the minimum frequency of light required to produce the photoelectric effect.

wave function (ψ)

a solution to the Schrödinger wave equation.

principal quantum number (n)

a positive integer describing the relative size and energy of an atomic orbital or group of orbitals in an atom.

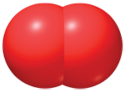
magnetic quantum number (m_ℓ)

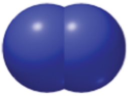
an integer that may have any value from $-\ell$ to $+\ell$, where ℓ is the angular momentum quantum number; it defines the orientation of an orbital in space.

spin magnetic quantum number (m_s)

either $+\frac{1}{2}$ or $-\frac{1}{2}$, indicating that the spin orientation of an electron is either up or down, respectively.

RICE PADDIES AND CLIMATE CHANGE Microorganisms growing in flooded rice paddies release methane gas, which is a more potent greenhouse gas than carbon dioxide.





8

Chemical Bonds What Makes a Gas a Greenhouse Gas?

PARTICULATE REVIEW

Breaking and Making Bonds

In Chapter 8 we learn how chemists model and represent the formation of chemical bonds between atoms.

When methane burns in air, oxygen is consumed, and carbon dioxide and water vapor are produced. Molecular models of the reactants and products are shown here. Write a balanced chemical equation describing this reaction.

- Which bonds and how many of them are broken during the combustion of 1 mole of methane?
- Which bonds and how many of them are formed during the combustion of 1 mole of methane?

(Review Section 3.3 if you need help.)

(Answers to Particulate Review questions are in the back of the book.)

PARTICULATE PREVIEW

Single, Double, or Triple Bond?

These space-filling models show an oxygen molecule, a fluorine molecule, and a nitrogen molecule. As you read Chapter 8, look for ideas that will help you answer these questions:

- One of the three molecules contains a single bond, one contains a double bond, and one contains a triple bond. Does a space-filling model tell you what kind of bond exists within a substance?
- What is the molecular formula for each substance? Does a molecular formula tell you what kind of bond exists within a substance?
- What information does a ball-and-stick model contain that a space-filling model does not?

Learning Outcomes

- LO1 Describe ways in which covalent, ionic, and metallic bonds are alike and ways in which they differ

  Sample Exercise 8.1

- LO2 Draw Lewis structures of molecular compounds and ionic compounds

  Sample Exercises 8.2, 8.3, 8.4, 8.5

- LO3 Predict the polarity of covalent bonds based on differences in electronegativity between the bonded atoms

  Sample Exercise 8.6

- LO4 Explain how molecules of some atmospheric gases absorb infrared radiation and contribute to the greenhouse effect
- LO5 Draw resonance structures and evaluate their contribution to the bonding in molecules and polyatomic ions using formal charges

  Sample Exercises 8.7, 8.8, 8.9, 8.10, 8.11, 8.12

- LO6 Describe how bond order, bond energy, and bond length are related, and estimate the enthalpy of a reaction (ΔH_{rxn}) from average bond energies

  Sample Exercise 8.13

FIGURE 8.1 The glass windows of a greenhouse allow sunlight to enter but trap the warm air inside. Greenhouse gases, such as CH_4 (methane) and CO_2 (carbon dioxide), behave in a similar fashion. Recent increases in atmospheric CO_2 concentrations have been linked to rising global temperatures and the threat of global climate change.

$$E_{\text{el}} \propto \frac{Q_1 \times Q_2}{d} \tag{6.3}$$

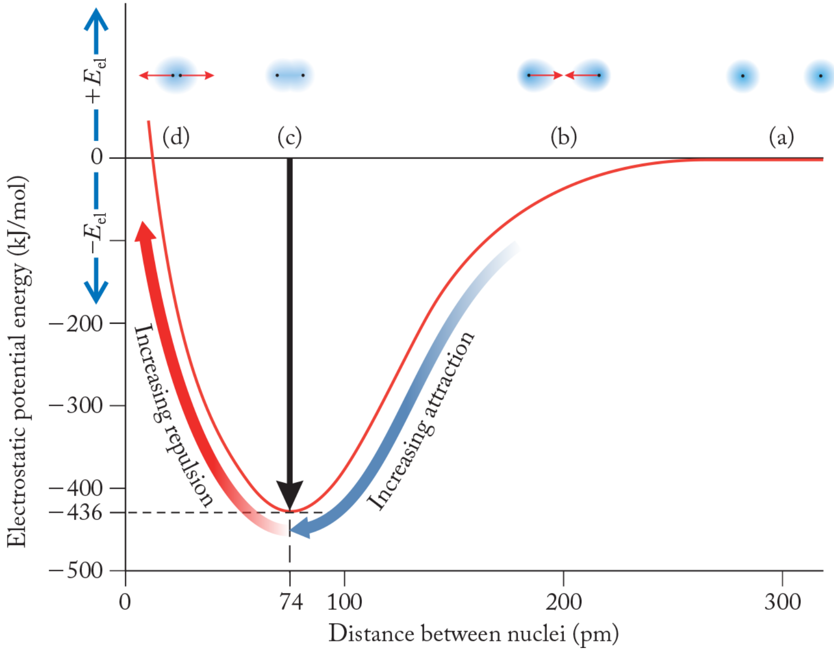


FIGURE 8.2 The electrostatic potential energy (E_{el}) profile of a H—H bond: (a) Two H atoms that are far apart do not interact, so $E_{el} = 0$. (b) As the atoms approach each other, mutual attraction between their positive nuclei and negative electrons causes E_{el} values to decrease. (c) At 74 pm, E_{el} reaches a minimum as the two atoms form a H—H bond. (d) If the atoms are even closer together, repulsion between their nuclei causes E_{el} to increase and destabilizes the bond.

8.1 Types of Chemical Bonds and the Greenhouse Effect

In Chapter 7 we saw that quantum theory describes matter's interaction with energy at the atomic level. In this chapter we continue our exploration of matter and energy as we step from considering individual atoms to explaining how atoms are bonded to one another in molecules and how molecules interact with energy.

We begin with molecules of carbon dioxide in Earth's atmosphere. Most scientists agree that recent increases in the average temperature of Earth's surface (about half a Celsius degree in the last half century) are linked to increases in the concentration of carbon dioxide and other *greenhouse gases* in the atmosphere. These gases trap Earth's heat in its atmosphere, much like panes of glass trap heat in a greenhouse or in a car on a hot summer day (**Figure 8.1**). The amount of some greenhouse gases in the atmosphere may surprise you. Energy production, livestock animals, landfills, and wetlands introduce more than 0.5 teragram CH_4 (1 teragram = 1 Tg = 1 million metric tons = 10^{12} g) into the atmosphere *every* day. Increases in atmospheric concentrations of other greenhouse gases have also been linked to human activity, particularly to increasing rates of fossil fuel combustion and the destruction of forests that would otherwise consume CO_2 during photosynthesis.

Were it not for the presence of atmospheric CO_2 and other greenhouse gases, Earth would be much colder than it is. Indeed, it would be too cold to be habitable. The *greenhouse effect* resulting from the presence of these gases has moderated Earth's average global temperature to within a narrow range, 15°C–17°C, for many thousands of years. However, during the last 60 years, atmospheric concentrations of CO_2 have increased from about 315 ppm to more than 400 ppm. The atmosphere has not contained this much CO_2 since more than half a million years ago, long before humans evolved.

Carbon dioxide allows solar radiation to pass through the atmosphere and warm Earth's surface, but it traps heat that would otherwise radiate from the warm surface back into space. Why is CO_2 so good at trapping heat? Heat is associated with the infrared region of the electromagnetic spectrum (Chapter 7). Carbon dioxide traps heat because it absorbs infrared radiation. To understand how CO_2 does this, whereas O_2 and N_2 do not, we need to learn more about the chemical bonds that hold atoms together in molecules.

Forming Bonds from Atoms

Fewer than 100 stable (nonradioactive) elements make up all the matter in our world. These elements combine to form more than 60 million compounds, and the number grows daily as chemists synthesize new ones. This multitude of compounds exists because they are more stable than their constituent elements. In other words, two atoms that are linked by a chemical bond tend to be lower in chemical energy than those same two atoms without a bond connecting them.

Why are bonded atoms more stable? The principal reason stems from the concept of electrostatic potential energy (E_{el}) between charged particles. Recall from Chapter 6 that E_{el} is directly proportional to the product of the charges (Q_1 and Q_2) on pairs of ions (or subatomic particles) and is inversely proportional to the distance (d) between them:

When we apply Equation 6.3 to particles of opposite charge, such as a cation–anion pair, the product of Q_1 and Q_2 is negative and so is the value of E_{el}. The value of E_{el} becomes more negative as the particles approach each other and the distance (d) between them decreases (review Figure 6.8). As the oppositely charged pair of ions moves very close together, however, their attraction to each other is offset by electrostatic repulsions between the ion's outer-shell electrons and between their positive nuclei. At the energy minimum in Figure 6.8, the forces of attraction and repulsion are in balance, and the ions are held together by a stable ionic bond.

CONNECTION Negative values of E_{el} quantify the attraction between particles of opposite charge; positive values relate to the repulsion of particles with the same charge, as described in Chapter 6.

This concept of electrostatic potential energy can also explain why two neutral atoms may come together to form a stable molecule. Let's consider the case of two hydrogen atoms (**Figure 8.2a**) that are sufficiently far apart that they do not interact with each other and have zero potential energy with respect to each other. As they approach each other (moving from right to left along the x axis of the graph), the proton in the nucleus of one H atom is attracted to the electron of the other, and vice versa. This mutual attraction produces a negative E_{el} in the (b) region of Figure 8.2. As the distance between the atoms decreases, the value of E_{el} continues to decrease, eventually reaching a minimum when the nuclei are 74 pm apart at point (c). At this optimal distance, the strengths of the attractions between the two nuclei and the two electrons are equal; they have formed a single covalent bond. They are no longer two separate H atoms but rather a more stable, single molecule of H_2. If the atoms move any closer together, the repulsion between their two positive nuclei more than offsets the mutual proton–electron attractions, so E_{el} rises rapidly with any further decrease in d in region (d) of Figure 8.2.

The distance between the atoms when E_{el} is at a minimum corresponds to the length of a H—H covalent bond; in this case, the H—H bond length is 74 pm. The value of E_{el} at this distance, -436 kJ/mol, is the energy *released* when 2 moles of hydrogen atoms bond together, forming 1 mole of H_2 molecules. Breaking all these bonds would require adding 436 kJ of energy to the molecules. This energy requirement is a measure of H—H bond energy, or *bond strength*. We explore the significance of bond length and bond strength in more detail in Section 8.7.

We can also use electrostatic potential energy to explain the interactions between the atoms in a solid piece of metal. As with atoms in molecules, the positive nucleus of each atom in a metallic solid is attracted to the electrons of the atoms that surround it. These attractions result in the formation of metallic bonds, which are unlike covalent bonds in that they are *not* a pair of electrons shared by two atoms. Instead, the shared electrons in metallic bonds are highly delocalized, forming a "sea" of mobile electrons that move freely among all the atoms in a metallic solid. This electron mobility makes metals good conductors of heat and electricity. We discuss metallic bonding in greater detail in Chapter 9.

TABLE 8.1 Types of Chemical Bonds

[illegible]			
[illegible]			
[illegible] Distribution			
Particulate Vie			Macroscopic V			

Table 8.1 summarizes some of the differences among covalent, ionic, and metallic bonds. As you consider these properties, keep in mind that many bonds do not fall exclusively into just one category, but rather have some covalent, ionic, and even metallic character.

CONNECTION In Chapter 1 we described a chemical bond as the energy that holds two atoms in a molecule together. A covalent bond was defined in Chapter 2 as a bond between two atoms created by sharing pairs of electrons.

SAMPLE EXERCISE 8.1 Describing Similarities and Differences in Bonding LO1

Figure 8.3 shows particulate representations of barium sulfate, carbon dioxide, and potassium chloride. Identify each representation, name the type of bonding present in each compound, and determine what particles are attracted to one another when the electrostatic potential energy is at a minimum.

Collect and Organize We are given the names and representations of three compounds. We need to determine what kind of particles (atoms, molecules, or ions) are present in each compound and each representation to identify the type of bonding and describe the electrostatic attractions. Table 8.1 summarizes the three types of bonds.

Analyze Barium sulfate is an ionic compound: the -*ate* ending of its name indicates that it contains oxoanions of sulfur bonded to Ba^{2+} cations. Carbon dioxide is a binary compound of two nonmetals. The *di*- prefix means that it is composed of molecules that each contain one atom of carbon bonded to two atoms of oxygen. The -*ide* ending of potassium chloride conveys that it is an ionic compound of K^+ cations (potassium is a group 1 metallic element) and Cl^- anions (chlorine is a group 17 nonmetal).

Solve Representations (i) and (iii) both depict ionic compounds with 1:1 ratios of cations to anions that are electrostatically attracted to form ionic bonds. The polyatomic ions in (i) each contain one S atom bonded to 4 O atoms and are held together by covalent bonds. Their presence means that (i) must represent $BaSO_4$, and (iii) must represent KCl. Each of the molecules represented in (ii) consist of covalent bonds that are formed by electrostatic attractions between one central carbon atom and two oxygen atoms.

Think About It In addition to covalent electrostatic attractions between atoms and ionic electrostatic attractions between ions, ionic compounds that contain polyatomic ions have both covalent and ionic electrostatic interactions.

Practice Exercise Figure 8.4 shows particulate representations of gold, calcium carbonate, and phosphorus. Identify each representation, name the type of bonding present in each substance, and determine which particles are attracted to one another.

(Answers to Practice Exercises are in the back of the book.)

Glossary

ionic bond

a chemical bond that results from the electrostatic attraction between a cation and an anion.

bond length

the distance between the nuclear centers of two atoms joined in a bond.

metallic bond

a chemical bond consisting of metal atoms sharing a “sea” of electrons.

delocalized electrons

electrons that are shared among more than two atoms.

FIGURE 8.5 Lewis symbols of the main group elements of the periodic table. Because elements in a family have similar outer-shell electron configurations, they have the same number of dots in their Lewis symbols, which represent valence electrons. N triple bond. In Section 8.7 we discuss the characteristics of these multiple bonds and compare them with those of single bonds.

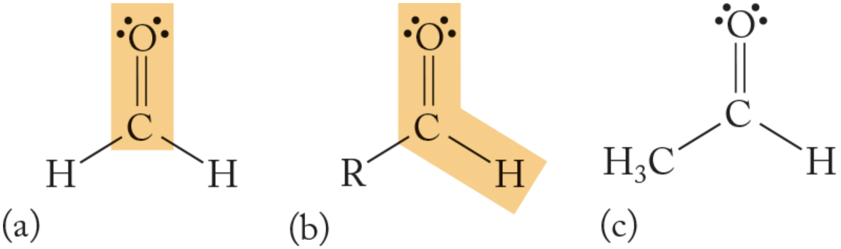

FIGURE 8.6 (a) Formaldehyde is the smallest member of the aldehyde family. The carbonyl group is highlighted. (b) All aldehydes contain a carbonyl group with a single bond to a hydrogen atom; R– represents any other organic group. The aldehyde group is highlighted. (c) Acetaldehyde is the next largest aldehyde; in acetaldehyde, R is CH_3.

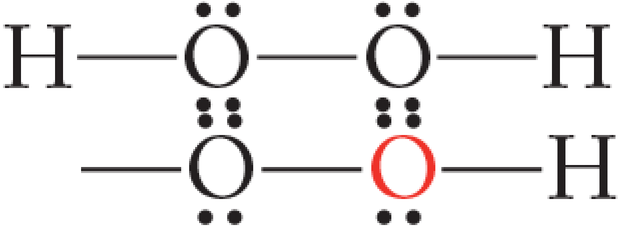
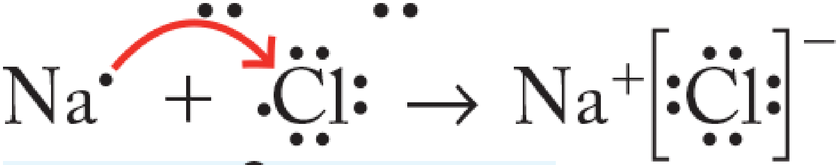
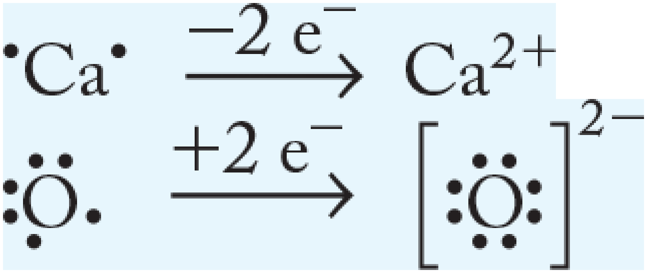
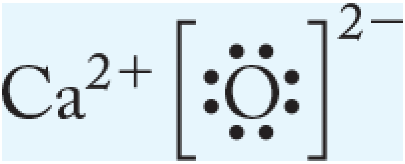








8.2 Lewis Structures

In 1916 American chemist Gilbert N. Lewis (1875–1946) proposed that atoms form chemical bonds by sharing electrons. He further suggested that through this sharing, each atom is surrounded by enough electrons to mimic the electron configuration of a noble gas. Today we associate such an electron configuration with filled *s* and *p* orbitals in the valence shells of atoms. Lewis's view of chemical bonding predated quantum mechanics and the notion of atomic orbitals, but it was consistent with what he called the octet rule: atoms of most main group elements lose, gain, or share electrons so that each atom has eight valence electrons (i.e., an *octet* of electrons). Hydrogen is an important exception to the octet rule—each of its atoms shares only a single pair of bonding electrons, thereby acquiring a "duet" instead of an octet. The space-filling models in Table 8.1 show the atoms involved in different types of bonding, but they do not show how their electrons are distributed. Lewis devised a way of representing individual valence electrons in atoms, to show how these electrons are distributed in various types of bonds.

CONNECTION The elements in groups 1, 2, and 13 through 18 in the periodic table are called main group elements (Chapter 2). The monatomic ions of main group elements (except H^+) have filled *s* and *p* orbitals in their outermost shell, so they are isoelectronic with a noble gas (Chapter 7).

Lewis Symbols

Lewis developed a system of symbols, called Lewis symbols or Lewis dot symbols, to represent the number of chemical bonds an atom typically forms to complete its octet. In other words, the Lewis symbol of an atom depicts its bonding capacity. A Lewis symbol consists of the symbol of an element surrounded by dots representing the valence electrons in one of its atoms. The dots are placed on the four sides of the symbol (top, bottom, right, and left). The order in which they are placed does not matter *if one dot is placed on each side before any dots are paired*. The number of *unpaired* dots in a Lewis symbol indicates the typical bonding capacity of the atom.

Figure 8.5 shows the Lewis symbols of the main group elements. Because all elements in a family have the same number of valence electrons, they all have the same arrangement of dots in their Lewis symbols. For example, the Lewis symbols of carbon and all other group 14 elements have four unpaired dots representing four unpaired electrons. Four unpaired electrons mean that a carbon atom has a bonding capacity of four: it typically forms four chemical bonds. In doing so, it completes its octet because these four bonds contain the carbon atom's original four valence electrons plus four more from the atoms with which it forms bonds. Similarly, the Lewis symbols of nitrogen and all other group 15 elements have five dots representing two paired electrons and three unpaired electrons. A nitrogen atom has a bonding capacity of three and typically forms three bonds to complete its octet.

There are some important exceptions to Lewis's octet rule, several of which involve H, Be, and B. Compounds having fewer than eight valence electrons around an atom are referred to as *electron-deficient* compounds in Lewis theory. In another type of electron deficiency, atoms in some molecules have incomplete octets because there are odd numbers of valence electrons in those molecules. Examples include NO and NO_2. We explore electron-deficient compounds and the chemical implications of the unpaired electrons in molecules in Section 8.6.

Before we start to use Lewis symbols to explore how elements form compounds, we need to keep in mind that the number of unpaired dots in the symbols indicates the number of bonds that the atoms of an element *typically* form. We see later in this chapter that atoms may exceed their bonding capacities in some molecules and polyatomic ions, and atoms fail to reach them in others. Bonding capacity is a useful concept, but treat it more as a guideline than a strict requirement.

Drawing Lewis Structures

The properties of molecular substances depend on which elements are included, the number of atoms of each element in each of their molecules, and how those atoms are bonded together. A Lewis structure is a two-dimensional representation of a molecule showing how the atoms in the molecule are connected. Because covalent bonds are *pairs* of shared valence electrons, Lewis structures focus on how these electron pairs, called bonding pairs, are distributed among the atoms in the molecule. In a Lewis structure, the pairs of electrons that are shared in chemical bonds are drawn with lines, as in the molecular structures we first saw in Chapter 1. A pair of electrons shared between two atoms is called a single bond. Electron pairs that are *not* involved in bond formation appear as pairs of dots on one atom. These unshared electron pairs are called lone pairs. Atoms with one or more lone pairs in their Lewis symbols frequently have that same number of lone pairs of electrons in the Lewis structures of the molecules they form.

The following guidelines describe a five-step approach to drawing Lewis structures. These initial guidelines are just a starting point in the discussion of molecular structure. We will continue to refine these guidelines as we draw structures for increasingly more challenging molecules and learn more about the distribution of electrons in bonds.

1. *Determine the number of valence electrons*. For a neutral molecule, count the valence electrons in all the atoms in the molecule. For a polyatomic ion, count the valence electrons and then add (for anions) or subtract (for cations) the number of electrons needed to account for the charge on the ion. This total number of valence electrons is used to form bonds and lone pairs in the Lewis structure.
2. *Arrange the symbols of the elements to show how the atoms are bonded and then connect them with single bonds (single pairs of bonding electrons)*. Put the atom with the greatest bonding capacity in the center. (If two elements have the same

bonding capacity, choose the one that is less electronegative, an atomic property we examine in Section 8.3.) Place the remaining atoms around the central atom and those that form the fewest bonds (such as hydrogen) around the periphery. Connect the atoms with single bonds. The resulting representation is often called a *skeletal structure*.

3. *Complete the octets of the atoms bonded to the central atom by adding lone pairs of electrons*. Place lone pairs on each of the outer atoms until each outer atom has an octet (including the two electrons used to connect it to the central atom in the skeletal structure). Remember that the same bonding electrons are used to complete the octets of both atoms they connect; in other words, bonding electrons count twice when completing octets, but only once when calculating the total number of valence electrons in a Lewis structure.
4. *Compare the number of valence electrons in the Lewis structure with the number determined in step 1*. If valence electrons remain unused in the structure, place lone pairs on the central atom (even if doing so means giving it more than an octet of valence electrons), until all the valence electrons counted in step 1 have been included in the Lewis structure.
5. *Complete the octet on the central atom*. If there is an octet on the central atom, the structure is complete. If there is less than an octet on the central atom, create additional bonds to it by converting one or more lone pairs of electrons on outer atoms into bonding pairs.

SAMPLE EXERCISE 8.2 Drawing the Lewis Structure of Chloroform LO2

Chloroform ($CHCl_3$) is a liquid with a low boiling point that was once used as an anesthetic in surgery. Draw its Lewis structure.

Collect and Organize We are given the molecular formula of chloroform, $CHCl_3$, and we can use the five-step approach described previously to generate the Lewis structure.

Analyze The formula $CHCl_3$ indicates that a chloroform molecule contains one carbon atom, one hydrogen atom, and three chlorine atoms. Because carbon is a group 14 element, it has four valence electrons and needs four more to complete its octet. Hydrogen, in group 1, has one valence electron in the 1*s* orbital and needs one more to complete its duet. Chlorine, in group 17, has seven valence electrons (in the 3*s* and 3*p* atomic orbitals) and needs one more to complete its octet.

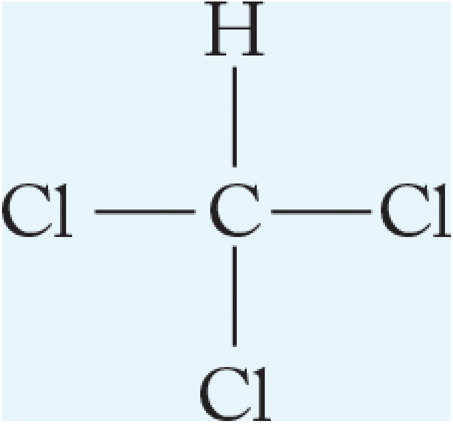
Solve

1. The number of valence electrons in the $CHCl_3$ molecule is

   Element:C + H + 3 Cl

   Valence electrons:4 + 1 + (3 × 7) = 26

2. The carbon atom has the most (four) unpaired electrons in its Lewis symbol and hence has the greatest bonding capacity. Therefore, C is the central atom in the molecule. Each H atom and each Cl atom needs one more electron to achieve the electron configuration of a noble gas, and so each forms one bond to the C atom:

3. In this structure the hydrogen atom has a duet because it shares a bonding pair of electrons with the central carbon atom. Each chlorine atom has a duet, too, but each needs an octet, so add three lone pairs of electrons to each of the three

chlorine atoms: 
4. This structure contains four pairs of bonding electrons and nine lone pairs, for a total of

   $(4 \times 2) + (9 \times 2) = 26$ electrons

   which is the number of electrons determined in step 1.

5. The carbon atom is surrounded by four bonds, which means eight electrons, so it has a full octet. The structure is complete.

Think About It In this example there was no need to change the structure in steps 4 and 5 because all the valence electrons were already included and all the atoms had an octet (or duet in the case of the hydrogen atom).

Practice Exercise Draw the Lewis structure of methane, CH_4.

SAMPLE EXERCISE 8.3 Drawing the Lewis Structure of Ammonia LO2

Draw the Lewis structure of ammonia, NH_3.

Collect, Organize, and Analyze The formula NH_3 indicates that each molecule contains one atom of nitrogen and three atoms of hydrogen. Nitrogen is a group 15 element with five valence electrons, three of which are unpaired, for a bonding capacity of 3. Each hydrogen atom has one valence electron in the 1*s* orbital and a bonding capacity of 1.

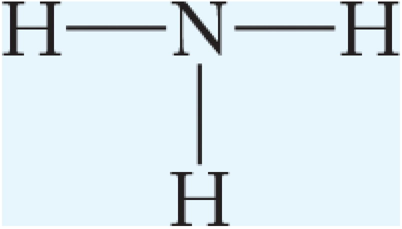
Solve

1. The number of valence electrons in the NH_3 molecule is

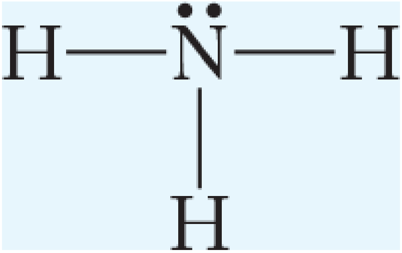
   Element:N + 3 H

   Valence electrons:5 + $(3 \times 1) = 8$

2. The nitrogen atom has the greater bonding capacity and is the central atom. (With a bonding capacity of 1, hydrogen can never be a central atom.) Connecting each H atom to the nitrogen atom with a covalent bond yields



3. Each bonded H atom has a complete duet of electrons.
4. The three bonds in the structure represent $3 \times 2 = 6$ valence electrons, but we need eight to match the number determined in step 1. We add the two remaining valence electrons as a lone pair on nitrogen:



5. The N atom now has an octet of electrons, so the Lewis structure is complete.

Think About It The Lewis symbol of the nitrogen atom contains two electrons that are paired and three that are unpaired. It is reasonable, therefore, that the nitrogen atom in NH_3 has one lone pair and three bonding pairs of electrons.

Practice Exercise Draw the Lewis structure of phosphorus trichloride.

Lewis Structures of Molecules with Double and Triple Bonds

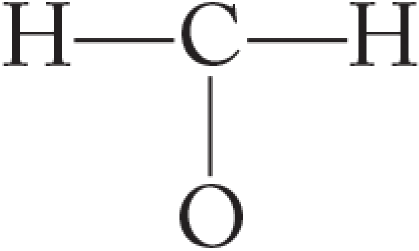
We can use Lewis structures to show the bonding in molecules in which two atoms share more than one pair of bonding electrons. A bond in which two atoms share *two* pairs of electrons is called a double bond. For example, when the two oxygen atoms in a molecule of O_2 share two pairs of electrons, they form an O□O double bond. Similarly, when the two nitrogen atoms in a molecule of N_2 share *three* pairs of electrons, they form a N≡

How do we know when a Lewis structure has a double or triple bond? Typically, we find out when we apply steps 3 through 5 in the guidelines. Suppose we fill the octets of all the atoms attached to the central atom in step 3, and in doing so we use all the valence electrons available. If we discover that the central atom does *not* have an octet, we can provide the needed electrons in step 5 by converting one or more lone pairs of electrons from one of the other atoms into a bonding pair. Drawing the Lewis structure for the organic molecule formaldehyde (H_2CO) illustrates one such application of the guidelines.

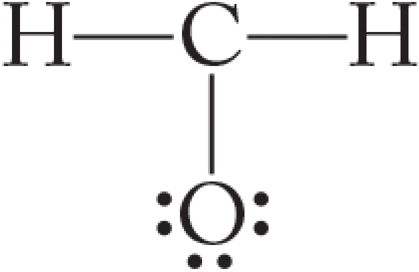
1. The total number of valence electrons is

Element:	C	+	2 H	+	O
Valence electrons:	4	+	(2 × 1)	+	6 = 12

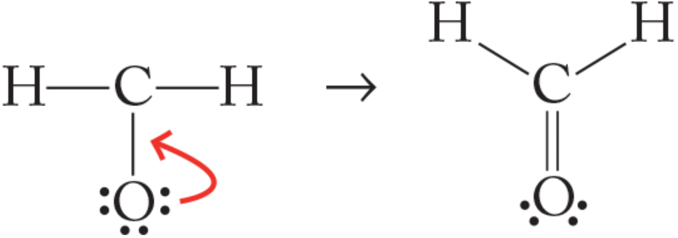
2. Of the three elements, carbon has the greatest bonding capacity (4), so it is the central atom. Connecting it with single bonds to the other three atoms yields:



3. Each H atom has a single covalent bond (2 electrons) completing its valence shell. Oxygen needs three lone pairs of electrons to complete its octet:



4. There are 12 valence electrons in this structure, which matches the number determined in step 1.
5. The central C atom has only 6 electrons. To provide the carbon atom with the 2 additional electrons it needs to have an octet—without removing any electrons from oxygen, which already has an octet—we convert one of the lone pairs on the oxygen atom into a bonding pair between C and O:



CONNECTION We have already seen a few families of organic molecules. We introduced carboxylic acids (RCOOH) and amines

(RNH_2, R_2NH, R_3N) in Chapter 4. We introduced alkanes (compounds of carbon atoms and hydrogen atoms linked by single bonds) in Chapter 2 and explored them further in Chapter 6. Remember that R– stands for any organic group. Table 2.6 lists many of the functional groups in organic compounds.

It does not matter which of the three lone pairs we move because they are equivalent. The central carbon atom now has a complete octet, and the oxygen atom still does. This structure makes sense because the four covalent bonds around carbon—two single bonds and one double bond—match its bonding capacity. Similarly, the double bond to oxygen makes sense because oxygen is a group 16 element with a bonding capacity of 2, and it has two bonds in this structure.

Notice that we have drawn the double bond and the two single bonds on the central carbon atom at an angle of about 120° from each other in the final structure; we have done the same thing with the lone pairs of electrons on oxygen with respect to the double bond. Electrons are negatively charged and repel each other, so we draw them as far apart from each other as possible. This logic is an important part of drawing three-dimensional structures of molecules in Chapter 9.

Formaldehyde is the smallest member of a family of organic compounds known as aldehydes. All aldehydes contain the functional group that consists of a carbon atom with a single bond to a hydrogen atom and a double bond to an oxygen atom (**Figure 8.6**). The $C=O$ group is called a carbonyl group. The fourth bond on the carbon atom connects to another hydrogen atom in formaldehyde, but in all other aldehydes it connects to another carbon-containing group, giving aldehydes a general formula of RCHO. It is not necessary for you to know how to name these compounds, but it is important for you to recognize the aldehyde functional group.

The five-step guidelines for drawing Lewis structures are particularly useful when molecules or polyatomic ions have a central atom bonded to atoms with lower bonding capacity. Many inorganic molecules, polyatomic ions, and small organic molecules (fewer than four carbon atoms) fit this description. To draw some larger Lewis structures, however, we may sometimes need to break the structure into subunits and consider more than one “central” atom, as in hydrogen peroxide:

In these cases, we treat each atom that is bonded to two other atoms as the “central atom” within a three-atom subunit, as shown by the oxygen atoms highlighted in red:

SAMPLE EXERCISE 8.4 Drawing the Lewis Structure of Acetylene LO2

Draw the Lewis structure of acetylene, C_2H_2, the hydrocarbon fuel used in oxyacetylene torches for welding and cutting metal.

Collect, Organize, and Analyze We are asked to draw the Lewis structure of acetylene, which has the molecular formula C_2H_2. We follow the five steps in the guidelines. Each molecule contains two atoms of carbon and two atoms of hydrogen. Carbon is a group 14 element with a bonding capacity of 4.

Solve

1. The total number of valence electrons is

   Element: 2 C + 2 H

   Valence electrons: $(2 \times 4) + (2 \times 1) = 10$

2. Of the two elements, carbon has the greater bonding capacity, so the two carbon atoms are placed in the center of the molecule. Connecting each carbon atom with single bonds to the other atoms, we have:

   H—C—C—H

3. Each H atom has a single covalent bond and a complete valence shell.
4. So far, the current structure has 6 valence electrons, but it should have 10. This means we must add two pairs of

electrons. We could add them as a lone pair on each of the two carbon atoms, or we could add them as a two bonding pairs between the two carbon atoms. The second option has the advantage of completing the octets of both carbon atoms (step 5), so that is the one we should use:

H—C≡

C—H

Think About It This structure makes sense because carbon has a bonding capacity of 4, and there are four covalent bonds around each carbon atom—one single bond and one triple bond—giving both atoms complete octets. Acetylene’s triple bond makes it the smallest member of the *alkyne* family (see Section 2.8).

Practice Exercise Determine the Lewis structure for carbon dioxide.

Lewis Structures of Ionic Compounds

Crystals of sodium chloride are held together by the attraction between oppositely charged Na^+ and Cl^- ions. As described in Chapter 7, atoms of sodium and the other group 1 elements achieve noble gas electron configurations by losing their valence-shell *s* electron, forming 1+ cations, whereas chlorine and the other group 17 nonmetals gain one electron as they form anions with 1− charges, as shown below. Therefore, the ions of group 1 (and group 2) elements have no valence-shell electrons, and their Lewis structures have no dots around them. On the other hand, nonmetals such as chlorine, which acquire electrons to achieve noble gas electron configurations, have filled *s* and *p* orbitals in their valence shells and complete octets:

The brackets indicate that all eight valence electrons are associated with the anion, and the charge of the ion is placed outside the bracket to indicate the overall charge of everything inside.

All alkali metal elements and alkaline earth elements tend to lose rather than share their valence electrons when bonding with nonmetals, in part because these two families of metals have low ionization energies. The cations they form by losing these electrons obey the octet rule because they have the electron configurations of the noble gases that precede the parent elements in the periodic table.

CONNECTION The ionization energy of an element (Section 7. 1 1) is the amount of energy required to remove 1 mole of electrons from 1 mole of atoms in the gas phase.

SAMPLE EXERCISE 8.5 Drawing Lewis Structures of Binary Ionic Compounds LO2

Draw the Lewis structure of calcium oxide.

Collect, Organize, and Analyze The *-ide* ending of calcium oxide tells us that it is a binary compound containing a metallic element and a nonmetal, which means it is an ionic compound. We learned in Chapter 7 that atoms of Ca and the other group 2 elements tend to form 2+ cations by losing their valence shell *s* electrons and that O atoms, like those of other group 16 elements, form monatomic ions by gaining 2 electrons.

Solve Formation of the calcium and oxide ions from their parent atoms leads to these Lewis symbols for the ions:

Combining the Lewis symbols of Ca^{2+} and O^{2-} ions yields this Lewis structure of CaO:

Think About It The lack of dots in the symbol of the Ca^{2+} ion reinforces the fact that atoms of Ca, like all main group metal atoms, lose all the electrons in their valence shells when they form monatomic cations. In contrast, atoms of nonmetals form monatomic anions with complete octets.

Practice Exercise Draw the Lewis structure of magnesium fluoride.

Glossary

octet rule

the tendency of atoms of main group elements to make bonds by gaining, losing, or sharing electrons to achieve a valence shell containing eight electrons (i.e., four electron pairs).

Lewis symbol (also called Lewis dot symbol

) a system in which the chemical symbol for an element is surrounded by one or more dots representing each of its atom’s valence electrons.

Lewis symbol (also called Lewis dot symbol

) a system in which the chemical symbol for an element is surrounded by one or more dots representing each of its atom’s valence electrons.

bonding capacity

the number of covalent bonds an atom forms to have an octet of electrons in its valence shell.

Lewis structure

a two-dimensional representation of the bonds and lone pairs of valence electrons in a molecule or polyatomic ion.

bonding pair

a pair of electrons shared between two atoms.

single bond

a chemical bond that results when two atoms share one pair of electrons.

lone pair

a pair of valence electrons that is not shared.

double bond

a chemical bond in which two atoms share two pairs of electrons.

triple bond

a chemical bond in which two atoms share three pairs of electrons.

aldehyde

an organic compound having a carbonyl group with a single bond to a hydrogen atom and a single bond to another atom or group of atoms, designated as R– in the general formula RCHO.

carbonyl group

a carbon atom with a double bond to an oxygen atom.

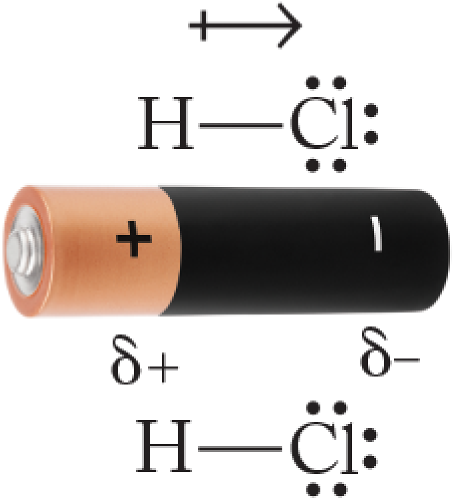

FIGURE 8.7 Just as a battery has positive and negative terminals, a polar bond such as the one in a molecule of HCl has positive and negative ends. The polarity of a bond is indicated by the arrow with a positive tail above the bond or by delta symbols (δ+ and δ−).

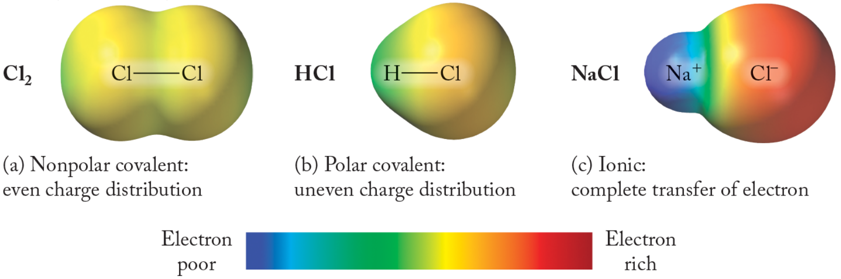

(a) Nonpolar covalent: even charge distribution

(b) Polar covalent: uneven charge distribution

(c) Ionic: complete transfer of electron

FIGURE 8.8 Variations in valence electron distribution are represented using colored surfaces in these molecular models. (a) In the covalent bond in Cl_2, the same color pattern on both ends of the bond means that the two atoms share their bonding pair of electrons equally. (b) Unequal sharing of the bonding pair of electrons in HCl is shown by the orange-red color of the Cl atom and the blue-green color around the H atom. (c) In NaCl, which is ionic, the violet color on the surface of the sodium ion indicates that it has a 1+ charge, whereas the deep red of the chloride ion reflects its 1− charge.

(a) Symmetric stretch (infrared inactive)

(b) Asymmetric stretch (infrared active)

(c) Bending mode (infrared active)

FIGURE 8.13 The arrows in these images show three of the ways in which the bonds in a molecule of CO_2 vibrate: (a) symmetric stretching of the C□O bonds, which produces no overall change in the polarity of the molecule; (b) asymmetric stretching, which produces side-to-side fluctuations in polarity that may result in absorption of infrared radiation; (c) bending, which produces up-and-down fluctuations that also may absorb infrared radiation.

N and O□O bonds in these molecules result in the absorption of infrared radiation? Explain why or why not.

8.3 Polar Covalent Bonds

When Lewis proposed that atoms form chemical bonds by sharing electrons, he knew that electron sharing in covalent bonds did not necessarily mean *equal* sharing. For example, Lewis knew that molecules of HCl ionized to form H^+ ions and Cl^- ions when HCl dissolves in water. To explain this phenomenon, Lewis proposed that the bonding pair of electrons in a molecule of HCl is closer to the chlorine end of the bond than to the hydrogen end. This unequal sharing makes the H—Cl bond a polar covalent bond. As a result, when the H—Cl bond breaks, the one shared pair of electrons remains with the Cl atom to form a Cl^- ion, simultaneously changing the H atom into an H^+ ion with no electrons.

This bond polarity in HCl means that the bond functions as a tiny electric *dipole*—that is, there is a slightly positive pole at the H end of the bond and a slightly negative pole at the Cl end, analogous to the positive and negative ends of a battery (**Figure 8.7**). Figure 8.7 also shows two representations we use to depict unequal sharing of bonding pairs of electrons. The arrow with a plus sign embedded in its tail (\) indicates the *direction of polarity*: the arrow points toward the more negative, electron-rich atom in the bond, and the position of the plus sign indicates the more positive, electron-poor atom. The other way to represent unequal sharing makes use of the lowercase Greek delta (δ) followed by a + or − sign. The deltas represent *partial* electrical charges, as opposed to the full electrical charges that accompany the complete transfer of one or more electrons when atoms become ions.

Figure 8.8 shows examples of the equal and unequal sharing of bonding pairs of electrons. In part (a), the two Cl atoms of Cl_2 share a pair of electrons equally in a nonpolar covalent bond; in part (b), HCl has a polar covalent bond; and in part (c), the ionic bond in NaCl results from electron transfer. In these images, the degree of charge separation is represented using color: yellow-green represents no charge separation (nonpolar covalent bonding), whereas colors near the violet end of the visible spectrum represent low electron density and those toward the red end represent high electron densities.

The American chemist Linus Pauling (1901–1994) developed the concept of electronegativity to explain bond polarity. Pauling assigned electronegativity values to the elements (**Figure 8.9**) based on the idea that the bonds between atoms of different elements are neither 100% covalent nor 100% ionic, but somewhere in between. The degree of ionic character of a bond depends on the differences in the abilities of the two atoms to attract the electrons they share: the greater the difference, the more ionic is the bond between them.

Electronegativity is a periodic property, with values generally increasing from left to right across a row in the periodic table and decreasing from top to bottom down a group. The reasons for these trends are essentially the same ones that produce similar trends in first ionization energies (see Figure 7.39). Increasing attraction between the nuclei of atoms and their outer-shell electrons as the atomic number increases across a row produces both higher ionization energies and greater electronegativities (**Figure 8.10a**). Within a group of elements, the weaker attraction between nuclei and outer-shell electrons with increasing atomic number leads to lower ionization energies and smaller electronegativities (**Figure 8.10b**). For these two reasons, the most electronegative elements—fluorine, oxygen, and nitrogen—are in the upper right corner of the periodic table, whereas the least electronegative elements—francium, cesium, and rubidium—are in the lower left corner. Other electronegativity scales have been developed with slightly different values from those proposed by Pauling; regardless of the scale you use, though, the trends in electronegativity remain the same as those shown in Figure 8.10.

Having defined electronegativity, let's elaborate on step 2 of the guidelines for drawing Lewis structures: *The central atom in a Lewis structure is often the atom with the lowest electronegativity.*

CONCEPT TEST

Draw arrows on the Lewis structure of CO_2 to indicate the polarity of the bonds.

(Answers to Concept Tests are in the back of the book.)

Polarity and Type of Bond

Comparing electronegativity values allows us to determine which end of a bond is relatively electron-rich and which end is relatively electron-poor. The greater the difference in electronegativity (ΔEN), the more uneven the distribution of electrons and the more polar the covalent bond. **Figure 8.11** shows this trend for compounds formed between hydrogen and the halogens. For example, a H—F bond is more polar than a H—Cl bond because the ΔEN between H (2.1) and F (4.0) is 1.9, whereas the ΔEN between H (2.1) and Cl (3.0) is 0.9.

Figure 8.12 provides an approximate scale for judging the degree of polarity in a chemical bond based on electronegativity differences. We saw in Figure 8.8a that a Cl—Cl bond is nonpolar covalent because the same atom on both ends of the bond means that ΔEN = 0. On the other end of the scale, electronegativity differences greater than about 2.0 are associated with the ionic compounds formed between metals and nonmetals. For example, calcium oxide is an ionic compound, and ΔEN = 2.5 for Ca (1.0) and O (3.5). Polar covalent bonds fall between nonpolar covalent and ionic bonds.

The scale in Figure 8.12 should be used judiciously because the correlation between ΔEN and bond character is far from perfect. Consider, for example, the bonds in LiCl and HF. The ΔEN values for both pairs of elements is 1.9, but the physical properties of LiCl (it is a crystalline solid that melts at 605°C) is typical of an ionic compound, whereas HF is a gas at room temperature as are nearly all molecular compounds with its small (20 g/mol) molar mass.

The presence of a double or triple bond, such as the carbon–oxygen double bond in the carbonyl group (C=O), does *not* change our assessment of the overall polarity of the bond. Oxygen is more electronegative than carbon, so the carbonyl group is polar, with the carbon atom bearing a partial positive charge and the oxygen a partial negative charge, as shown here in formaldehyde:

SAMPLE EXERCISE 8.6 Comparing the Polarity of Bonds LO3

Rank, in order of increasing polarity, the bonds formed between: O and C, Cl and Ca, N and S, and O and Si. Are any of these bonds ionic?

Collect and Organize We are given four pairs of atoms and asked to rank them according to the polarity of the bond each pair forms and to identify any ionic bonds in the set.

Analyze The polarity of a bond is related to the difference in electronegativities of the atoms in the bond. If the electronegativity difference is 2.0 or greater, the bond is considered ionic. We need to refer to the Pauling electronegativities (Figure 8.9) to judge the relative polarity.

Solve Calculate the electronegativity difference between the atoms:

These electronegativity differences are proportional to the polarity of the bonds formed between the pairs of atoms. Therefore, ranking them in order of increasing polarity we have:

N—S $<$ O—C $<$ O—Si $<$ Cl—Ca

The bond between Cl and Ca is considered ionic because $\Delta\text{EN} = 2.0$.

Think About It Calcium is a metal and chlorine is a nonmetal, so the result indicating that the bond between them is ionic is reasonable. Ionic bonds tend to be formed between metals and nonmetals. Two of the other bonds, N—S and O—C, connect pairs of nonmetals, and the O—Si bond connects a nonmetal with a metalloid. We expect these three bonds to be covalent.

Practice Exercise Which of the following pairs forms the most polar bond: O and S; Be and Cl; N and H; C and Br? Which, if any, of the pairs would form ionic bonds?

Vibrating Bonds and Greenhouse Gases

Vibrational Modes

Chemical bonds are not rigid (see the discussion of thermal energy in Chapter 6). They vibrate a little, stretching and bending like tiny atomic-sized springs (**Figure 8.13**). These vibrations have natural frequencies, which match the frequencies of infrared electromagnetic radiation. This match, coupled with the unequal sharing of bonding electrons, allows some atmospheric molecules containing polar covalent bonds—such as CO_2—to absorb infrared radiation emitted by Earth’s surface. As a result, heat that might have dissipated into space is trapped in the atmosphere by these molecules, contributing to the atmospheric greenhouse effect (see Section 8.1). Understanding the energetics of bond vibrations goes beyond the scope of this book, but the basic ideas presented here provide a useful picture of the interaction between bond vibrations and infrared radiation.

Greenhouse Effect

Molecules with polar bonds may absorb photons, much like electrons in atoms absorb radiation and form excited states (see Section 7.4). The radiation absorbed by polar covalent bonds that result in vibrations is typically in the infrared region of the electromagnetic spectrum (see Figure 7.7). These vibrations result in tiny fluctuating electrical fields associated with the separation of partial charges in the polar covalent bonds in the molecule. These fluctuations can alter the strengths of the fields or even create new ones, depending on the nature of the vibration. When the frequencies of the polar covalent bond vibrations match the frequencies of photons of infrared radiation, the molecules may absorb those photons. Scientists say these vibrations are *infrared active*. This is the molecular mechanism behind the greenhouse effect. The presence of fluctuating electrical fields in molecules is further evidence that covalent bonds involve shared electrons.

Not all polar bond vibrations result in absorption of infrared radiation. For example, two kinds of stretching vibrations can occur in a molecule of CO_2, which has two C=O bonds. One is a *symmetric* stretching vibration (Figure 8.13a) in which the two C=O bonds stretch and then compress at the same time. In this case the two fluctuating electrical fields produced by the two C=O bonds cancel each other out, and no infrared absorption or emission is possible. This vibration is said to be *infrared inactive*. However, when the bonds stretch such that one gets shorter as the other gets longer (Figure 8.13b), the changes in charge separation do *not* cancel. This *asymmetric* stretch produces a fluctuating electrical field that enables CO_2 to absorb infrared radiation, so this vibration is infrared active. Molecules can also bend (Figure 8.13c) producing fluctuating electrical fields. Because the frequencies of the asymmetric stretching and bending of the bonds in CO_2 are in the same range as the frequencies of infrared radiation emitted from Earth’s surface, carbon dioxide is a potent greenhouse gas.

CONCEPT TEST

Nitrogen and oxygen make up about 99% of the gases in the atmosphere. Could the stretching of the N≡

Glossary

polar covalent bond

a bond characterized by unequal sharing of bonding pairs of electrons between atoms.

bond polarity

a measure of the extent to which bonding electrons are unequally shared.

electronegativity

a relative measure of the ability of an atom to attract electrons in a bond to itself.

ionic character

an estimate of the magnitude of charge separation in a covalent bond.

Learning Objectives

- Predict the polarity of covalent bonds based on differences in electronegativity between the bonded atoms **Return to Sample Exercise 8.6**

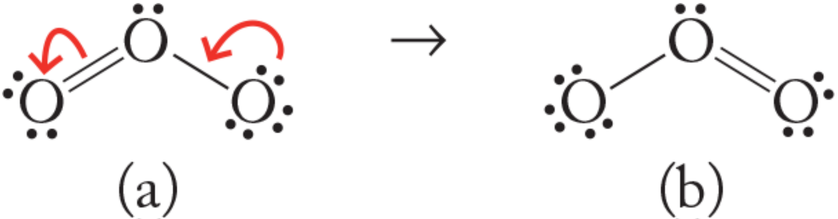
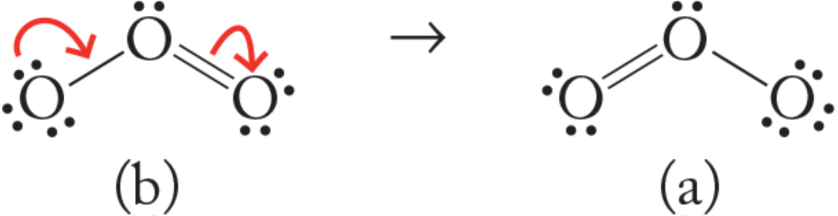
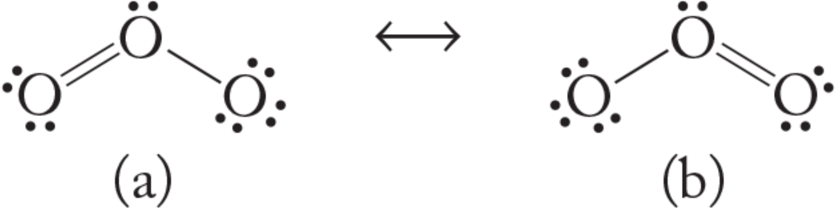
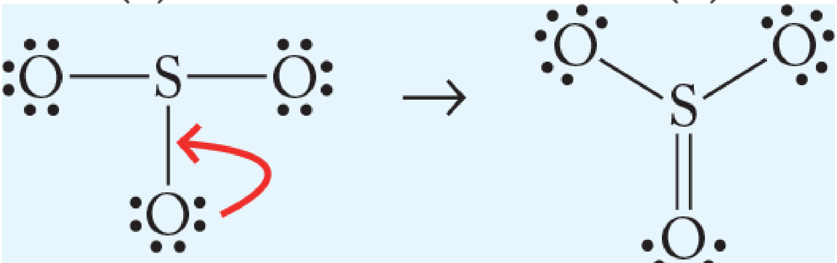
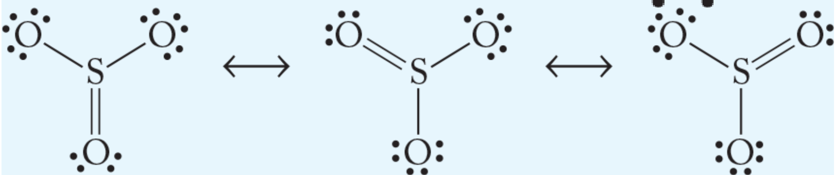
FIGURE 8.15 The molecular structure of ozone is an average of the two resonance structures shown at the top of the figure. Both bonds in ozone are 128 pm long, a value between the average length of an O□O single bond (148 pm) and the average length of an O□O double bond (121 pm). The intermediate value for the ozone bond length indicates that in an ozone molecule, the bonds are neither single bonds nor double bonds, but something in between.

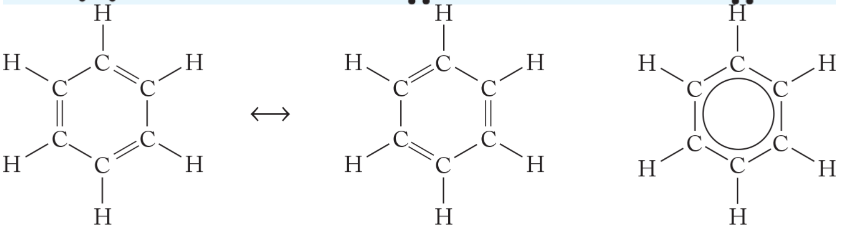












(a) (b)

FIGURE 8.16 (a) The molecular structure of benzene is an average of two equivalent resonance structures. (b) The average is frequently represented by a circle inside the hexagonal ring of single bonds, indicating completely uniform delocalization of the electrons in the bonds around the ring.

8.4 Resonance

The atmosphere contains two types of molecular oxygen. Most of it is O_2, but trace concentrations of ozone (O_3) are also present. Ozone in the lower atmosphere can damage crops, harm trees, and lead to human health problems. Ozone present in the upper atmosphere, on the other hand, shields life on Earth from potentially harmful ultraviolet radiation from the Sun.

Ozone is a *triatomic* (three-atom) molecule produced naturally when lightning (**Figure 8.14**) strikes O_2 molecules in the atmosphere. Ozone accounts for the pungent odor you may have smelled after a severe thunderstorm. Ozone (O_3) and diatomic oxygen (O_2) have the same empirical formula: O. Different molecular forms of the same element, such as O_2 and O_3, are called allotropes of the element and have different chemical and physical properties. Ozone, for example, is an acrid, pale blue gas that is toxic even at low concentrations, whereas O_2 is a colorless, odorless gas that is essential for most life-forms.

The different molecular formulas of allotropes mean that they have different molecular structures. Let's draw the Lewis structure for ozone (O_3) using our five-step approach. Oxygen is a group 16 element, so it has 6 valence electrons. The total number of valence electrons in an ozone molecule, then, is $3 \times 6 = 18$ (step 1). Connecting the three O atoms with single bonds (step 2), we have

O—O—O

Completing the octets of the two outer atoms (step 3) gives

This structure contains 16 electrons. We determined in step 1 that there are 18 valence electrons in the molecule, so we add a lone pair to the central oxygen atom (step 4):

This structure leaves the central atom two electrons short of an octet, so we convert one of the lone pairs on one of the outer O atoms (e.g., the one on the left end of the molecule) into a bonding pair (step 5):

We could just as well have used a lone pair from the O atom on the right, which would have given us

Which structure is correct? Interestingly, experimental evidence indicates that *neither* structure is accurate. Scientists have determined that both bonds in ozone have the same length. Because a double bond between two atoms is always shorter than a single bond between the same two atoms (see Section 8.7), the structure of ozone cannot consist of one single bond and one double bond. **Figure 8.15** shows that the length of the two bonds in O_3 (128 pm) is in between the length of an O—O single bond (148 pm) and an O=O double bond (121 pm). One way to explain this result is to assume that the bonding pattern of O_3 is an average of the two structures drawn previously:

In other words, each pair of oxygen atoms is held together by the equivalent of 1.5 bonds. However, this average does *not* mean that the molecule spends half its time as the left-hand structure in Figure 8.15 and half as the right-hand structure. It always has three bonding pairs spread out evenly on the two sides of the central atom.

To better understand this bonding pattern, consider what happens when the bonding electrons and the lone pair electrons in structure (a) below are rearranged as shown by the red arrows:

This rearrangement produces structure (b). The process is completely reversible, so that the electron pairs in structure (b) could just as easily be rearranged into the pattern in structure (a):

The two structures are equivalent. We use a double-headed reaction arrow between the structures to indicate that they are equivalent and that the actual structure is a blend of the two:

The ability to draw two equivalent Lewis structures for the ozone molecule illustrates an important concept in Lewis's theory called resonance: the existence of multiple Lewis structures, called resonance structures (or *resonance hybrids*), for a given bonding arrangement of atoms. To determine whether resonance occurs in a molecule, we need to determine whether there can be alternative bond arrangements inside the molecule—that is, arrangements in which the positions of some electron pairs change but the positions of the atoms stay the same. One indicator of the possibility of resonance is the presence of both single and double bonds from a central atom to two or more atoms of the same element, as we just saw in ozone.

Because all resonance structures are Lewis structures by definition, the five-step guidelines still apply to drawing resonance structures. Because all the atoms in ozone are oxygen, an oxygen atom must be the central atom. Two additional issues, however, must be raised at this point, both of which relate to the concept of bonding capacity. First, oxygen atoms *typically* form two bonds, but Lewis theory allows both more and fewer bonds than are implied by the Lewis symbol of an atom. Remember that the resonance structures for ozone suggest that the oxygen atoms are held together by the equivalent of 1.5 bonds. Second, in previous examples we have used differences in typical bonding capacity as a criterion to select a central atom. As we deal with more molecules, the situation frequently arises that several atoms in one molecule may have the same bonding capacity. In that case, the selection of the central atom is based on electronegativity, with the least electronegative atom chosen as the central atom in the Lewis structure. Sample Exercise 8.7 explores the Lewis structure of just such a compound.

SAMPLE EXERCISE 8.7 Drawing Resonance Structures of a Molecule LO5

Sulfur trioxide (SO_3) is a pollutant produced in the atmosphere when the SO_2 from natural and industrial sources combines with O_2. Draw all the possible resonance structures of SO_3, assuming sulfur obeys the octet rule.

Collect and Organize Each SO_3 molecule contains one atom of sulfur and three atoms of oxygen. We need to draw all resonance structures, which means at least two different Lewis structures with the same atom placement but different bonding patterns.

Analyze Both sulfur and oxygen are in group 16, so each contributes 6 valence electrons, and each has a typical bonding capacity of 2. The electronegativity of sulfur (2.5) is less than that of oxygen (3.5).

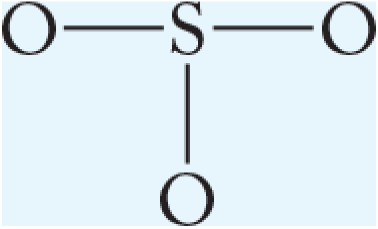
Solve

1. The number of valence electrons in the SO_3 molecule is

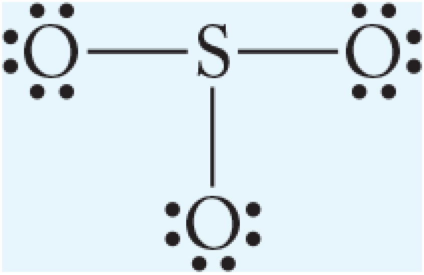
   Element:S + 3 O

   Valence electrons:6 + $(3 \times 6) = 24$

2. Because sulfur is less electronegative, we select it as the central atom. Connecting it with single bonds to the three O atoms:



3. Each O atom gets three lone pairs of electrons to complete its octet:



4. There are 24 valence electrons in the structure in step 3, which matches the number determined in step 1.
5. The central S atom has only 6 electrons in the structure of step 3. To complete its octet, we convert a lone pair on one of the oxygen atoms into a bonding pair:

The sulfur atom now has a complete octet, and the Lewis structure is complete.

Because the three oxygen atoms are equivalent in the structure in step 3, we cannot arbitrarily choose one of them and ignore the others in forming a double bond. Therefore, three resonance structures describe the bonding in SO_3:

Think About It It makes sense that SO_3 has three resonance structures because three equivalent O atoms are bonded to the central S atom, and any one of the O atoms could be the one with the double bond.

Practice Exercise Draw all possible resonance structures for sulfur dioxide.

We can also draw resonance structures for polyatomic ions. In doing so, we need to account for the charge on each ion, which means adding the appropriate number of valence electrons to a polyatomic anion and subtracting the appropriate number from a polyatomic cation.

SAMPLE EXERCISE 8.8 Drawing Resonance Structures of a Polyatomic Ion LO5

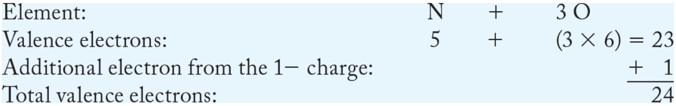
Draw all the resonance structures for the nitrate ion (NO_3^-).

Collect and Organize We are asked to draw the resonance structures for the NO_3^- ion, which contains one nitrogen atom and three oxygen atoms. The charge of the ion is 1−.

Analyze Nitrogen is a group 15 element, so it has 5 valence electrons per atom and a bonding capacity of 3. Oxygen is in group 16, so it has 6 valence electrons and a bonding capacity of 2. The 1− charge means the polyatomic ion has one additional valence electron.

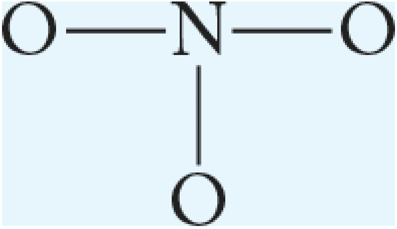
Solve

1. The number of valence electrons is

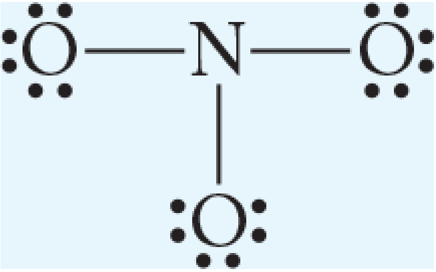


Element:	N	+	3 O
Valence electrons:	5	+	$(3 \times 6) = 23$
Additional electron from the 1− charge:			+ 1
Total valence electrons:			24

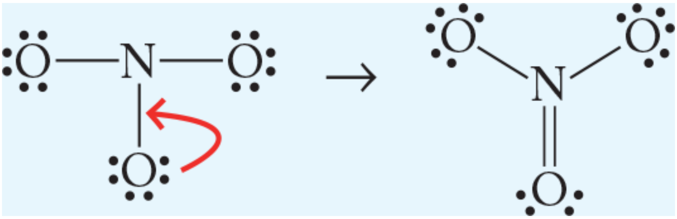
2. The nitrogen atom has the higher bonding capacity and the lower electronegativity, so N is the central atom in a NO_3^- ion. Connecting N with single bonds to the three O atoms gives:



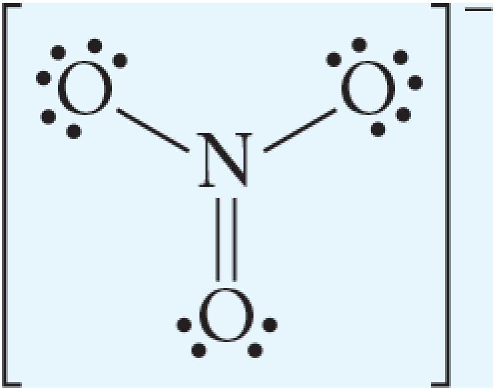
3. Each O atom needs three lone pairs of electrons to complete its octet:



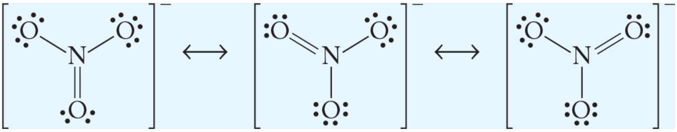
4. There are 24 valence electrons in this structure, which matches the number determined in step 1.
5. The central N atom has only 6 electrons. To provide it with 2 more to complete its octet, we convert a lone pair on one of the oxygen atoms into a bonding pair:



The nitrogen atom now has a complete octet. Adding brackets and the ionic charge, we have a complete Lewis structure:



Using the O atom to the left or right of the central N atom to form the double bond, instead of the O atom below N, creates two additional resonance structures (i.e., three in all):



Think About It It makes sense that the NO_3^- ion has three resonance structures because three equivalent O atoms are bonded to the central N atom, and any one of the O atoms could be the one with the double bond. The additional electron from the negative charge on the ion means that NO_3^- has the same number of valence electrons as SO_3 (Sample Exercise 8.7), which also has the same number of resonance structures. Nitrogen in neutral molecules typically has a bonding capacity of 3, but in these resonance structures it forms four bonds.

Practice Exercise Draw all the resonance forms of the azide ion (N_3^-) and the nitronium ion (NO_2^+).

Resonance also occurs in larger organic molecules that have alternating single and double bonds. Molecules of benzene (C_6H_6), for example, contain six-membered rings of carbon atoms with alternating single and double carbon–carbon bonds (**Figure 8.16a**). When we fix the atoms in a molecule of benzene in place, we have two equivalent ways to draw the single and double bonds. To depict their equivalency, chemists frequently draw benzene molecules with circles in the centers (**Figure 8.16b**). This symbol emphasizes that the six carbon–carbon bonds in the ring are all identical and intermediate in character between single and double bonds. (Experimental evidence confirms that all six carbon–carbon bonds in benzene are equivalent.)

Because of the carbon–carbon double bonds in the structure, you might think that benzene would be in the family of alkenes. It turns out, however, that the double bonds in benzene (and other molecules where resonance influences the character of the bonds) react differently than the double bonds in alkenes. As a result, benzene and compounds with similar molecular structures are classified separately as *aromatic compounds*. We explore aromatic compounds in Chapter 9, where we develop models of bonding that enable us to envision the differences between alkenes like ethylene and aromatic compounds like benzene.

Glossary

allotropes

different molecular forms of an element.

resonance

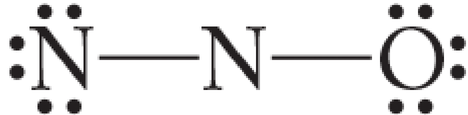
a characteristic of electron distributions when two or more equivalent Lewis structures can be drawn for one compound.

resonance structure

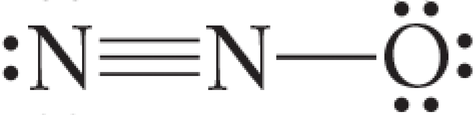
one of two or more Lewis structures with the same arrangement of atoms but different arrangements of bonding pairs of electrons.

Learning Objectives

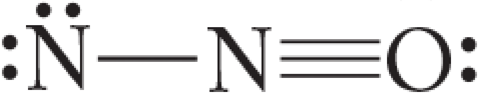
- Draw resonance structures and evaluate their contribution to the bonding in molecules and polyatomic ions using formal charges **Return to Sample Exercises 8.7, 8.8, 8.9, 8.10, 8.11, 8.12**
- Draw resonance structures and evaluate their contribution to the bonding in molecules and polyatomic ions using formal charges **Return to Sample Exercises 8.7, 8.8, 8.9, 8.10, 8.11, 8.12**

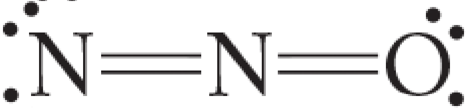


N triple bond:



O triple bond:





$$FC = \begin{pmatrix}\text{number of}\\ \text{valence e}^-\end{pmatrix} - \left[\begin{matrix}\text{number of}\\ \text{nonbonding e}^-\end{matrix} + \frac{1}{2}\begin{pmatrix}\text{number of e}^-\\ \text{in bonding pairs}\end{pmatrix}\right] \quad (8.1)$$

$$FC = 5 - \left[2 + \tfrac{1}{2}(6)\right] = 0$$

N—O structure contributes the most to the bonding in N_2O, the middle structure (N□N□O) also contributes to the bonding. We know this because the length of the bond between the two nitrogen atoms is between the length of a N□N bond and the length of a N≡N bond, and the nitrogen–oxygen bond is a little shorter than a typical N—O single bond.

8.5 Formal Charge: Choosing among Lewis Structures

Now that we have explored the structure of ozone, let's turn our attention to the structure of dinitrogen monoxide (N_2O), another atmospheric pollutant also known as nitrous oxide or, more commonly, laughing gas. It is so named because people who inhale high concentrations of N_2O usually laugh spontaneously. Gaseous nitrous oxide has long been used as an anesthetic in dentistry because it has a narcotic effect.

In the lower atmosphere, nitrous oxide concentrations range between 0.1 and 1.0 ppm. It is produced naturally by bacterial action in soil and through human activities such as agriculture and sewage treatment. It is occasionally in the news because its concentration in the troposphere (the atmosphere at ground level) has been increasing. Along with CO_2 and other gases, N_2O may be contributing to global warming.

To draw the Lewis structure of nitrous oxide, first count the number of valence electrons: 5 each from the two nitrogen atoms and 6 from the oxygen atom for a total of $(2 \times 5) + 6 = 16$. The central atom is a nitrogen atom because N has a higher bonding capacity and is less electronegative than O. Connecting the atoms with single bonds, we have

N—N—O

Completing the octets of the outer atoms gives a structure with 16 valence electrons, which is the number determined in step 1:

However, there are only two bonds and thus only 4 valence electrons on the central N atom. To give it 4 more electrons, we need to convert lone pairs on the surrounding atoms to bonding pairs. Which lone pairs do we choose? We could use two lone pairs from the N atom on the left to form a N≡

Alternatively, we could use two lone pairs on the O atom to make a N≡

Or we could use one pair from each terminal atom to make two double bonds:

Which of these resonance structures is best? We have seen that in some sets of resonance structures, such as those of O_3, SO_3, and NO_3^-, all the structures are equivalent, so no one of them is any more important than another in conveying the actual bonding in the molecule. This is not the case, however, with the resonance forms of N_2O. To decide which resonance form in a nonequivalent set is the most important and comes closest to representing the actual bonding pattern in a molecule, we use the concept of formal charge.

A formal charge (FC) is not a real charge but rather a measure of the number of electrons *formally assigned* to an atom in a molecular structure, compared with the number of electrons in the free (i.e., nonbonded) atom. To determine a formal charge, we follow a series of steps to calculate the number of electrons formally assigned to each atom in each resonance structure.

Calculating Formal Charge of an Atom in a Resonance Structure

For each atom:

1. Determine the number of valence electrons in the free atom.
2. Count the number of nonbonding electrons on the atom in the structure.
3. Count the number of electrons in bonds on the atom and divide that number by 2.
4. Sum the results of steps 2 and 3 and subtract that sum from the number determined in step 1.

Summarizing these steps in the form of an equation, we have

Once we have determined the formal charges, we then use the following three criteria to select the preferred structure:

1. The preferred structure is the one with formal charges of zero.
2. If no such structure can be drawn, or if the structure is that of a polyatomic ion, then the best structure is the one in which most atoms have formal charges equal to zero or closest to zero.
3. Any negative formal charges should be on the atom(s) of the most electronegative element(s).

The calculation of formal charge incorporates the assumption that each atom is formally assigned all its nonbonding electrons and shares its bonding electrons equally with the atoms at the other ends of the bonds. We can confirm that the three resonance forms of N_2O are not equivalent by calculating the formal charges in each structure.

In **Table 8.2** we have colored the lone pairs of electrons red and the shared pairs green to make it easier to track the quantities of these electrons in the formal charge calculation for N_2O. The numbers of valence electrons in the free atoms are shown in blue.

To illustrate one of the formal charge calculations in the table, consider the N atom at the left end of the left resonance structure. The Lewis dot symbol of nitrogen reminds us that free nitrogen atoms have 5 valence electrons. In this structure, the N atom has 2 electrons in a lone pair and 6 electrons in three shared (bonding) pairs. Using Equation 8.1 to calculate the formal charge on this N atom,

which is the first value in the bottom row of the table. The results of similar formal charge calculations for all the other atoms in the three resonance structures complete the row. The sum of the formal charges on the three atoms in each structure is zero, as it should be for a neutral molecule. When we analyze the formal charges of atoms in a polyatomic ion, the formal charges on its atoms must add up to the charge on the ion.

Now we must apply the three criteria for selecting the preferred resonance structure of N_2O. The first thing to note about these sets of formal charges is that in none of them are all three formal charges zero, meaning that criterion 1 is not met. The next step is to identify which structure has the most formal charge values that are the closest to zero, such as -1 or $+1$. On this count we have a tie between the structure on the left $(0,\ +1,\ -1)$ and the one in the middle $(-1,\ +1,\ 0)$.

TABLE 8.2 Formal Charge Calculations for the Resonance Structures of N_2O

Step			5 5 6 Number of valence electrons			
4 0 4 Number of electrons in lone pairs			
4 8 4 Number of shared electrons			
0 −2 +1 +1 −1 0 +1			

To break the tie, we invoke the third criterion and answer the question, “In which structure is the negative formal charge on the more electronegative atom?” The answer is the structure on the left, which has an oxygen atom with a formal charge of −1. This structure, then, is the best of the three in representing the actual bonding in a molecule of N_2O.

From experimental measurements, we know that although the N ≡

CONCEPT TEST

What is the formal charge on a sulfur atom that has three lone pairs of electrons and one bonding pair?

SAMPLE EXERCISE 8.9 Selecting Resonance Structures on the Basis of Formal Charges LO5

Which of the following resonance forms best describes the actual bonding in a molecule of CO_2?

Collect, Organize, and Analyze The preferred structure is the one in which the formal charges are closest to zero and any negative formal charges are on the more electronegative atom. In this case, oxygen is a group 16 element, so it is more electronegative than carbon, a group 14 element. Each free carbon atom has 4 valence electrons, and free oxygen atoms have 6 valence electrons each.

Solve We use Equation 8.1 to find the formal charge on each atom, and we can illustrate the results in a table:

Formal Charge Calculations for the Resonance Structures of CO_2

Step			1 Number of valence electrons 6 4 6			
2 Number of electrons in lone pairs 4 0 4			
3 Number of shared electrons 4 8 4			
4 $FC = [\text{valence } e^- - (\text{lone pair } e^- + \frac{1}{2} \text{ shared } e^-)]$ 0 −1 0 0 0 +1			

The formal charges are zero on all the atoms in the middle resonance structure with the two double bonds. Therefore, this structure best represents the actual bonding in a molecule of CO_2.

Think About It All three resonance structures are valid in that the atoms are in the same positions and the sum of the formal charges is zero, as they must be for a neutral molecule. The center structure best represents the actual bonding in CO_2 because its atoms all have formal charges of zero.

Practice Exercise Which resonance structure of the nitronium ion ($NO_2{}^+$) contributes the most to the actual bonding in this ion?

Using the resonance structures for N_2O once again, let's examine the link between the formal charge on an atom in a resonance structure and the bonding capacity of that atom. The Lewis symbol of nitrogen, which has three unpaired electrons, indicates that a nitrogen atom can complete its octet by forming three bonds. The two unpaired electrons in the Lewis symbol of oxygen indicate that the bonding capacity of an oxygen atom is 2. In the N_2O resonance structures in Table 8.2, the nitrogen atom with three bonds has a formal charge of zero (the left N in the first structure), and the oxygen atom with two bonds has a formal charge of zero (the O in the middle structure). As a rule—and assuming the octet rule is obeyed—atoms have formal charges of zero in resonance structures in which the numbers of bonds they form match their bonding capacities. If an atom forms one more bond than its bonding capacity, such as an oxygen atom with three bonds (O in the third structure in the table), the formal charge is $+1$. If the atom forms one fewer bond than the bonding capacity, such as an oxygen atom with one bond (O in the first structure in the table), the formal charge is -1.

Glossary

formal charge (FC)	a value calculated for an atom in a molecule or polyatomic ion by determining the difference between the number of valence electrons in the free atom and the sum of lone-pair electrons plus half of the electrons in the atom's bonding pairs.

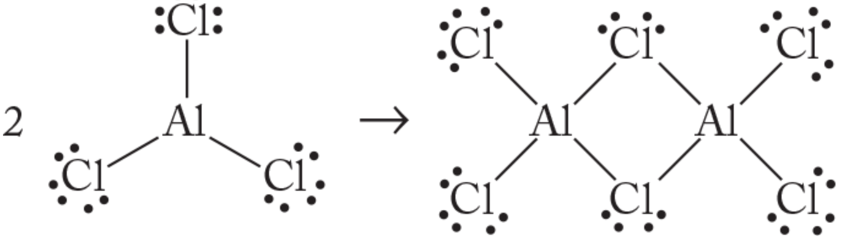

FIGURE 8.19 Aluminum chloride has a complete octet on aluminum by sharing a pair of electrons with one Cl atom from a second molecule of $AlCl_3$.

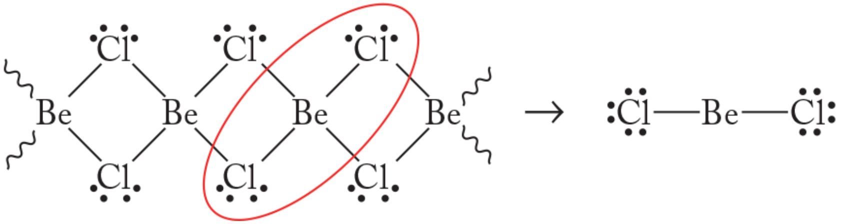

FIGURE 8.20 The chain structure of solid beryllium chloride, with bridging chlorine atoms, changes to discrete $BeCl_2$ molecules in the gas phase. Each beryllium atom in the solid has a completed octet. In the gas phase, each Be atom is surrounded by only four electrons.

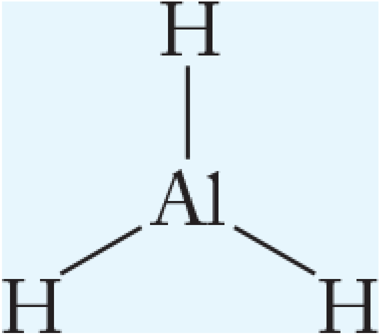


8.6 Exceptions to the Octet Rule

Nitric oxide (NO) is a simple and small molecule, and yet one with important roles in biology and medicine. It is crucial as a regulator of blood flow and is also a principal mediator of neurological signals for many physical and pathological processes. It is a known bioproduct in organisms ranging from bacteria to plants and higher animals, including humans. Pharmaceuticals such as nitroglycerine, used to relieve angina (chest pain caused by impaired blood flow to the heart), and Viagra, used to treat erectile dysfunction, act by producing NO *in vivo* to improve blood flow. Earth's atmosphere also contains trace concentrations of NO along with NO_2, both of which are generated in the environment by human activities such as welding (**Figure 8.17**) and driving gasoline-burning vehicles; these molecules contribute to photochemical smog formation in urban areas. NO and NO_2 illustrate the limitations of the octet rule. Each has an odd number of valence electrons per molecule, which means that at least one atom in each molecule cannot have a complete octet.

Odd-Electron Molecules

NO is produced in the environment when high temperatures in vehicle engines or other sources lead to the reaction

The nitric oxide then reacts with atmospheric oxygen to produce nitrogen dioxide:

Nitric oxide is highly reactive in living systems as well as in the atmosphere because it is an odd-electron molecule. To understand the implications of this, let's draw its Lewis structure. Nitric oxide has 11 valence electrons (5 from nitrogen and 6 from oxygen). There is no central atom, so we start with a single bond between N and O and then complete the octet around O, which is the more electronegative element:

We then place the remaining 3 electrons around the N atom:

This leaves the N atom short 3 valence electrons. We can increase the number of electrons around N from 5 to 7 by converting a lone pair on the O atom into a bonding pair:

This change has the added advantage of creating a double-bonded O atom, which gives it a formal charge of zero. The formal charge on the N atom is also zero. The only problem with the structure is that N does not have an octet: it has only 7 electrons. Because nitrogen is less electronegative than oxygen, it is reasonable that we "short-change" it when there are insufficient electrons to complete the octets of both atoms. The existence of NO is evidence that there are exceptions to the octet rule. When that happens, the most representative Lewis structures are those that come *as close as possible* to producing zero formal charges and complete octets.

Compounds that have odd numbers of valence electrons are called free radicals. They are typically very reactive species because it is often energetically favorable for them to acquire an electron from another molecule or ion. This characteristic makes them excellent oxidizing agents and is responsible for the damage they may cause to materials or living tissue with which they come in contact.

SAMPLE EXERCISE 8.10 Drawing Lewis Structures of Odd-Electron Molecules LO5

Draw the resonance structures of nitrogen dioxide (NO_2), assign formal charges to the atoms, and suggest which structure may best represent the actual bonding in the molecule.

Collect, Organize, and Analyze Each molecule contains one atom of nitrogen (bonding capacity 3) and two atoms of oxygen (bonding capacity 2). Nitrogen dioxide is an odd-electron molecule, so we anticipate that one of the atoms will have an incomplete octet. We analyze the resonance structures by assigning formal charges to select the one most representative of the actual bonding in the molecule.

Solve The number of valence electrons is

Element:N + 2 O

Valence electrons:5 + $(2 \times 6) = 17$

Nitrogen is less electronegative than oxygen and has the greater bonding capacity, so it is the central atom:

O—N—O

Completing the octets on the O atoms gives

There are 16 valence electrons in this structure, but we need 17 to match the number available in the molecule. We add 1 more electron to the N atom:

There are only 5 valence electrons around the N atom—3 fewer than the 8 we need. We can increase the number from 5 to 7 by converting a lone pair on one of the O atoms to a bonding pair, giving the formal charges shown in red:

An equivalent resonance form can be drawn with the double bond on the right side:

These structures are equivalent: each has a charge of $1+$ on the nitrogen atom, one oxygen atom with a $1-$ charge, and one oxygen atom with a charge of 0 (zero).

Think About It The two Lewis structures are equivalent because the two O atoms in each structure are equivalent. The structures do not satisfy the octet rule, but the formal charges of the atoms are close to zero, and the negative formal charge is on the atom of the more electronegative element. Both O atoms have complete octets, leaving the less electronegative N atom one electron short in this odd-electron molecule.

Practice Exercise Nitrogen trioxide (NO_3) may form in polluted air when NO_2 reacts with O_3. Draw the resonance structures of NO_3 and use formal charges to select the preferred structure(s).

Molecules in Which Atoms Form More than Four Bonds

In some molecules, such as PCl_5 and SF_6, atoms of nonmetals in the third row and below in the periodic table appear to have more than an octet of valence electrons:

The five covalent bonds in PCl_5 and the six in SF_6 represent a total of 10 and 12 valence electrons around the central P and S atoms, respectively. All the atoms in both structures have formal charges of zero, so the two structures seem to be perfectly acceptable representations of the bonding in these molecules. How, though, can P and S atoms be surrounded by more than 8 valence electrons? Understanding the bonding in a compound such as SF_6 is important to understanding its potency as a greenhouse gas (**Figure 8.18**).

Over the years, chemists have debated several explanations for what many have called the *hypervalency* of phosphorus, sulfur, and other nonmetals in the third row and below in the periodic table. You might think that because elements in the third row of the periodic table and beyond have empty *d* orbitals that perhaps they use these to form additional bonds. However, recent studies employing high-speed computers and programs that allow chemists to predict the contributions that different atomic orbitals make in bond formation have shown that *d* orbitals contribute little to the bonding in molecules like PCl_5 and SF_6. We explore another theory of covalent bond formation in Chapter 9 that explains the bonding in these molecules without incorporating valence shell *d* orbitals.

Just because some atoms may have more than 8 valence electrons within certain compounds does not necessarily mean they always do. Rather, this tends to happen in these circumstances:

1. When they bond with strongly electronegative elements—particularly F, O, and Cl.
2. When doing so results in a structure in which the atoms have formal charges that are closer to zero.

Lewis Structures: Atoms with More than an Octet

Consider, for example, the S atom in a $SO_4{}^{2-}$ ion. Following the usual steps to draw its Lewis structure and assign formal charges, we get

The sum of the formal charges on atoms in the ion is $2-$, which is equal to the overall ionic charge, as it should be. Could this Lewis structure be redrawn so that at least some of the formal charges are zero? Converting one lone pair of electrons on each of two O atoms into bonding pairs gives the following:

Each O atom still has a complete octet, but the S atom accommodates 12 electrons. In this structure the formal charge on the S atom is 0, as are the formal charges on two of the four O atoms. There is still a formal charge of -1 on the other two oxygen atoms, which sums to the overall $2-$ charge of the ion. We could draw the two double bonds to any two of the O atoms, which means the structure is stabilized by resonance.

We can draw the Lewis structure of H_2SO_4 by combining two hydrogen ions (H^+) to the two oxygen atoms with $1-$ charges:

Each hydrogen atom has achieved its duet of electrons, each oxygen atom has an octet, and every atom has a formal charge of zero.

Based on the preceding formal charge analyses, we might conclude that the preferred bonding pattern in SO_4^{2-} ions and molecules of H_2SO_4 includes two S=O double bonds and zero formal charges all around. However, experimental evidence suggests that although the two structures with zero formal charges do contribute to the bonding of SO_4^{2-} and H_2SO_4, structures that obey the octet rule and have no S=O double bonds contribute as well. Thus, the actual bonding in these particles is an average of the structures with an octet and the structures with more than an octet of valence electrons.

SAMPLE EXERCISE 8.11 Drawing a Lewis Structure Containing an Atom with More than Four Bonds LO5

Draw the Lewis structure for the phosphate ion (PO_4^{3-}) that minimizes the formal charges on its atoms.

Collect, Organize, and Analyze Each ion contains one atom of phosphorus and four atoms of oxygen and has an overall charge of 3−. Phosphorus and oxygen are in groups 15 and 16 and have bonding capacities of 3 and 2, respectively. Phosphorus has an atomic number greater than 12 ($Z = 15$), so it may exhibit hypervalency.

Solve The number of valence electrons is

Phosphorus has the greater bonding capacity (3), so it is the central atom:

The addition of three lone pairs of electrons to each O atom completes their octets:

There are 32 valence electrons in this structure, which matches the number determined for the ion. Therefore, it is a complete Lewis structure of a polyatomic ion once we add the brackets and electrical charge:

Each O has a single bond and a formal charge of -1; the four bonds around the P atom are one more than its bonding capacity, so its formal charge is $+1$. The sum of the formal charges, $[+1 + 4(-1)]$, matches the $3-$ charge on the ion.

We can reduce the formal charge on P by increasing the number of bonds to it, and we can do that by converting a lone pair on one of the O atoms into a bonding pair:

At the same time, we change a single-bonded O atom into a double-bonded O atom and thereby make its formal charge zero. Therefore, the structure on the right is the one that minimizes formal charges.

Think About It The structure on the right has the double bond drawn to the O atom at the bottom of the structure, but it could have been drawn to any one of the other O atoms. This means that the structure is stabilized by resonance, producing four equivalent P—O bonds in which each pair of atoms is held together by the equivalent of 1.25 bonds, much like the 1.5 bonds between each pair of O atoms in molecules of ozone (see Section 8.4).

Practice Exercise Draw the resonance structures of the selenite ion (SeO_3^{2-}) that minimize the formal charges on the atoms.

Lewis Structures: Atoms with Less than an Octet

When fluorine combines with boron, a compound with the formula BF_3 is isolated. The electronegativity difference between boron and fluorine is 2.0, which puts BF_3 on the borderline between ionic and covalent compounds. If BF_3 contains three fluoride anions and a B^{3+} cation, then the ions are isoelectronic with a noble gas. Boron trifluoride, however, does not have the physical properties associated with an ionic compound; it is a gas that condenses at −101°C. What does the Lewis structure for BF_3 look like?

Boron trifluoride has a total of 24 valence electrons (step 1):

Element:B + 3 F

Valence electrons:3 + $(3 \times 7) = 24$

Boron has a greater bonding capacity (3) than fluorine (1), so B is the central atom (step 2). Connecting three fluorine atoms to the boron atom and completing the octets on fluorine (step 3) gives us a structure with the requisite number of valence electrons (step 4) on each F but not on the boron atom.

Formal charges are minimized in this structure; however, boron shares only 6 electrons and has no electrons in lone pairs. If we share an additional pair of electrons from one of the three F atoms, as shown in the resulting three resonance forms, we can complete the octets of all the atoms:

But forming a B□F double bond results in unfavorable formal charges, particularly for the F atom. We do not expect a positive formal charge on the most electronegative of all elements.

How do we resolve this conflict? The B—F bond lengths in BF_3 are all equal, but shorter than the B—F single bonds in the BF_4^- ion:

As we see in the next section, multiple bonds are generally shorter than single bonds. This suggests that all four of the following resonance forms contribute to the molecular structure of BF_3:

The atoms in the other group 13 halides complete their octets in different ways. For example, in aluminum chloride, the aluminum atom shares a lone pair of electrons with a chlorine atom in a second molecule, so that all the atoms in Al_2Cl_6 have a complete octet (**Figure 8.19**). The structure for Al_2Cl_6 is observed only in the liquid (or molten) phase. In the gas phase, aluminum chloride exists as discrete molecules of $AlCl_3$, like BF_3.

Do compounds containing elements other than group 13 ever have less than an octet around the central atom? The answer depends on which phase of the material we are considering. For example, as a solid, beryllium chloride consists of long chains of chlorine-bridged Be atoms (**Figure 8.20**) in which all atoms have completed octets. Above 800 K, $BeCl_2$ exists in the gas phase as discrete molecules in which the beryllium shares only two pairs of electrons with chlorine—much less than an octet. In general, H, Be, B, and Al are the elements most likely to have less than an octet of electrons.

SAMPLE EXERCISE 8.12 Drawing Lewis Structures of Compounds with Less than an Octet LO5

Two of the compounds used in the electronics industry to make thin films of aluminum metal are (a) $Li^+[AlH_4]^-$ and (b) AlH_3. Draw the Lewis structures of these ionic and molecular compounds.

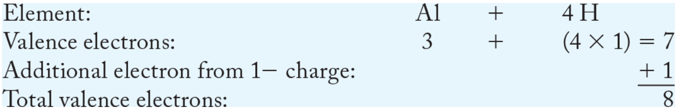
Collect, Organize, and Analyze The formula of lithium aluminum hydride, $Li^+[AlH_4]^-$, indicates that it contains Li^+ cations and $AlH_4{}^-$ anions. Lithium and hydrogen each have 1 valence electron and aluminum has 3 valence electrons. We use the steps outlined in Section 8.2 to draw Lewis structures for both compounds. Aluminum is the central atom in $AlH_4{}^-$ and AlH_3 because each hydrogen atom can form only one bond.

Solve

1. The lithium atom has lost its valence electron to form a Li^+ ion, so its Lewis symbol is Li^+:

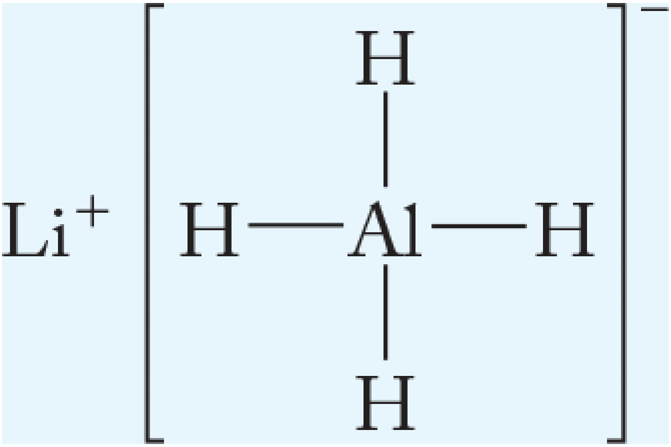
$$\mathrm{Li} \xrightarrow{-e^-} \mathrm{Li}^+$$

The total number of valence electrons in $AlH_4{}^-$ is:



Element:	Al	+	4 H
Valence electrons:	3	+	(4 × 1) = 7
Additional electron from 1− charge:			+ 1
Total valence electrons:			8

Connecting the four H atoms to the Al with single bonds results in a Lewis structure in which aluminum has a complete octet and each hydrogen atom has a complete duet.



2. The total number of valence electrons in AlH_3 is:

Element:Al + 3 H

Valence electrons:3 + $(3 \times 1) = 6$

In this case we can complete the duets of each H atom, but the aluminum atom is left with only 6 electrons, two fewer than a complete octet.

Think About It The aluminum atom in AlH_3 must have less than an octet because there are only 6 total valence electrons. As a result, AlH_3 reacts readily with the lone pair on nitrogen in $N(CH_3)_3$, for example, to form $AlH_3 \cdot N(CH_3)_3$. In $AlH_4{}^-$, the additional H atom and the overall negative charge on the anion each account for 1 electron to complete the octet on aluminum.

Practice Exercise The boiling point of sodium chloride is approximately 1700 K ($\approx$ 1427°C). In the gas phase, NaCl particles with the formula Na_2Cl_2 have been identified. Draw the Lewis structure for this particle and identify which atom does not have a complete octet.

The Limits of Bonding Models

Given the structures of SF_6, BF_3, and other exceptions to the octet rule, does the octet rule have any validity at all? The point to remember is that the octet rule is just a *model*. The octet rule works remarkably well in many cases to predict the number of covalent bonds between main group elements and to predict the composition of ionic compounds. However, the true nature of the chemical bond is much more subtle and shows great variability among the myriad chemical compounds that have been discovered.

What about the validity of formal charges? How can F, the most electronegative atom, carry a $+1$ formal charge in BF_3? Like Lewis structures, formal charges represent a model for identifying resonance forms that contribute most to the bonding in a molecule. Sometimes our model does not fit the observed data as well as we would like. In the case of BF_3, the observed B—F distances suggest that resonance forms containing B=F double bonds are important.

If aluminum chloride is a covalently bonded molecule, why do aqueous solutions of $AlCl_3$ conduct electricity? Why doesn't BF_3, with an electronegativity difference of 2.0, behave similarly? Why does $AlCl_3$ display ionic properties when ΔEN for Al—Cl bonds is only 1.5? In part, the answer lies in the partial ionic character of polar bonds. The greater difference in electronegativity between B and F ($\Delta EN = 2.0$) suggests that B—F bonds have more ionic character than Al—Cl bonds. The fact that $AlCl_3$ does dissolve in water, forming a solution that conducts electricity, points to the limitations of the octet rule as a model. Other considerations must be taken into account—namely, it is not only the ionic character of the bond but also bond energy and the resultant chemical reactivity of each compound that matter.

The significance of molecules with atoms surrounded by less than or more than an octet is that they challenge our models for bonding and push us toward better explanations for what we observe. We explore questions about bonding in more detail in Chapter 9, but before we do, let’s look at some experimental data about the bond lengths and bond energies of covalent bonds. As measurable quantities, these parameters allow us to test our model of the chemical bond as proposed by Gilbert Lewis.

Glossary

free radical

an odd-electron molecule with an unpaired electron in its Lewis structure.

FIGURE 8.23 The combustion of 1 mole of methane requires that 4 moles of C□H bonds and 2 moles of O□O bonds be broken. These processes require an enthalpy change of about +2648 kJ. In the formation of 4 moles of O□H bonds and 2 moles of C□O bonds, there is an enthalpy change of about −3450 kJ. The overall reaction is exothermic: 2648 kJ −3450 kJ = −802 kJ.

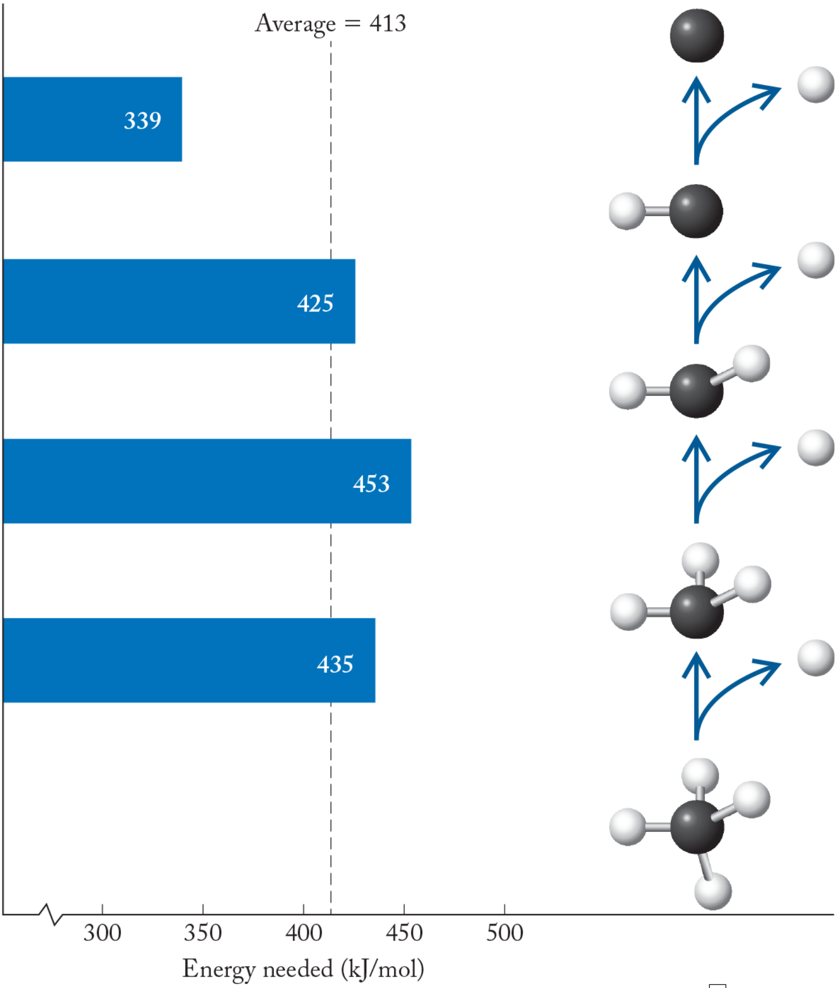

FIGURE 8.24 The energies needed to break the four C□H bonds in methane are not the same. ≡N triple bond (941 kJ/mol) is more than twice the bond energy of the N□N double bond and more than five times that of the N—N single bond. The large amount of energy required to break N≡N triple bonds is one reason why N_2 participates in so few chemical reactions.

$$\begin{aligned}\Delta H_{\text{rxn}} &= \sum \Delta H_{\text{bonds breaking}} - \sum \Delta H_{\text{bonds forming}} \qquad (8.4)\\ &= [(4\ \cancel{\text{mol}} \times 413\ \text{kJ}/\cancel{\text{mol}}) + (2\ \cancel{\text{mol}} \times 498\ \text{kJ}/\cancel{\text{mol}})]\\ &\quad -[(4\ \cancel{\text{mol}} \times 463\ \text{kJ}/\cancel{\text{mol}}) + (2\ \cancel{\text{mol}} \times 799\ \text{kJ}/\cancel{\text{mol}})]\\ &= -802\ \text{kJ}\end{aligned}$$

$$\text{H—H} \quad + \quad :\ddot{\underset{\cdot\cdot}{\text{Cl}}}\text{—}\ddot{\underset{\cdot\cdot}{\text{Cl}}}: \;\rightarrow\; 2\ \text{H—}\ddot{\underset{\cdot\cdot}{\text{Cl}}}:$$

H—H	436 kJ/mol
Cl—Cl	243 kJ/mol
H—Cl	431 kJ/mol

$$\begin{aligned}\Delta H_{\text{rxn}} &= \sum \Delta H_{\text{bond breaking}} - \sum \Delta H_{\text{bond forming}}\\ &= \left[(1\ \cancel{\text{mol}} \times 436\ \text{kJ}/\cancel{\text{mol}}) + (1\ \cancel{\text{mol}} \times 243\ \text{kJ}/\cancel{\text{mol}})\right]\\ &\quad -\left[(2\ \cancel{\text{mol}} \times 431\ \text{kJ}/\cancel{\text{mol}})\right.\\ &= -183\ \text{kJ}\end{aligned}$$

8.7 The Lengths and Strengths of Covalent Bonds

In Section 8.4 we discussed the equivalent resonance structures of ozone. We noted that the true nature of the two oxygen–oxygen bonds in O_3 is reflected in their equal bond length, 128 pm, which is between the length of a typical O□O double bond (121 pm) and an O—O single bond (148 pm), as shown in **Figure 8.21**. We used these results to conclude that there are effectively 1.5 bonds between the atoms in a molecule of O_3. In this section we explore this use of bond length and bond strength to rationalize and validate molecular structures. We also use bond strengths to estimate the enthalpy changes that occur in chemical reactions.

Bond Length

The length of the bond between any two atoms depends on the identity of the atoms and on whether the bond is single, double, or triple (**Table 8.3**). The number of bonds between two atoms is called the bond order. As bond order increases, bond length decreases, as we can see by comparing the lengths of the C—C, C□C, and C

Measurements of the bond lengths in many molecules indicate that there are small differences in bond lengths for any given covalent bond. For example, the C—H and C□O bond lengths in formaldehyde (**Figure 8.22b**) are close to but not the same as the C—H bond length in CH_4 and the C□O bond length in CO_2.

CONCEPT TEST

Rank the following molecules in order of decreasing lengths of their nitrogen–oxygen bonds: NO, NO_2, N_2O.

Bond Energies

The energy changes associated with chemical reactions depend on how much energy is required to break the bonds in the reactants and how much is released as the atoms recombine to form products. For example, in the methane combustion reaction

$$CH_4(g) + 2\ O_2(g) \rightarrow CO_2(g) + 2\ H_2O(g)$$

the C—H bonds in CH_4 and the O=O bonds in O_2 must be broken before the C=O bonds in CO_2 and the O—H bonds in H_2O can form. (In reality, some bond formation occurs simultaneously with bond breaking; it is not completely sequential.) Breaking bonds is endothermic (the blue “energy in” arrow in **Figure 8.23**), and forming bonds is exothermic (the red “energy out” arrow). If a chemical reaction is exothermic, as is methane combustion, more energy is released in forming the bonds in molecules of products than is consumed in breaking the bonds in molecules of reactants.

Bond energy, or *bond strength*, is usually expressed in terms of the enthalpy change (ΔH) that occurs when 1 mole of a bond in the gas phase is broken. Bond energies for some common covalent bonds are listed in Table 8.3. The values in Table 8.3 are all positive because bond breaking is always endothermic. As we first mentioned in Section 8.1, the quantity of energy needed to break a bond depends on the identity of the two bonded atoms and the bond order and is equal in magnitude but opposite in sign to the quantity of energy released when that same bond forms.

Like bond lengths, the bond energies in Table 8.3 are average values because bond energies vary depending on the structure of the rest of the molecule (Figure 8.22). For example, the bond energy of a C=O bond in carbon dioxide is 799 kJ/mol, but the C=O bond energy in formaldehyde is only 743 kJ/mol.

Another view of the variability in bond energy comes from breaking the C—H bonds in CH_4 in a step-by-step fashion, as shown in **Figure 8.24**. The data show that the chemical environment of a bond affects the energy required to break it: breaking the first C—H bond in methane requires less energy than breaking the second but more than breaking the third or fourth. The total energy needed to break all four C—H bonds is 1652 kJ/mol, which is an average of 413 kJ/mol per bond.

The relationship between bond order and bond energy is also apparent in Table 8.3. The bond energy of the O=O double bond, at 498 kJ/mol, is more than three times that of the O—O single bond. In general, the bond energy for a pair of atoms increases as their bond order increases. For example, the bond energy of the N

In the combustion of 1 mole of CH_4 (Figure 8.23), 4 moles of C—H bonds and 2 moles of O□O bonds must be broken. The formation of 1 mole of CO_2 and 2 moles of H_2O requires the formation of 2 moles of C□O bonds and 4 moles of O—H bonds. The net change in energy resulting from breaking and forming these bonds can be estimated from average bond energies. We can take an inventory of the bond energies involved:

Bond Energies (Δ*H*) and Energy Changes in the Combustion of 1 Mol CH_4

[illegible]
[illegible] mol × 413 kJ/mol
[illegible] mol × 498 kJ/mol
[illegible] mol × 463 kJ/mol
[illegible] mol × 799 kJ/mol

CONNECTION In Chapter 6 we calculated the difference between the sums of heats of formation of products and of reactants to estimate the heat of reaction.

Next, we estimate the enthalpy change of the overall reaction using. Equation 8.4:

SAMPLE EXERCISE 8.13 Estimating Heats of Reaction from Average Bond Energies LO6

Use the average bond energies in Table 8.3 to estimate ΔH_{rxn} for the reaction in which HCl(*g*) is formed from H_2(*g*) and Cl_2(*g*):

Collect and Organize We are asked to estimate the value of ΔH_{rxn} of a gas-phase reaction from the bond energies of the reactants and products. Average bond energy values are listed in Table 8.3.

Analyze The Lewis structures of the reactants and products tell us that 1 mole of H—H bonds and 1 mole of Cl—Cl bonds are broken and 2 moles of H—Cl bonds form during the reaction. The average values of these bonds from Table 8.3 are:

Energy is consumed when bonds break and is released when they form. Two moles of H—Cl bonds form during the reaction and twice the H—Cl bond energy value is more than the sum of the H—H and Cl—Cl bond energies, so there should be an overall release of energy, that is, $\Delta H_{\mathrm{rxn}} < 0$.

Solve Using the above information in Equation 8.4:

Think About It In this exercise the Lewis structures provided information about the number and types of bonds that were broken and formed during the reaction. However, you may sometimes only know the identities of the reactants and products in a gas-phase reaction and will have to first write a balanced chemical reaction for the reaction and then draw Lewis structures of the reactants and products to develop an inventory of the bonds broken and formed.

As predicted, ΔH_{rxn} is less than zero, which means the reaction is exothermic. The reaction involves the formation of 2 moles of a gaseous compound from its component elements in their standard states. Therefore, ΔH_{rxn} should be close to two times the standard heat of formation ($\Delta H^\circ_{\mathrm{f}}$) of HCl. That value (see Appendix 4) is -92.3 kJ/mol. Multiplying by 2 moles, we get -184.6 kJ, which is quite close to the calculated ΔH_{rxn} value.

Practice Exercise Use average bond energies to calculate ΔH_{rxn} for the reaction of H_2 and N_2 to form ammonia:

CONCEPT TEST

Suggest a reason, based on bond energies, why O_2 is much more reactive than N_2.

In this chapter we have explored the nature of the covalent bonds that hold together molecules and polyatomic ions. These bonds owe their strength to the presence of pairs of electrons shared between nuclei of atoms. Sharing does not necessarily mean equal sharing, and unequal sharing coupled with bond vibration accounts for the ability of some atmospheric gases to absorb and emit infrared radiation. As a result, these gases function as greenhouse gases.

Early in the chapter we noted that moderate concentrations of greenhouse gases are required for climate stability and to make our planet habitable. The escalating concern of many is that Earth's climate is being destabilized by too much of a good thing. Policies made by the world's governments will soon have a significant impact on the problem of global warming, one way or the other. As an informed member of the world community, you will have the opportunity to influence how those policy decisions are made.

SAMPLE EXERCISE 8.14 Integrating Concepts: Moth Balls

A compound often referred to by the abbreviation PDB is the active ingredient in most moth balls. It is also used to control mold and mildew, as a deodorant, and as a disinfectant. Tablets containing it are often stuck under the lids of garbage cans or placed in the urinals in public restrooms, producing a distinctive aroma. Molecules of PDB have the following skeletal structure:

1. Draw the Lewis structure of PDB and note any nonzero formal charges.
2. Is the structure stabilized by resonance? If so, draw all resonance structures.
3. Which, if any, of the bonds in the structure you drew are polar?
4. Predict the average carbon–carbon bond length and bond strength in the structure you drew.

Collect and Organize We are given the skeletal structure of a molecule and are asked to draw its Lewis structure, including all resonance structures, and to perform a formal charge analysis. We are also asked to identify any nonpolar bonds in the structure and to predict the length and strength of the carbon–carbon bonds. Bond polarity depends on the difference in electronegativities of the bonded atoms, which are given in Figure 8.9. Table 8.3 lists average lengths and energies (strengths) of covalent bonds.

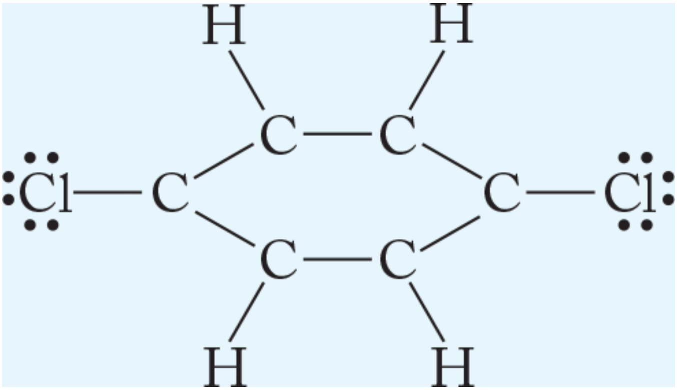
Analyze The five-step procedure used in Sample Exercises 8.2 through 8.5 to draw Lewis structures of other small molecules should be useful in drawing the Lewis structure of PDB. Resonance structures for PDB, like those for benzene (Figure 8.16), should be possible if there are alternating single and double carbon–carbon bonds in PDB's six-membered ring of carbon atoms.

Solve

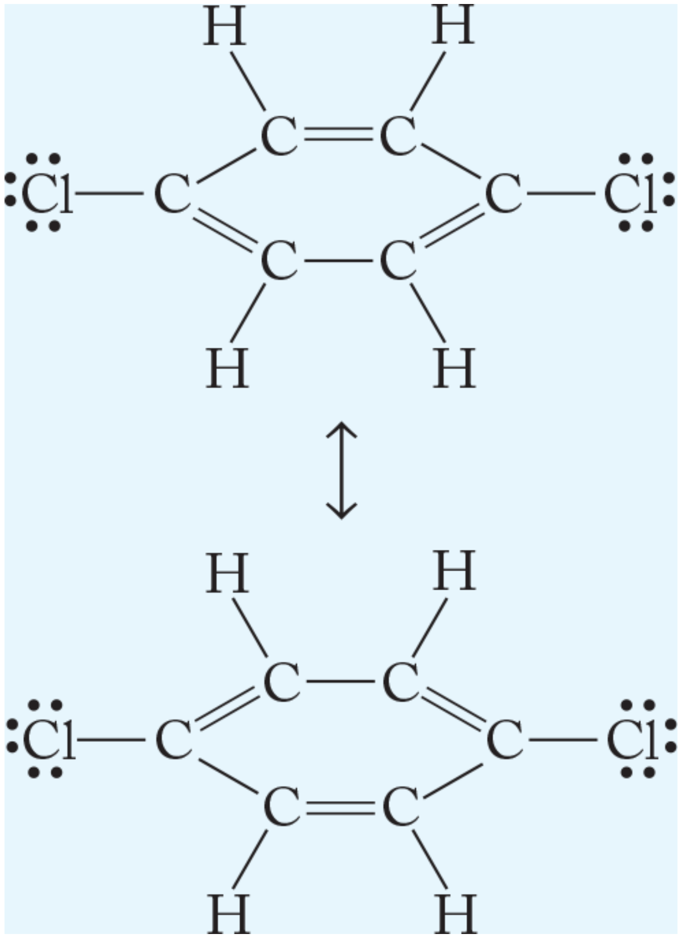
1. and b. The number of valence electrons is

Element:	6 C	+	2 Cl	+	4 H
Valence electrons:	(6×4)	+	(2×7)	+	$(4 \times 1) = 42$

Completing the octets on the Cl atoms:



gives a structure with 36 valence electrons (12 bonding pairs and 6 lone pairs). We have 6 more electrons to place to reach 42, and none of the six carbons in the ring has an octet of electrons. Instead, each participates in three bonds, so each needs two more electrons. Placing a lone pair on every other C gives those three C atoms an octet of electrons but leaves the other three with only 6 electrons. If we convert the three lone pairs into three carbon–carbon double bonds, each C atom will have an octet, provided we distribute them evenly around the ring to avoid any C atoms with five bonds. Two equivalent resonance structures can be drawn to show the bonding pattern:



Resonance stabilizes the structure of PDB. Each C atom has four bonds and each H and Cl atom has one bond, so every atom has the number of bonds that matches its bond capacity. This means that all formal charges are zero.

1. The differences in electronegativities for the bonded pairs of atoms are

C—C $\Delta EN = 0$
Cl—C $\Delta EN = 3.0 - 2.5 = 0.5$
C—H $\Delta EN = 2.5 - 2.1 = 0.4$

Based on ΔEN values, we may conclude that the bonds between carbon and chlorine atoms are polar bonds and the bonds between pairs of carbon atoms are not polar. However, the bonds between pairs of elements with small ΔEN values (0.4 or less and especially C—H bonds) are considered *essentially* nonpolar.

2. The even distribution of a total of 9 bonding pairs of electrons among 6 C atoms means that, on average, each pair shares 1.5 pairs of bonding electrons. The corresponding bond length and bond strength should be about halfway between those of C—C single and C═C double bonds, given in Table 8.3:

   Approximate bond length:

   $[(154 + 134)/2]$ pm $=$ 144 pm

   Approximate bond strength:

   $[(348 + 614)/2]$ kJ/mol $=$ 481 kJ/mol

Think About It The resonance structures closely resemble those of benzene, which is reflected in the common name of PDB, p*ara*-dichlorobenzene. The two polar C—Cl bonds in PDB are oriented *in opposite directions*. Thus, the unequal sharing of the bonding pair of electrons in the Cl—C bond on the left side of the molecule is offset by the unequal sharing of the bonding pair of electrons in the C—Cl bond on the right side. In Chapter 9 we explore how offsetting bond polarities in symmetrical molecules like this one explain why substances such as PDB are nonpolar overall.

Glossary

bond order

the number of bonds between atoms: 1 for a single bond, 2 for a double bond, and 3 for a triple bond.

bond energy

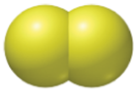
the energy needed to break 1 mole of a covalent bond in a molecule or in a polyatomic ion in the gas phase.

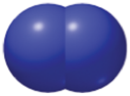
Endnotes

- The bond energy of the C□O bond in CO_2 is 799 kJ/mol.Return to reference a

Learning Objectives

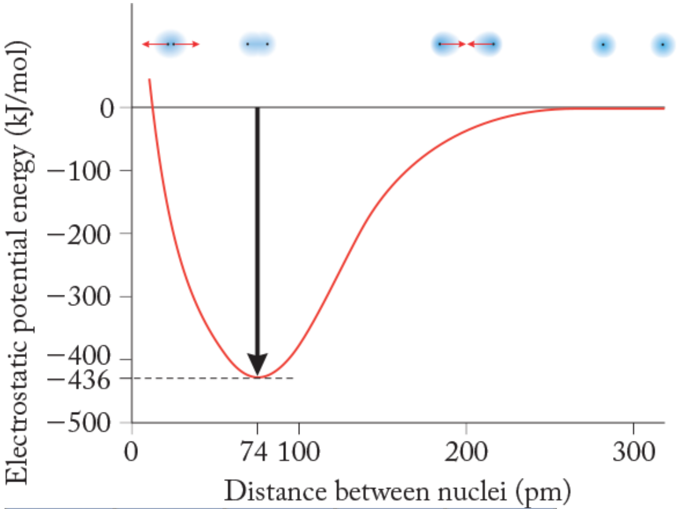
- Describe how bond order, bond energy, and bond length are related, and estimate the enthalpy of a reaction (δH_{rxn}) from average bond energies **Return to Sample Exercise 8.13**

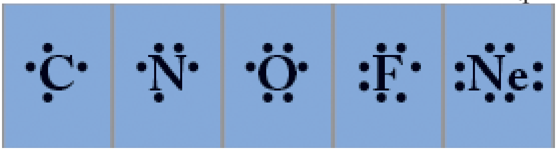




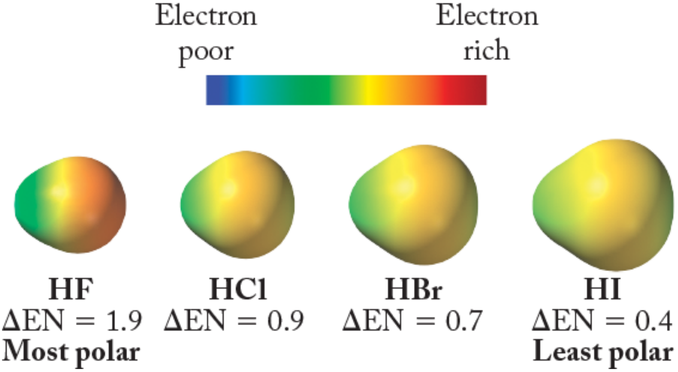
SUMMARY

- LO1 A chemical bond results when two atoms share electrons (a covalent bond) or when two ions are attracted to each other (an ionic bond). The atoms in metallic solids pool their electrons to form metallic bonds. (Section 8.1)





- LO2 Lewis symbols use dots to represent paired and unpaired electrons in the ground states of atoms. The number of unpaired electrons indicates the number of bonds the element is likely to form—that is, its bonding capacity. Chemical stability is achieved when atoms have eight electrons in their valence *s* and *p* orbitals, following the octet rule. A Lewis structure shows the bonding pattern in molecules and polyatomic ions; pairs of dots represent lone pairs of electrons that do not contribute to bonding. A single bond consists of a single pair of electrons shared between two atoms; there are two shared pairs in a double bond and three shared pairs in a triple bond. (Section 8.2)



- LO3 Unequal electron sharing between atoms of different elements results in polar covalent bonds. Bond polarity is a measure of how unequally the electrons in covalent bonds are shared. Greater polarity results from larger differences in the electronegativities of the bonded atoms. Electronegativity is a relative measure of the ability of an atom to attract electrons in a bond to itself. Polarity of bonds in molecules of atmospheric gases may lead to the absorption of infrared radiation, which contributes to the greenhouse effect. (Section 8.3)
- LO4 Covalent bonds behave more like flexible springs than rigid rods. They can undergo a variety of bond vibrations. The vibrations of polar bonds may create fluctuating electrical fields that allow molecules to absorb infrared (IR) electromagnetic radiation. When atmospheric gases absorb IR radiation, they contribute to the greenhouse effect. (Section 8.3)
- LO5 Two or more Lewis structures—called resonance structures—can sometimes be drawn for one molecule or polyatomic ion. The actual bonding pattern in a molecule is a combination of resonance structures. The preferred resonance structure of a molecule is one in which the formal charges (FC) on its atoms are zero or as close to zero as possible, and any negative formal charges are on the more electronegative atoms. The formal charge on an atom in a Lewis structure is

the difference between the number of valence electrons in the free atom and the sum of the number of electrons in lone pairs and half the number of electrons in bonding pairs on the bonded atom. Free radicals include reactive molecules that have an odd number of valence electrons and contain atoms with incomplete octets. Atoms of elements in the third row of the periodic table with $Z > 12$ and beyond may accommodate more than an octet of electrons. (Sections 8.4, 8.5, 8.6)

- LO6 Bond order is the number of bonding pairs in a covalent bond. Bond energy is the enthalpy change, ΔH, required to break 1 mole of a covalent bond in the gas phase; energy changes in chemical reactions depend on the energy required to break bonds in the reactants and the energy released when new bonds are formed in the products. Bond length is the distance between the nuclear centers of two bonded atoms. As the bond order between two atoms increases, the bond length decreases and the bond energy increases. (Sections 8.1, 8.7)

PARTICULATE PREVIEW WRAP-UP

The space-filling models look identical and do not tell us which bonds are present in these molecules. O_2, F_2, and N_2 are the molecular formulas for the oxygen, fluorine, and nitrogen molecules, respectively, from left to right. The molecular formulas do not tell us which bonds are present in a molecule, either, but a ball-and-stick model would show a single bond as one stick, a double bond as two sticks, and a triple bond as three sticks.

PROBLEM-SOLVING SUMMARY

Type of Problem	Concepts and Equations	**Sample Exercises**
Describing differences in covalent, ionic, and metallic bonds	All bonds exist as a result of electrostatic attractions. Ionic bonds form between cations and anions, both of which can be polyatomic ions. Covalent bonds form between atoms of nonmetals or metalloids. Metallic bonds form from the	8.1

	delocalization of electrons across atoms of metallic elements.	
Drawing Lewis structures for molecules, ions, and ionic compounds	Connect the atoms with single covalent bonds, distribute the valence electrons to give each outer atom (except H) eight valence electrons; use multiple bonds where necessary to complete the central atom's octet.	8.2–8.5
Comparing bond polarities	Calculate the difference in electronegativity (ΔEN) between the two bonded atoms; if ΔEN $\geq$ 2.0, the bond is considered ionic.	8.6
Drawing resonance structures of molecules and polyatomic ions	Include all possible arrangements of covalent bonds in the molecule when more than one equivalent structure can be drawn.	8.7, 8.8
Selecting resonance structures on the basis of formal charges	Calculate formal charges by using $$FC = \left(\begin{array}{c}\text{number of}\\ \text{valence } e^-\end{array}\right) - \left[\left(\begin{array}{c}\text{number of}\\ \text{nonbonding } e^-\end{array}\right) + \frac{1}{2}\left(\begin{array}{c}\text{number of } e^-\\ \text{in bonding pairs}\end{array}\right)\right] \quad (8.1)$$ Select structures with formal charges closest to zero and with negative formal charges on the most electronegative atoms.	8.9
Drawing Lewis structures of odd-electron molecules	Distribute the valence electrons in the Lewis structure to leave the most electronegative atom(s) with eight valence electrons and the least electronegative atom with the odd number of electrons.	8.10
Drawing Lewis structures containing atoms with more than an octet of valence electrons	Distribute the valence electrons in the Lewis structure such that atoms of elements with Z > 12 have more than eight valence electrons if more than four bonds are needed or if doing so results in a structure with formal charges closer to zero.	8.11
Drawing Lewis structures with an incomplete octet	Distribute the valence electrons in the Lewis structure, allowing atoms of elements such as Be, B, and Al to have fewer than eight valence electrons if needed.	8.12
Estimating heats of reaction from average bond energies	Multiply bond energies by the number of bonds and calculate using $$\Delta H_{\text{rxn}} = \sum \Delta H_{\text{bonds breaking}} - \sum \Delta H_{\text{bonds forming}} \quad (8.4)$$	8.13

VISUAL PROBLEMS

(Answers to boldface end-of-chapter questions and problems are in the back of the book.)

Which of the elements highlighted in Figure P8.1 have Lewis symbols that contain (a) two dots, (b) four dots, (c) six dots, (d) eight dots?

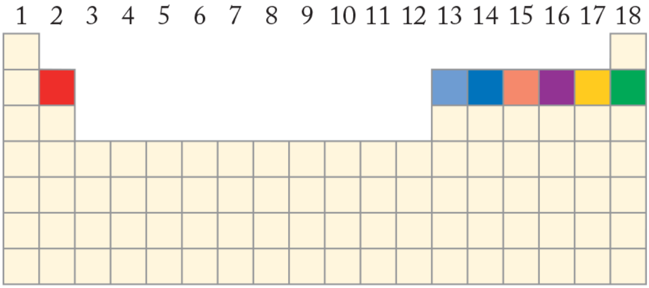


FIGURE P8.1

Which of the elements highlighted in Figure P8.1 form ions whose Lewis symbols have no dots?

Which of the elements highlighted in Figure P8.1 has the greatest bonding capacity?

Which of the elements highlighted in Figure P8.1 form monatomic ions whose Lewis symbols have four pairs of dots? (*Hint*: See Figure 2.20.)

Which of the elements highlighted in Figure P8.1 has the greatest electronegativity?

Which two of the highlighted elements in Figure P8.1 form the bonding pair with the most ionic character?

Which of the Lewis symbols in Figure P8.7 correctly portrays the most stable ion of magnesium?

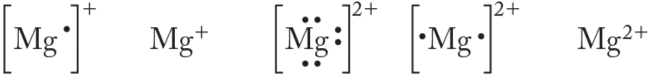

FIGURE P8.7

Which Lewis symbol in Figure P8.8 correctly portrays a stable monatomic ion?

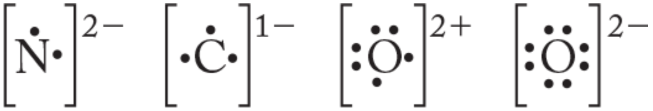

FIGURE P8.8

Note: The color scale used in Problems 8.9 through 8.11 is the same as in Figure 8.8, where violet means low electron density and red means high electron density.

Which of the drawings in Figure P8.9 best represents the distribution of electron density in LiF?

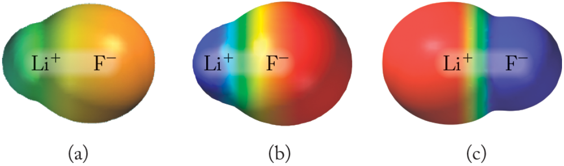

FIGURE P8.9

Which of the drawings in Figure P8.10 best represents the distribution of electron density in ClBr?

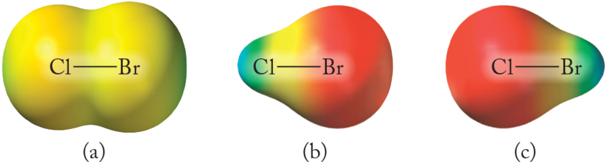

FIGURE P8.10

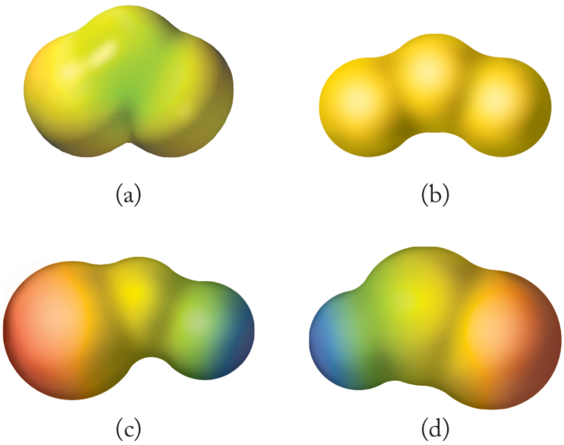
Which of the drawings in Figure P8.11 most accurately represents the distribution of electron density in SO_2? Explain your



answer.

FIGURE P8.11

Which of the drawings in Figure P8.12 most accurately represents the distribution of electrical charge in ozone? Explain your answer.

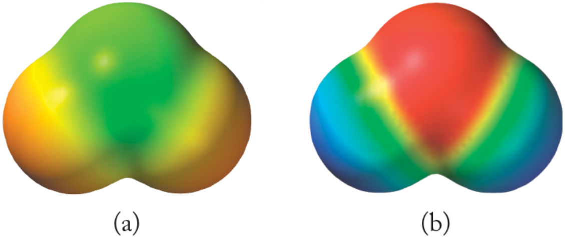


FIGURE P8.12

Figure P8.13 shows two graphs of electrostatic potential energy versus internuclear distance. One is for a pair of potassium and chloride ions, and the other is for a pair of potassium and fluoride ions. Which is which?

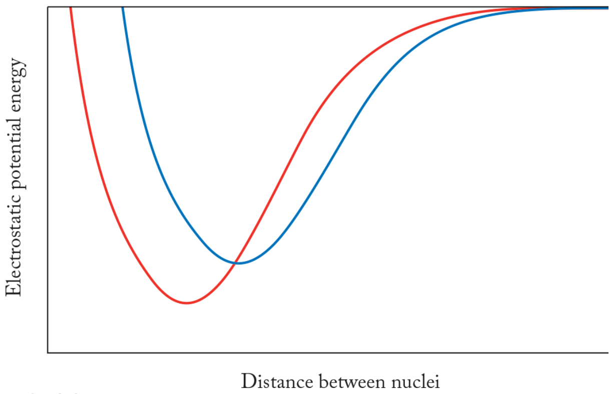

FIGURE P8.13

Water in the atmosphere is a greenhouse gas, which means its molecules are transparent to visible light but may absorb photons of infrared radiation. Which of the three modes of bond vibration shown in Figure P8.14 are infrared active? (The angle between the O—H bonds in H_2O is 104.5°. The reason why is discussed in Chapter 9.)

FIGURE P8.14

Explain why the structures in Figure P8.15 are not all resonance forms of the molecule S_2O.

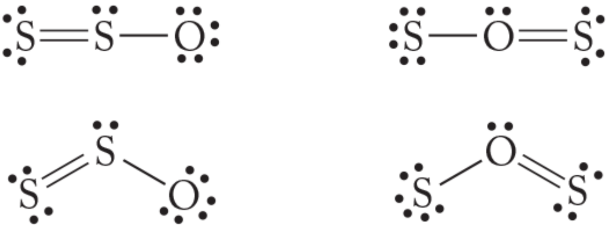

FIGURE P8.15

Are the three structures in Figure P8.16 resonance forms of the thiocyanate ion (SCN^-)? Explain why or why not.

FIGURE P8.16

Describe the errors in the Lewis structures in Figure P8.17. Assume the skeletal structures shown are correct.

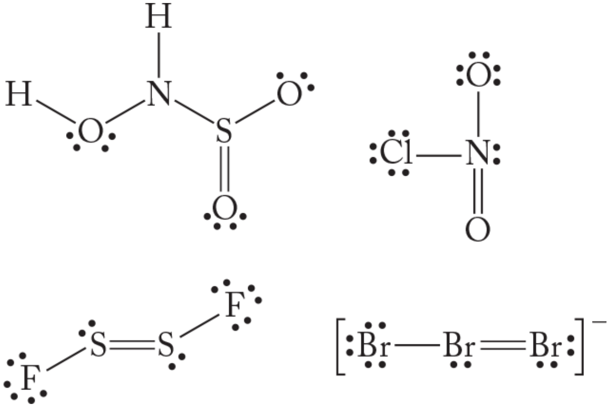

FIGURE P8.17

In each of the three pairs of resonance structures in Figure P8.18, which structure contributes more to the bonding in the molecule or molecular ion?

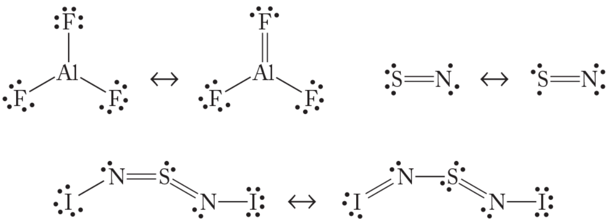

FIGURE P8.18

Which line in the graph in Figure P8.19 best represents the relationship between bond order and bond length? What would a graph of bond order versus bond energy look like?

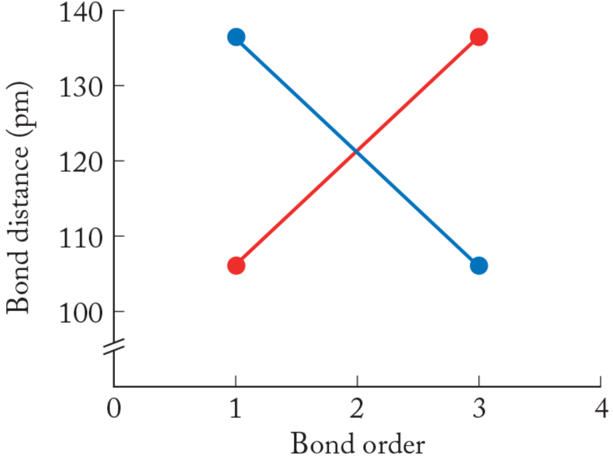

FIGURE P8.19

Use representations [A] through [I] in Figure P8.20 to answer questions (a)–(f).

1. Which hydrocarbon has the strongest carbon–carbon bond?
2. Which hydrocarbon has the weakest carbon–carbon bond?
3. Could [B] and/or [G] absorb an infrared photon through an asymmetric stretch and contribute to the greenhouse effect?
4. Label the most polar bond in [C] and in [D], using both the arrow (\) and $\delta+$ and $\delta-$ notations.
5. Which process is exothermic?
6. Which representation demonstrates a key limitation of Lewis

structures?

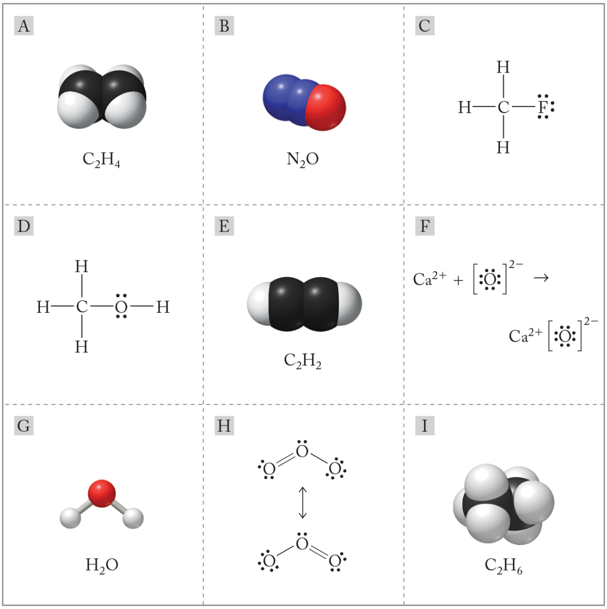

FIGURE P8.20

QUESTIONS AND PROBLEMS

Types of Chemical Bonds

Concept Review

In a hydrogen molecule, interactions between which subatomic particles cause electrostatic potential energy to decrease as two H atoms approach each other?

What name is given to the distance at which electrostatic potential energy between the atoms in a diatomic molecule is at a minimum?

In a halite (NaCl) crystal, which particles are electrostatically attracted to one another and which particles repel each other?

Describe two factors that explain why the magnesium and oxide ions in solid MgO are more strongly attracted to each other than the potassium and bromide ions in KBr?

Problems

Identify the type of bonding in each substance, and then for each pair of substances, describe the similarities and differences between the types of bonding.

1. Ni(*s*), $S_8(s)$
2. Ni(*s*), $Na_2S(s)$
3. $SO_2(g)$, $Na_2S(s)$
4. Ni(*s*), $Na_2SO_4(s)$
5. $S_8(s)$, $Na_2SO_4(s)$
6. $Na_2S(s)$, $Na_2SO_4(s)$

Identify the type of bonding in each substance, and then for each pair of substances, describe the similarities and differences between the types of bonding.

1. Ag(*s*), $Cl_2(g)$
2. Ag(*s*), AgCl(*s*)
3. $Cl_2(g)$, AgCl(*s*)
4. Ag(*s*), $Ag_2CO_3(s)$
5. $Cl_2(g)$, $Ag_2CO_3(s)$
6. AgCl(*s*), $Ag_2CO_3(s)$

Lewis Structures

Concept Review

Does the number of valence electrons in a neutral atom ever equal the atomic number?

Does the number of valence electrons in a neutral atom ever equal the group number?

Do all the elements in a group in the periodic table have the same number of valence electrons?

Distinguish between an atom’s valence electrons and its total electron count.

Which groups among main group elements have an odd number of valence electrons?

Some of his critics described G. N. Lewis’s approach to explaining covalent bonding as an exercise in double counting and therefore invalid. Explain the basis for this criticism.

Does the octet rule mean that a diatomic molecule must have 16 valence electrons?

Why would you not expect to find hydrogen atoms in the bonding arrangement X—H—X?

Problems

Draw Lewis symbols of atoms of lithium, magnesium, and aluminum.

Draw Lewis symbols of atoms of nitrogen, oxygen, fluorine, and chlorine.

How would you change the arrays of dots in each of the Lewis symbols in Figure P8.37 to correct any errors?

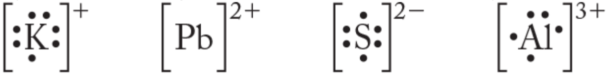

FIGURE P8.37

How would you change the arrays of dots in each of the Lewis symbols in Figure P8.38 to correct any errors?

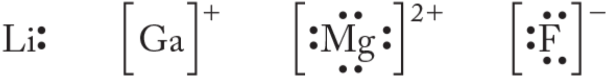

FIGURE P8.38

Draw Lewis symbols for In^+, I^-, Ca^{2+}, and Sn^{2+}. Which ions have a complete valence-shell octet?

Draw Lewis symbols of Xe, Sr^{2+}, Cl, and Cl^-. How many valence electrons are in each atom or ion?

Sodium ions are isoelectronic with a noble gas.

1. Identify this noble gas.
2. Does this noble gas have the same Lewis symbol as a sodium ion?

In what ways are the Lewis symbols for the oxide anion and the argon atom similar?

Draw the Lewis symbol of an ion that has the following:

1. $1+$ charge and 1 valence electron
2. $3+$ charge and 0 valence electrons

Draw the Lewis symbol of an ion that has the following:

1. $1-$ charge and 8 valence electrons
2. $1+$ charge and 5 valence electrons

How many valence electrons does each of the following species contain? (a) BN; (b) HF; (c) OH^-; (d) CN^-

How many valence electrons does each of the following species contain? (a) N_2^+; (b) CS^+; (c) CN; (d) CO

Draw Lewis structures for the following diatomic molecules and ions: (a) CO; (b) O_2; (c) ClO^-; (d) CN^-.

Draw Lewis structures for the following diatomic molecules and ions: (a) F_2; (b) NO^+; (c) SO; (d) HI.

Greenhouse Gases Chlorofluorocarbons (CFCs) are linked to the depletion of stratospheric ozone. They are also greenhouse gases. Draw Lewis structures for the following CFCs:

1. CF_2Cl_2 (Freon 12)
2. Cl_2FCCF_2Cl (Freon 113, containing a C—C bond)
3. C_2ClF_3 (Freon 1113, containing a C□C bond)

Draw Lewis structures for the organic compounds shown and answer the following questions. Assume the skeletal structures in Figure P8.50 are correct.

1. Which of these molecules is an alkyne?
2. Which of these molecules contains an aldehyde functional group?

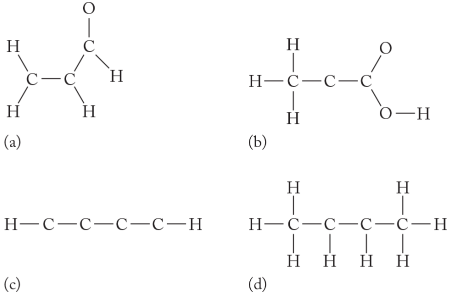

FIGURE P8.50

Skunks and Rotten Eggs Many sulfur-containing organic compounds have characteristically foul odors: butanethiol ($CH_3CH_2CH_2CH_2SH$) is responsible for the odor of skunks, and rotten eggs smell the way they do because they produce tiny amounts of pungent hydrogen sulfide (H_2S). Draw the Lewis structures for $CH_3CH_2CH_2CH_2SH$ and H_2S.

Acid in Ants Formic acid (HCOOH) is the smallest organic acid and was originally isolated by distilling red ants. Draw its Lewis structure if the atoms are connected as shown in Figure P8.52.

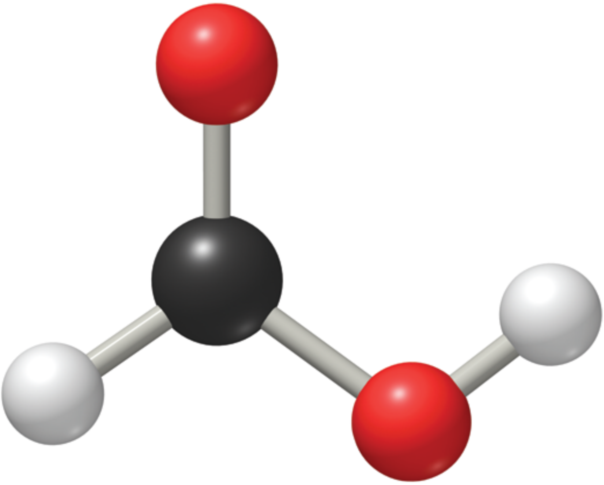

FIGURE P8.52

Chlorine Bleach Chlorine combines with oxygen in several proportions. Dichlorine monoxide (Cl_2O) is used in the manufacture of bleaching agents. Potassium chlorate ($KClO_3$) is used in oxygen generators aboard aircraft. Draw the Lewis structures for Cl_2O and ClO_3^- (Cl is the central atom).

Dangers of Mixing Cleansers Labels on household cleansers caution against mixing bleach with ammonia (Figure P8.54) because the reaction produces monochloramine (NH_2Cl) and hydrazine (N_2H_4), both of which are toxic:

$$NH_3(aq) + OCl^-(aq) \rightarrow NH_2Cl(aq) + OH^-(aq)$$

$$NH_2Cl(aq) + NH_3(aq) + OH^-(aq) \rightarrow N_2H_4(aq) + Cl^-(aq) + H_2O(\ell)$$

Draw the Lewis structures for monochloramine and hydrazine.

P8.54

Polar Covalent Bonds

Concept Review

How can we use electronegativity to predict whether a bond between two atoms is likely to be covalent or ionic?

How do the electronegativities of the elements change across a period and down a group?

Explain, based on atomic structure, why trends in electronegativity are related to trends in atomic size.

Is the element with the most valence electrons in a period also the most electronegative? Explain.

What is meant by the term *polar covalent bond*?

What factor is responsible for the existence of polar covalent bonds?

Describe how atmospheric greenhouse gases act like the panes of glass in a greenhouse.

Understanding the Greenhouse Effect Water vapor in the atmosphere contributes more to the greenhouse effect than carbon dioxide, yet water vapor is not considered an important factor in global warming. Propose a reason why.

Increasing concentrations of nitrous oxide in the atmosphere may be contributing to climate change. Is the ability of N_2O to absorb infrared radiation due to nitrogen–nitrogen bond stretching, nitrogen–oxygen bond stretching, or both? Explain your answer.

Atmospheric oxygen (O_2) is not a greenhouse gas, but atmospheric ozone (O_3) is. What types of bond vibration in molecules of O_3 are infrared active?

Problems

Which of the following bonds are polar: C—Se, C—O, Cl—Cl, O□O, N—H, C—H? In the bond or bonds that you selected, which atom has the greater electronegativity?

Which is the least polar bond: C—Se, C□O, Cl—Br, O□O, N—H, C—H?

In which of the following binary compounds is the bond expected to have the *least* ionic character? LiCl; CsI; KBr; NaF

In which of the following compounds is the bond between the atoms expected to have the most covalent character? $AlCl_3$; $AlBr_3$; AlI_3; GaF_3

Which bond in Figure P8.69 is polar and has a correctly drawn polarity arrow?

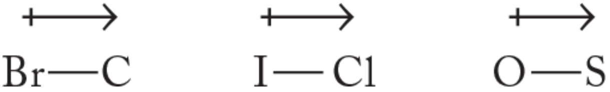

FIGURE P8.69

Which bond in Figure P8.70 is polar and has a correctly drawn polarity arrow?

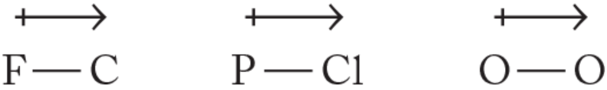

FIGURE P8.70

Which bond in the following is correctly labeled?

$\overset{\delta-}{\mathrm{O}}-\overset{\delta+}{\mathrm{H}}$ $\quad$ $\overset{\delta-}{\mathrm{C}}-\overset{\delta+}{\mathrm{Cl}}$ $\quad$ $\overset{\delta-}{\mathrm{Br}}-\overset{\delta+}{\mathrm{Br}}$

Which bond in the following is correctly labeled?

$\overset{\delta+}{\mathrm{Na}}-\overset{\delta-}{\mathrm{Cl}}$ $\quad$ $\overset{\delta+}{\mathrm{Li}}-\overset{\delta-}{\mathrm{F}}$ $\quad$ $\overset{\delta+}{\mathrm{Si}}-\overset{\delta-}{\mathrm{F}}$

Which substance has the most polar covalent bonds: PF_3, S_8, RbCl, or SF_2?

Atoms of which element are held together by nonpolar covalent bonds: lithium, phosphorus, or xenon?

Resonance

Concept Review

Explain the concept of resonance.

How does resonance influence the stability of a molecule or an ion?

What factors determine whether a molecule or ion exhibits resonance?

What structural features do all the resonance forms of a molecule or ion have in common?

Explain why NO_2 is more likely to exhibit resonance than CO_2.

Are these two skeletal structures resonance forms: X—X—O and X—O—X? Explain.

Problems

Draw Lewis structures for fulminic acid (HCNO), showing all resonance forms.

Draw Lewis structures for hydrazoic acid (HN_3), showing all resonance forms.

Oxygen and nitrogen combine to form a variety of nitrogen oxides, including the following two unstable compounds, each with two nitrogen atoms per molecule: N_2O_2 and N_2O_3. Draw Lewis structures for these molecules, showing all resonance forms.

Oxygen and sulfur combine to form a variety of sulfur oxides. Some are stable molecules and some, including S_2O_2 and S_2O_3, decompose when they are heated. Draw Lewis structures for these two compounds, showing all resonance forms.

The O–O bond distance in F_2O_2 is about 20% shorter than in hydrogen peroxide.

1. Draw Lewis structures for both F_2O_2 and H_2O_2.
2. It was proposed that F_2O_2 has a resonance form of $[FO_2]^+F^-$. Draw a Lewis structure for this “ionic” form of

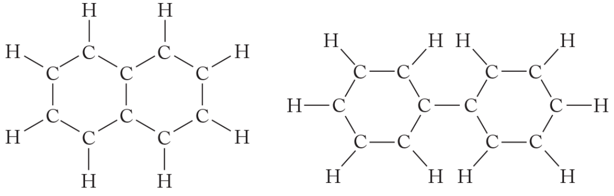
F_2O_2 and explain how the structure is consistent with the observed O–O distance.

The nitrogen–oxygen bond distance in NOF_3 is shorter than in $NO(CH_3)_3$.

1. Draw Lewis structures for NOF_3 and $NO(CH_3)_3$.
2. It was proposed that NOF_3 has a resonance form of $[NOF_2]^+F^-$. Draw a Lewis structure for this “ionic” form of NOF_3 and explain how the structure is consistent with the observed N–O distance.

Chemists can use the octet rule to predict the structures of new compounds to synthesize. Draw Lewis structures showing all resonance forms for the hypothetical compound ClSeNSO, where the atoms are connected in the order they are written.

Aromatic rings can connect to make larger molecules. The skeletal structures of two such molecules are shown in Figure P8.88. Draw Lewis structures for both molecules, showing all resonance forms.



(a) (b)

FIGURE P8.88

Formal Charge: Choosing among Lewis Structures

Concept Review

Describe how formal charges are used to choose between possible molecular structures.

How do the electronegativities of elements influence the selection of which Lewis structure is favored?

In a molecule containing S and O atoms, is a structure with a negative formal charge on sulfur more likely to contribute to bonding than an alternative structure with a negative formal charge on oxygen? Explain.

In a cation containing N and O, why do Lewis structures with a positive formal charge on nitrogen contribute more to the actual bonding in the molecule than do those structures with a positive formal charge on oxygen?

Problems

Hydrogen isocyanide (HNC) has the same elemental composition as hydrogen cyanide (HCN), but the H atom in HNC is bonded to the nitrogen atom. Draw a Lewis structure for HNC and assign formal charges to each atom. How do the formal charges on the atoms differ in the Lewis structures for HCN and HNC?

Molecules in Interstellar Space Hydrogen cyanide (HCN) and cyanoacetylene (HC_3N) have been detected in the interstellar regions of space and in comets close to Earth (Figure P8.94). Draw Lewis structures for these molecules and assign formal charges to each atom. The hydrogen atom is bonded to the carbon atom in both cases.

FIGURE P8.94

Origins of Life The discovery of polyatomic organic molecules such as cyanamide (H_2NCN) in interstellar space has led some scientists to believe that the molecules from which life began on Earth may have come from space. Draw Lewis structures for cyanamide and select the preferred structure based on formal charges.

Nitromethane (CH_3NO_2) reacts with hydrogen cyanide to produce $CNNO_2$ and CH_4:

$$HCN(g) + CH_3NO_2(g) \rightarrow CNNO_2(g) + CH_4(g)$$

1. Draw Lewis structures for CH_3NO_2, showing all resonance forms.
2. Draw Lewis structures for $CNNO_2$, showing all resonance forms, based on the two possible skeletal structures shown in Figure P8.96. Assign formal charges, and predict which structure is more likely to exist.
3. Are the two structures of $CNNO_2$ resonance forms of each other?

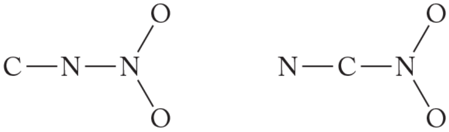


FIGURE P8.96

The formaldehyde molecule contains one carbon atom, one oxygen atom, and two hydrogen atoms. Lewis structures can be drawn that have either carbon or oxygen as the central atom.

1. Draw these structures and use formal charges to predict the more likely structure for formaldehyde.
2. Are the two structures you drew resonance forms of each other?

Draw all resonance forms of S_4N^- and assign formal charges. The atoms are arranged as SSNSS.

Nitrogen is the central atom in molecules of nitrous oxide (N_2O). Draw Lewis structures for another possible arrangement: N—O—N. Assign formal charges and suggest a reason that this structure is *un*likely to be stable.

Use formal charges to determine which resonance form of each of the following ions is preferred: (a) CNO^-; (b) NCO^-; (c) CON^-.

Exceptions to the Octet Rule

Concept Review

Are all odd-electron molecules exceptions to the octet rule?

Describe the factors that contribute to the stability of structures in which the central atoms have more than eight valence electrons.

Why do C, N, O, and F atoms in covalently bonded molecules and ions have no more than eight valence electrons?

Do atoms with $Z > 12$ *always* expand their valence shell? Explain your answer.

Problems

In which of the following molecules does the sulfur atom have more than eight valence electrons? (a) SF_6; (b) SF_5; (c) SF_4; (d) SF_2

In which of the following molecules does the phosphorus atom have more than eight valence electrons? (a) $POCl_3$; (b) PF_5; (c) PF_3; (d) P_2F_4 (which has a P—P bond)

How many electrons are there in the covalent bonds surrounding the central atom in the following species? (a) $(CH_3)_3Al$; (b) B_2Cl_4; (c) SO_3; (d) SF_5^-

How many electrons are there in the covalent bonds surrounding the central atom in the following species? (a) $POCl_3$; (b) $InCl_5^{2-}$; (c) FBO; (d) PF_4^-

Draw Lewis structures for NOF_3 and POF_3 in which the group 15 element is the central atom and the other atoms are bonded to it. What differences are there in the types of bonding in these molecules?

The phosphate anion is common in minerals. The corresponding nitrogen-containing anion, NO_4^{3-}, is unstable but can be prepared by reacting sodium nitrate with sodium oxide at 300°C. Draw Lewis structures for each anion. What are the differences in bonding between these ions?

Dissolving NaF in selenium tetrafluoride (SeF_4) produces $NaSeF_5$. Draw Lewis structures for SeF_4 and SeF_5^-. In which structure does Se have more than eight valence electrons?

Reaction between NF_3, F_2, and SbF_3 at 200°C and 100 atm pressure gives the ionic compound NF_4SbF_6:

$NF_3(g) + 2\ F_2(g) + SbF_3(g) \rightarrow NF_4SbF_6(s)$

Draw Lewis structures for the ions in this product.

Ozone Depletion The compound Cl_2O_2 plays a role in ozone depletion in the stratosphere, where it serves as a reservoir of Cl atoms that catalyze the destruction of O_3. Draw a Lewis structure for Cl_2O_2 based on the arrangement of atoms in Figure P8.113. Does either of the chlorine atoms in the structure have more than eight valence electrons?

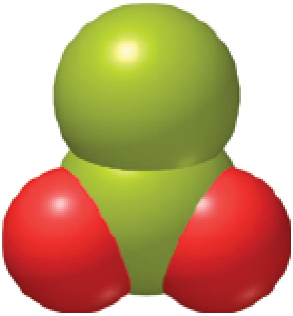

FIGURE P8.113

Trimethylaluminum reacts with dimethylamine, $(CH_3)_2NH$, forming methane and $Al_2(CH_3)_4[N(CH_3)_2]_2$ by the following balanced chemical equation:

$2\ (CH_3)_3Al + 2\ HN(CH_3)_2 \rightarrow 2\ CH_4 + Al_2(CH_3)_4[N(CH_3)_2]_2$

Draw the Lewis structures for the reactants and products. Must any of these structures contain atoms with fewer than eight valence electrons?

Which of the following chlorine oxides are odd-electron molecules? (a) Cl_2O_7; (b) Cl_2O_6; (c) ClO_4; (d) ClO_3; (e) ClO_2

Which of the following nitrogen oxides are odd-electron molecules? (a) NO; (b) NO_2; (c) NO_3; (d) N_2O_4; (e) N_2O_5

Which of the Lewis structures in Figure P8.117 contributes most to the bonding in CNO?

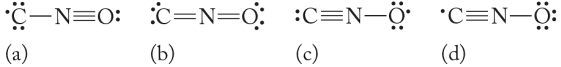

FIGURE P8.117

Which of the Lewis structures in Figure P8.118 are *un*likely to contribute to the bonding in NCO?

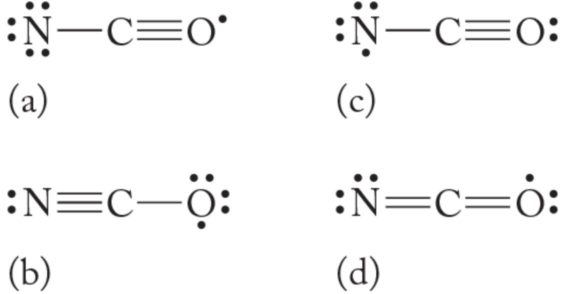

FIGURE P8.118

Using Lewis structures, explain why dimethylaluminum chloride is more likely to exist as $(CH_3)_4Al_2Cl_2$ than as $(CH_3)_2AlCl$.

Some have argued that SF_6 has ionic resonance forms that do not require more than eight valence electrons for S. Draw a resonance structure consistent with this hypothesis and assign formal charges to each atom. Is this resonance form better than or the same as the one with more than eight valence electrons?

When left at room temperature, mixtures of BF_3 and BCl_3 are found to contain significant amounts of BF_2Cl and $BFCl_2$. Use Lewis structures to explain the origin of the latter two compounds.

Reaction between $[XeF]^+[Sb_2F_{11}]^-$ and Xe in SbF_5 yields a product containing a bright blue $[Xe_4]^+$ cation with a linear arrangement of four Xe atoms (Figure P8.122).

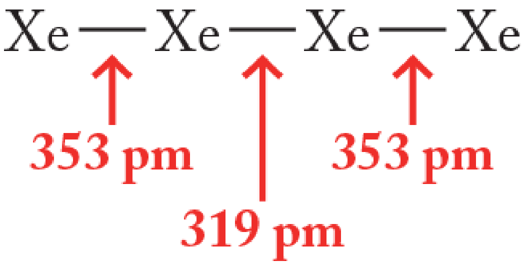

FIGURE P8.122

1. How many valence electrons are in XeF^+?
2. Draw Lewis structures for Xe_4^+, including any resonance forms.
3. How do the calculated bond distances help you choose between the resonance forms for Xe_4^+?

The Lengths and Strengths of Covalent Bonds

Concept Review

Do you expect the nitrogen–oxygen bond length in the nitrate ion to be the same as in the nitrite ion? Explain.

Why is the oxygen–oxygen bond length in O_3 different from the one in O_2?

Explain why the nitrogen–oxygen bond lengths in N_2O_4 (which has a nitrogen–nitrogen bond) and N_2O are nearly identical (118 and 119 pm, respectively).

Do you expect the sulfur–oxygen bond lengths in SO_3^{2-} and SO_4^{2-} ions to be about the same? Why?

Rank NO_2^-, NO^+, and NO_3^- in order of (a) increasing nitrogen–oxygen bond lengths and (b) increasing bond energies.

Rank CO, CO_2, and CO_3^{2-} in order of (a) increasing carbon–oxygen bond lengths and (b) increasing bond energies.

Do you expect the boron–fluorine bond energy to be the same in BF_3 and F_3BNH_3?

The boron–oxygen distances in the BO_2^+ cation are equal. Does this mean the bond order of the B—O bond is two? Explain.

Why must the stoichiometry of a reaction be known to estimate the enthalpy change from bond energies?

Why must the structures of the reactants and products be known to estimate the enthalpy change of a reaction from bond energies?

When calculating the enthalpy change for a chemical reaction by using bond energies, why is it important to know the phase (solid, liquid, or gaseous) for every compound in the reaction?

If the energy needed to break 2 moles of C□O bonds is greater than the sum of the energies needed to break the O□O bonds in 1 mole of O_2 and vaporize 1 mole of carbon, why does the combustion of pure carbon release heat?

Problems

Note: Use the average bond energies in Table 8.3 to answer Problems 8.135 through 8.146.

Use average bond energies to estimate the enthalpy changes of the following reactions:

$N_2(g) + 13\ H_2(g) \rightarrow 2\ NH_3(g)$
$N_2(g) + 22\ H_2(g) \rightarrow H_2NNH_2(g)$
$2\ N_2(g)\ 3.\ O_2(g) \rightarrow 2\ N_2O(g)$

Use average bond energies to estimate the enthalpy changes of the following reactions:

$CO_2(g)\ +1.\ H_2(g) \rightarrow H_2O(g) + CO(g)$

$N_2(g) + 2O_2(g) \rightarrow 2\ NO(g)$
$C(s) + CO_2(g) \rightarrow 2\ CO(g)$

(*Hint*: The enthalpy of sublimation of graphite, C(*s*), is 719 kJ/mol.)

The combustion of CO to CO_2 releases 283 kJ/mol. What is the bond energy of the carbon–oxygen bond in carbon monoxide?

Use average bond energies to estimate the standard enthalpy of formation of HF gas.

Estimate how much less energy is released during the incomplete combustion of 1 mole of methane to carbon monoxide and water vapor than in the complete combustion to carbon dioxide and water vapor.

Estimate how much more energy is released by the reaction

$C(s) + O_2(g) \rightarrow CO_2(g)$

than by the reaction

$C(s) + \frac{1}{2} O_2(g) \rightarrow CO(g)$

Estimate ΔH_{rxn} for the following reaction:

$4\ NH_3(g) + 7\ O_2(g) \rightarrow 4\ NO_2(g) + 6\ H_2O(g)$

The value of ΔH_{rxn} for the reaction

$2\ H_2S(g) + 3\ O_2(g) \rightarrow 2\ SO_2(g) + 2\ H_2O(g)$

is $-$ 1036 kJ. Estimate the energy of the bonds in SO_2.

A molecular view of the combustion of CS_2 is shown in Figure

P8.143. If the standard enthalpy of combustion of CS_2 is − 1102 kJ/mol, what is the average bond energy for the carbon–sulfur bonds in CS_2?

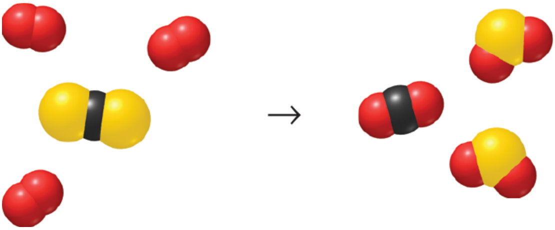

FIGURE P8.143

The standard enthalpy of reaction for the decomposition of carbon oxysulfide (COS) to CO_2 and CS_2, as shown in Figure P8.144, is − 1.9 kJ/mol. Are the apparent bond energies of the carbon–sulfur and carbon–oxygen bonds in COS stronger or weaker than in CS_2 and CO_2, respectively?

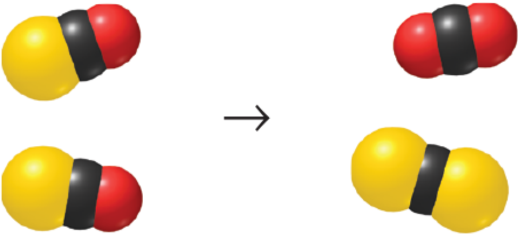

FIGURE P8.144

Carbon and oxygen form three oxides: CO, CO_2, and carbon suboxide (C_3O_2).

1. Draw a Lewis structure for C_3O_2 in which the three carbon atoms have this bonding arrangement: C—C—C.
2. Predict whether the carbon–oxygen bond lengths in the carbon suboxide molecule are equal.

Spectroscopic analysis of the linear molecule N_4O reveals that the nitrogen–oxygen bond length is 135 pm and that there are three nitrogen–nitrogen bond lengths: 148, 127, and 115 pm. Draw the Lewis structure for N_4O that is consistent with these observations.

Additional Problems

Why do we draw the Lewis symbol for the potassium ion without any “dots” to represent electrons?

Based on the Lewis symbols in Figure P8.148, predict to which group in the periodic table each element X belongs.

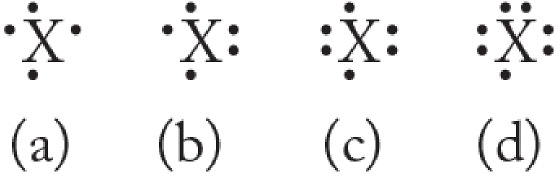

FIGURE P8.148

Use formal charges to predict whether the atoms in carbon disulfide are arranged as CSS or SCS.

HClO, $HClO_2$, and $HClO_3$ represent a family of weak acids. Draw their Lewis structures, using formal charges to predict the best arrangement of atoms. Show any resonance forms of the molecules.

Chemical Weapons Phosgene is a poisonous gas first used in chemical warfare during World War I. It has the formula $COCl_2$ (C is the central atom).

1. Draw its Lewis structure.
2. Phosgene kills because it reacts with water in nasal passages, in the lungs, and on the skin to produce carbon dioxide and hydrogen chloride. Write a balanced chemical equation for this process, showing the Lewis structures for the reactants and products.

The dinitramide anion [$N(NO_2)_2{}^-$] was first isolated in 1996. The arrangement of atoms in $N(NO_2)_2{}^-$ is shown in Figure P8.152.

1. Complete the Lewis structure for $N(NO_2)_2{}^-$, including any

resonance forms, and assign formal charges.

2. Explain why the nitrogen–oxygen bond lengths in $N(NO_2)_2^-$ and N_2O should (or should not) be similar.
3. $N(NO_2)_2^-$ was isolated as $[NH_4^+][N(NO_2)_2^-]$. Draw the Lewis structure for NH_4^+.

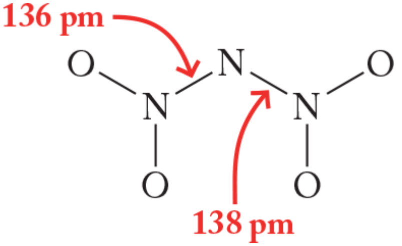

FIGURE P8.152

Sulfonylamine ($HNSO_2$) was first prepared in 2016. The two arrangements for the atoms are shown in Figure

P8.153.

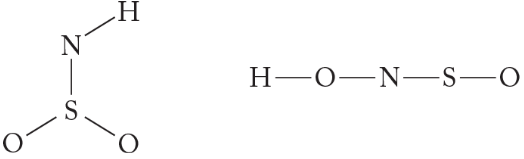

FIGURE P8.153

1. Complete the Lewis structures for each arrangement, including any resonance forms.
2. Do the two arrangements lead to the same S–N bond order?
3. Which arrangement might you expect based on formal charges?
4. Predict an approximate S–O bond length for the two arrangements.

Sulfonylazide (HSO_3N_3) was first reported in 2016. Using the arrangement of the atoms shown in Figure P8.154, draw Lewis structures for HSO_3N_3 with

1. all atoms except H with a complete octet.
2. the lowest formal charges on sulfur.

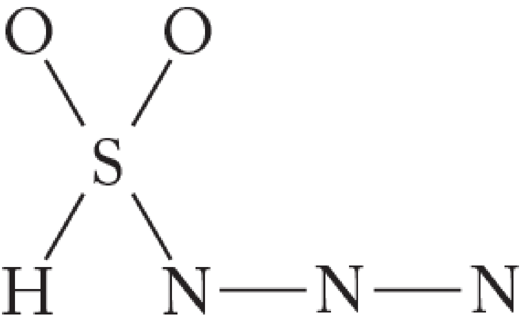

FIGURE P8.154

A compound with the formula Cl_2O_6 decomposes to a mixture of ClO_2 and ClO_4. Draw two Lewis structures for Cl_2O_6: one with a chlorine–chlorine bond and one with a Cl—O—Cl arrangement of atoms. Draw a Lewis structure for ClO_2.

$Cl_2O_6 \rightarrow ClO_2 + ClO_4$

Dichlorine heptoxide (Cl_2O_7) decomposes by the following reaction:

$Cl_2O_7 \rightarrow ClO_4 + ClO_3$

1. Draw two Lewis structures for Cl_2O_7: one with a chlorine–chlorine bond and one with a Cl—O—Cl arrangement of atoms.
2. Draw a Lewis structure for ClO_3.

The odd-electron molecule CN dimerizes to give cyanogen (C_2N_2).

1. Draw a Lewis structure for CN and predict which arrangement for cyanogen is more likely: NCCN or CNNC.
2. Cyanogen reacts slowly with water to produce oxalic acid ($H_2C_2O_4$) and ammonia; the Lewis structure for oxalic acid is shown in Figure P8.157. Compare this structure with your answer in part (a). When the actual structures of molecules have been defined experimentally, the structures have been

used to refine Lewis structures. Does this structure increase your confidence that the structure you selected in part (a) may be the better one?

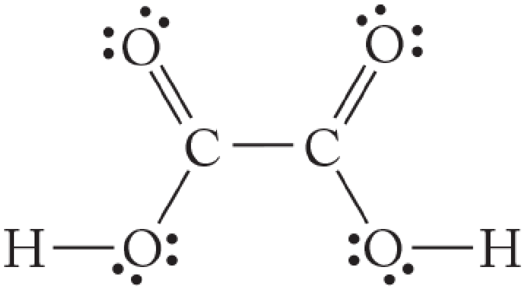

FIGURE P8.157

Draw all resonance forms for the molecules NSF and HBS where S and B are the central atoms, respectively. Include possible ionic structures for NSF.

The molecular structure of sulfur cyanide trifluoride (SF_3CN) has been shown to have the arrangement of atoms with the bond lengths indicated in Figure P8.159. Complete the Lewis structure for SF_3CN and assign formal charges.

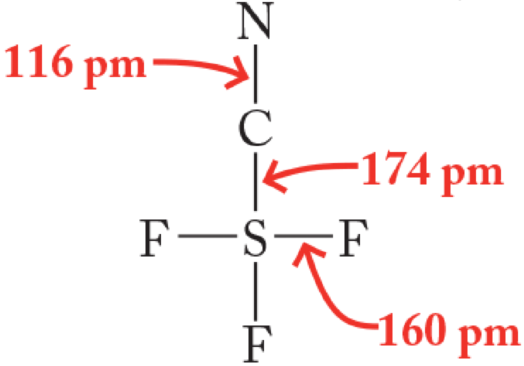

FIGURE P8.159

Strike-Anywhere Matches Heating phosphorus with sulfur gives P_4S_3, a solid used in the heads of strike-anywhere matches (Figure P8.160). P_4S_3 has the Lewis structure framework shown. Complete the Lewis structure so that each atom has the optimal formal charge.

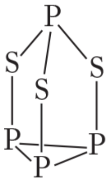

FIGURE P8.160

The heavier group 16 elements can expand their valence shell. The $TeOF_6^{2-}$ anion was first prepared in 1993. Draw the Lewis structure for $TeOF_6^{2-}$.

Sulfur in the Environment Sulfur is cycled in the environment through compounds such as dimethyl sulfide (CH_3SCH_3), hydrogen sulfide (H_2S), and the sulfite and sulfate ions. Draw Lewis structures for these four species. Are more than eight valence electrons needed to minimize the formal charges for any of these species?

How many pairs of electrons does xenon share in the following molecules and ions? (a) XeF_2; (b) $XeOF_2$; (c) XeF^+; (d) XeF_5^+; (e) XeO_4

Consider a hypothetical structure of ozone that is cyclic (the atoms form a ring) such that its three O atoms are at the corners of a triangle. Draw the Lewis structure for this molecule.

Bond lengths and electrostatic potential mapping provide experimental evidence about covalent bonds present in a molecule. Which of these would help characterize the bonding in a compound with the formula A_2X in terms of the following?

1. distinguishing between these two bonding patterns: X—A—A and A—X—A
2. distinguishing between these resonance forms: A—X≡A, A□X□A, and A≡X—A

Explosive Cation The highly explosive linear N_5^+ cation was first isolated in 1999 by reaction of N_2F^+ with HN_3:

$N_2F^+ + HN_3 \rightarrow N_5^+ + HF$

Draw the Lewis structures for the reactants and products, including all resonance forms.

Jupiter's Atmosphere The ionic compound NH_4SH was detected in the atmosphere of Jupiter (Figure P8.167) by the *Galileo* space probe in 1995. Draw the Lewis structure for NH_4SH. Why couldn't there be a covalent bond between the nitrogen and sulfur atoms, making NH_4SH a molecular compound?

FIGURE P8.167

Antacid Tablets Antacids commonly contain calcium carbonate, magnesium hydroxide, or both. Draw the Lewis structures for calcium carbonate and magnesium hydroxide.

A *cyclic* polynitrogen anion, N_5^-, can be trapped as a salt with Co^{2+}.

1. Draw Lewis structures for N_5^-, including all resonance forms.
2. Predict the N□N bond order and estimate the N—N bond distance.

Draw Lewis symbols for $B(CN)_3^-$, $B(CN)_4^-$, and $B_2(CN)_6^{2-}$. $B_2(CN)_6^{2-}$ contains a B—B bond. Do all three molecular ions follow the octet rule?

Draw a Lewis structure for $AlFCl_2$, the second product in the synthesis of Cl_2O_2 in the following reaction:

$$FClO_2(g) + AlCl_3(s) \rightarrow Cl_2O_2(g) + AlFCl_2(s)$$

Draw Lewis structures for BF_3 and $(CH_3)_2BF$. The B—F distance in both molecules is the same (130 pm). Does this observation support the argument that all the boron–fluorine bonds in BF_3 are single bonds?

Which of the following molecules and ions contains an atom with more than eight valence electrons? (a) Cl_2; (b) ClF_3; (c) ClI_3; (d) ClO^-

Which of the following molecules contains an atom with more than eight valence electrons? (a) XeF_2; (b) $GaCl_3$; (c) ONF_3; (d) SeO_2F_2

A *linear* polynitrogen anion, N_5^-, was isolated for the first time in 1999.

1. Draw the Lewis structures for four resonance forms of linear N_5^-.
2. Assign formal charges to the atoms in the structures in part (a) and identify the structures that contribute the most to the bonding in N_5^-.

3. Compare the Lewis structures for N_5^- and N_3^-. In which ion do the nitrogen–nitrogen bonds have the higher average bond order?

Carbon tetroxide (CO_4) was discovered in 2003.

1. Draw the Lewis structure for CO_4, assuming the atoms are arranged as shown in Figure P8.176.

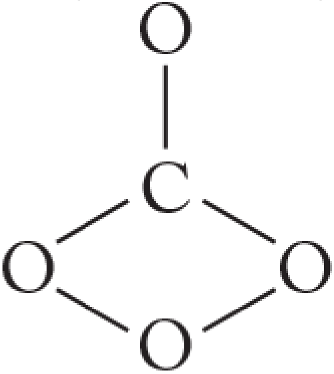

FIGURE P8.176

2. Are there any resonance forms for the structure you drew that have zero formal charges on all atoms?
3. Can you draw a structure in which all four oxygen atoms in CO_4 are bonded to carbon?

Plot the electronegativities of elements with $Z = 3$ to 9 (y-axis) versus their first ionization energies (x-axis). Is the plot linear? Use your graph to predict the electronegativity of neon, whose first ionization energy is 2080 kJ/mol.

Use the data in Figures 7.39 and 8.9 to plot electronegativity as a function of first ionization energy for the main group elements of the fifth row of the periodic table. From this plot estimate the electronegativity of xenon, whose first ionization energy is 1170 kJ/mol.

The cation N_2F^+ is isoelectronic with N_2O.

1. What does it mean to be isoelectronic?
2. Draw the Lewis structure for N_2F^+. (*Hint*: The molecule

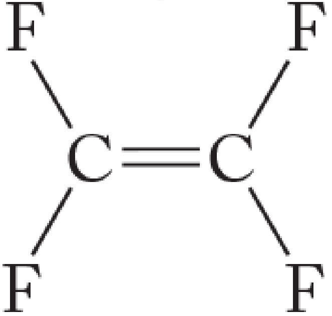
contains a nitrogen–nitrogen bond.)

3. Which atom has the +1 formal charge in the structure you drew in part (b)?
4. Does N_2F^+ have resonance forms?
5. Could the middle atom in the N_2F^+ ion be a fluorine atom? Explain your answer.

Ozone Depletion Methyl bromide (CH_3Br) is produced naturally by fungi. Methyl bromide has also been used in agriculture as a fumigant, but this use is being phased out because the compound has been linked to ozone depletion in the upper atmosphere.

1. Draw the Lewis structure for CH_3Br.
2. Which bond in CH_3Br is more polar, carbon–hydrogen or carbon–bromine?

All the carbon–fluorine bonds in tetrafluoroethylene (Figure P8.181) are polar, but experimental results show that the molecule is nonpolar. Draw arrows on each bond to show the direction of polarity and suggest a reason why the molecule is nonpolar overall.



Tetrafluoroethylene **FIGURE P8.181**

Atoms of Xe have complete octets, yet the compound XeO_2 exists.

How is this possible?

Free radicals increase in stability, and hence decrease in reactivity, if they have more than one atom in their structure that can carry the unpaired electron.

1. Draw Lewis structures for the three free radicals formed from CF_2Cl_2 in the stratosphere—ClO, Cl, and CF_2Cl—and use this principle to rank them in order of reactivity.
2. Free radicals are “neutralized” when they react with each other, forming an electron pair (a single covalent bond) between two atoms. This is called a *termination reaction* because it shuts down any reaction that was powered by the free radical. Predict the formula of the molecules that are produced when the chlorine free radical reacts with each of the free radicals in part (a).

Glossary

ionic bond

a chemical bond that results from the electrostatic attraction between a cation and an anion.

metallic bond

a chemical bond consisting of metal atoms sharing a “sea” of electrons.

Lewis symbol (also called Lewis dot symbol)

a system in which the chemical symbol for an element is surrounded by one or more dots representing each of its atom’s valence electrons.

bonding capacity

the number of covalent bonds an atom forms to have an octet of electrons in its valence shell.

octet rule

the tendency of atoms of main group elements to make bonds by gaining, losing, or sharing electrons to achieve a valence shell containing eight electrons (i.e., four electron pairs).

Lewis structure

a two-dimensional representation of the bonds and lone pairs of valence electrons in a molecule or polyatomic ion.

lone pair

a pair of valence electrons that is not shared.

single bond

a chemical bond that results when two atoms share one pair of electrons.

double bond

a chemical bond in which two atoms share two pairs of electrons.

triple bond

a chemical bond in which two atoms share three pairs of electrons.

polar covalent bond

a bond characterized by unequal sharing of bonding pairs of electrons between atoms.

bond polarity

a measure of the extent to which bonding electrons are unequally shared.

electronegativity

a relative measure of the ability of an atom to attract electrons in a bond to itself.

resonance structure

one of two or more Lewis structures with the same arrangement of atoms but different arrangements of bonding pairs of electrons.

formal charge (FC)

a value calculated for an atom in a molecule or polyatomic ion by determining the difference between the number of valence electrons in the free atom and the sum of lone-pair electrons plus half of the electrons in the atom’s bonding pairs.

free radical

an odd-electron molecule with an unpaired electron in its Lewis structure.

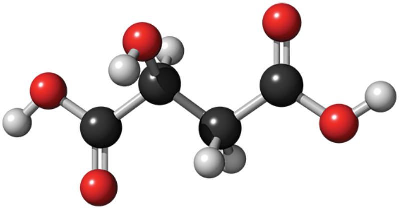
bond order

the number of bonds between atoms: 1 for a single bond, 2 for a double bond, and 3 for a triple bond.

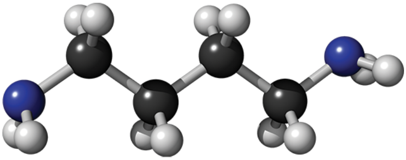
bond energy

the energy needed to break 1 mole of a covalent bond in a molecule or in a polyatomic ion in the gas phase.

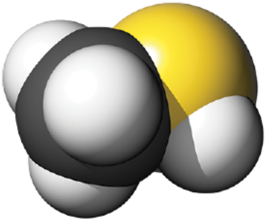
CILANTRO IS A FRAGRANT HERB Its flavor appeals to many people, but to others it tastes like soap. These very different tastes can be attributed to genetic differences in how the shapes of molecules fit into biomolecular sites that send signals to the region of the brain that interprets taste.



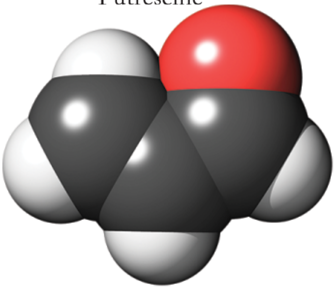
Malic acid



Putrescine



Methyl mercaptan,
present in human "bad breath"



Acrolein,
present in smoky barbeque

Molecular Geometry
Shape Determines Function

PARTICULATE REVIEW

Smelly Molecules and Functional Groups

In Chapter 9 we explore the connection between molecular shape and properties such as taste and smell. Two molecules with very different smells are shown here. Malic acid is responsible for the smell and taste of apples, whereas putrescine is the smell associated with rotting flesh in a cadaver.

- What is the molecular formula for malic acid?
- What is the molecular formula for putrescine?
- Identify the functional groups present in both molecules.

  (Review Section 2.8 if you need help.)

(Answers to Particulate Review questions are in the back of the book.)

PARTICULATE PREVIEW

Smelly Molecules and Shapes

Your ability to detect a substance by smell depends on its elemental composition and on the shape of its molecules. As you read Chapter 9, look for ideas that will help you answer these questions about the shapes of the molecules shown here:

- Draw Lewis structures for both methyl mercaptan and acrolein.

- What are the approximate bond angles around the sulfur and carbon atoms in methyl mercaptan and around the central carbon atom in acrolein?
- Are either or both molecules planar; that is, do all their atoms lie in one plane?

Learning Outcomes

- LO1 Use VSEPR and the concept of steric number to predict the bond angles in molecules and the shapes of molecules with one central atom

  Sample Exercises 9.1, 9.2, 9.3

- LO2 Predict whether a substance is polar or nonpolar based on its molecular structure

  Sample Exercise 9.4

- LO3 Use atomic orbital hybridization and valence bond theory to explain orbital overlap, bond angles, and molecular shapes

  Sample Exercises 9.5, 9.6, 9.8

- LO4 Draw condensed and skeletal structures of organic compounds

  Sample Exercise 9.7

- LO5 Identify molecular structures that are stabilized by delocalized π electrons
- LO6 Recognize chiral molecules
- LO7 Draw molecular orbital (MO) diagrams of diatomic molecules and use MO theory to predict bond order and to explain magnetic properties and spectra

  Sample Exercises 9.9, 9.10, 9.11

- LO8 Use MO theory to describe metallic bonding and the properties of doped and undoped semiconductors

  Sample Exercise 9.12

FIGURE 9.1 The Lewis structure of CO_2 matches its true molecular structure, but the Lewis structure of CH_4 does not because the C—H bonds in CH_4 extend in three dimensions.

9.1 Biological Activity and Molecular Shape

Hold your hands out in front of you, palms up, fingers extended. Now rotate your wrists inward so that your thumbs point straight up. Your right hand looks the same as the image your left hand makes in a mirror. Does that mean your two hands have the same shape? If you have ever tried to put your right hand in a glove made for your left, you know that they do not have the same shape. Many other objects in our world have a “handedness” about them, from headphones to scissors to golf clubs to shoes.

This chapter focuses on the importance of shape at the molecular level. For example, the compound that produces the refreshing aroma of spearmint has the molecular formula $C_{10}H_{14}O$. The compound responsible for the musty aroma of caraway seeds has the same molecular formula *and* the same Lewis structure. To understand how two compounds can be so much alike and still have different properties, we must consider their structures in three dimensions.

We perceive a difference in aromas in part because each molecule has a unique site where it attaches to our nasal membranes. Just as a left hand only fits a left glove, the spearmint molecule fits only the spearmint-shaped site, and the caraway molecule fits only the caraway-shaped site. This behavior, called molecular recognition, enables biomolecular structures such as nasal membranes to recognize and react when a molecule with a particular shape fits into a part of the structure known as an *active site*. Many of the substances we ingest, from food to pharmaceuticals, exert physiological effects because their molecules are recognized by and become bound to active sites in biomolecules.

The shape of a compound’s molecules can affect many of its properties, such as its physical state at room temperature, its solubility in water and other solvents, its aroma, its biological activity, and its reactivity with other compounds. In Chapter 8 we drew Lewis structures to describe bonding in molecules, but Lewis structures are only two-dimensional representations of how atoms and the electron pairs that surround them are arranged in molecules. Lewis structures show how atoms are connected in molecules, but they do not show how the atoms are arranged in three dimensions, nor do they necessarily show the overall shape of the molecules.

To illustrate this point, consider the Lewis structures and ball-and-stick models of carbon dioxide and methane (**Figure 9.1**). The linear arrangement of atoms and bonding electrons in the Lewis structure for CO_2 corresponds to the actual linear shape of the molecule, as represented by the ball-and-stick model. The angle between the two C□O bonds is 180°, just as in the Lewis structure. The Lewis structure of methane, on the other hand, does not convey the true three-dimensional orientation of the four C—H bonds in each molecule. The 90° angles between bonds in the planar Lewis structure are not close to the three-dimensional H—C—H bond angles of 109.5°.

Several theories of covalent bonding account for and predict the shapes of molecules. In this chapter we begin by examining small molecules with single central atoms, and we gradually apply these theories to larger molecules. We start with the shared pairs and lone pairs of electrons described by Lewis theory and then predict how those pairs should be oriented about a central atom to minimize their interactions and produce the most stable molecular structure. As we will see, each theory accurately predicts electron-pair orientations, molecular shapes, and the properties of molecular compounds.

Glossary

bond angle

the angle (in degrees) defined by lines joining the centers of two atoms to the center of a third atom to which they are chemically bonded.

$$\text{SN} = \begin{pmatrix}\text{number of atoms}\\ \text{bonded to central atom}\end{pmatrix} + \begin{pmatrix}\text{number of lone pairs}\\ \text{on central atom}\end{pmatrix} \quad (9.1)$$

FIGURE 9.2 Electron-pair geometries depend on the steric number (SN) of the central atom. In these images, there are no lone pairs of electrons on the central atoms (red dots), so the molecular geometries are the same as the electron-pair geometries. The images show bond angles for different numbers of atoms located on the surface of a sphere and bonded to an atom at the center of the sphere. The blue lines define the geometric forms that give the

molecular shapes their names. Parts (b) and (d) show spheres rotated 90° so the equatorial plane is clearly visible.

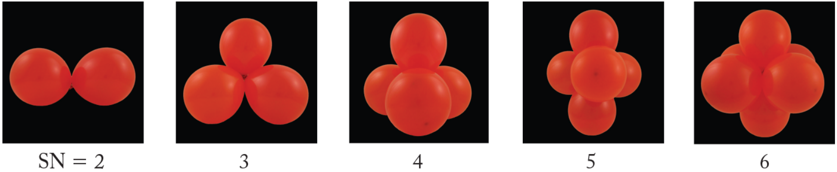

FIGURE 9.3 Balloons charged with static electricity repel each other and align themselves as far apart as possible when tied together. In doing so, they mimic the locations of electron pairs about a central atom. Each balloon represents one electron pair. Note the similarities between the balloons and the diagrams in Figure 9.2.

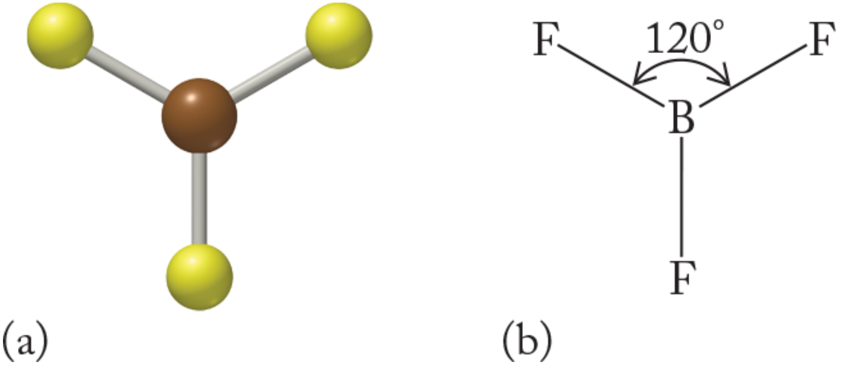

FIGURE 9.4 (a) The ball-and-stick model of BF_3 shows the orientation of the atoms. (b) All F—B—F bond angles are 120° in this trigonal planar molecular geometry.

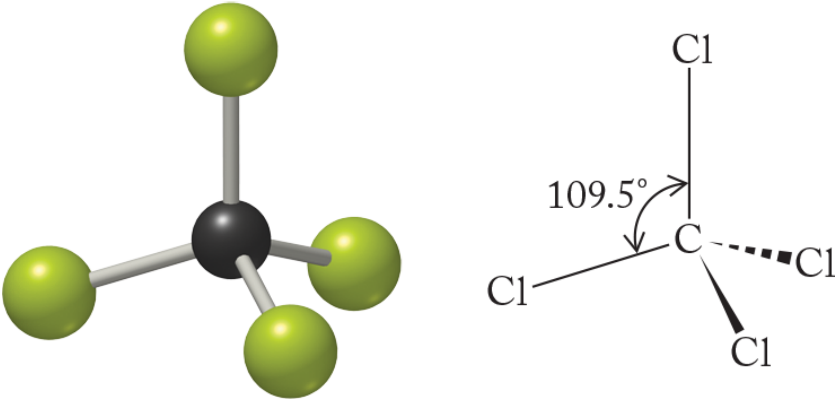

FIGURE 9.5 The ball-and-stick model shows the actual orientation of the atoms in carbon tetrachloride in three dimensions. All Cl—C—Cl bond angles are 109.5° in this tetrahedral molecular

geometry.

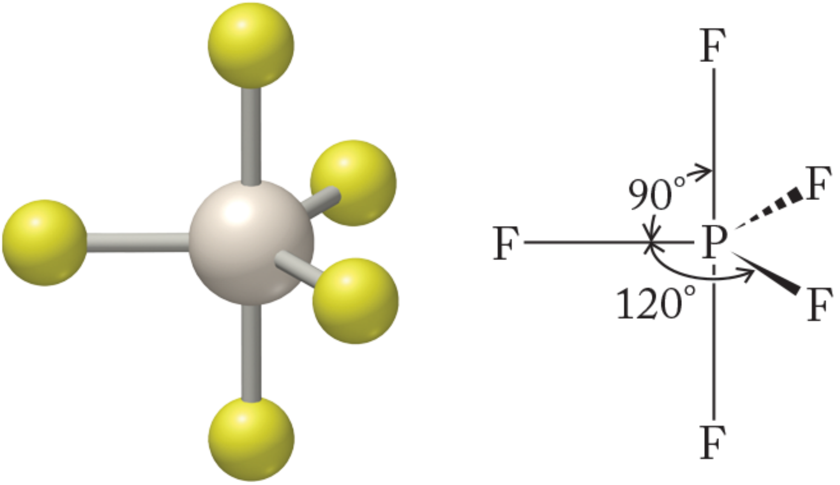

FIGURE 9.6 The ball-and-stick model shows the actual orientation of the atoms in phosphorus pentafluoride. The P–F bonds located around the equator of the imaginary sphere are 120° apart. Each of them is 90° from the two bonds connecting F atoms in the axial positions (at the north and south poles). The resulting molecular geometry is trigonal bipyramidal.

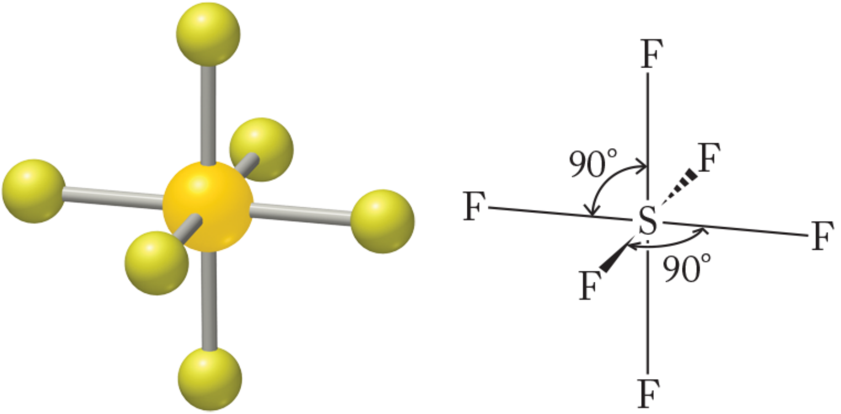

FIGURE 9.7 The ball-and-stick model of SF_6 shows how the six fluorine atoms are oriented in three dimensions about the sulfur atom. All the F–S–F bond angles are 90° in this octahedral

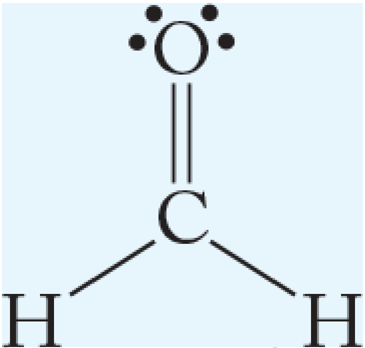
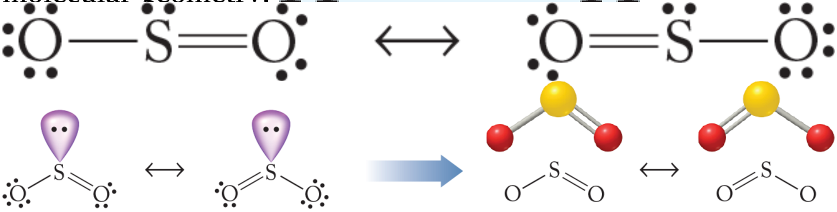
molecular geometry.

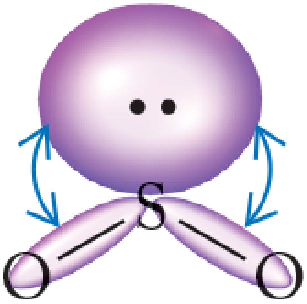




(a) Electron-pair geometry = trigonal planar

(b) Molecular geometry = bent

FIGURE 9.8 (a) The electron-pair geometry of SO_2 is trigonal planar because the steric number of the S atom is 3; it is bonded to two atoms and has one lone pair of electrons. (b) The molecular geometry is bent because the central sulfur atom in the structure has no bonded atom in the third position, only a lone pair of electrons.



O—S—O bond angle < 120°

FIGURE 9.9 The lone pair of electrons on the central sulfur atom in SO_2 occupies more space (larger purple region) than the electron pairs in the S□O bonds (smaller purple regions). The increased repulsion (represented by the double-headed arrows), resulting from the larger volume occupied by the lone pair, forces the oxygen

atoms closer together, making the O□S□O bond angle slightly less than the ideal value of 120°.

9.2 Valence-Shell Electron-Pair Repulsion (VSEPR) Theory

Valence-shell electron-pair repulsion (VSEPR) theory is based on a fundamental chemical principle—namely, electrons have negative charges and repel each other. VSEPR theory applies this principle by incorporating the assumption that pairs of valence electrons are arranged about central atoms in ways that minimize repulsions between the pairs. To predict molecular shape by using VSEPR theory, we must consider two things:

- Electron-pair geometry, which defines the relative positions in three-dimensional space of all the bonding pairs and lone pairs of valence electrons on the central atom
- Molecular geometry, which defines the relative positions in three-dimensional space of the atoms in a molecule

The electron-pair geometry of a molecule may or may not be the same as its molecular geometry. The presence of lone pairs on the central atom makes the difference. To accurately predict molecular geometry, we first need to know the electron-pair geometry. If there are no lone pairs of electrons, then the process is simplified because the electron-pair geometry *is* the molecular geometry. Let's begin with this simple case and consider the shapes of molecules that have various numbers of bonds around a central atom and no lone pairs on the central atom.

CONCEPT TEST

In your own words, explain how electron-pair geometry and molecular geometry are related and how they are different.

(Answers to Concept Tests are in the back of the book.)

Central Atoms with No Lone Pairs

To determine the geometry of a molecule, we start by drawing its Lewis structure. From the Lewis structure, we determine the steric number (SN) of the central atom, which is the sum of the number of atoms bonded to that atom and the number of lone pairs in its valence shell:

Because we are focused on molecules in which the central atom has *no* lone pairs, the steric number equals the number of atoms bonded to the central atom. In evaluating the shapes of these molecules, we generate five common shapes that describe both the electron-pair geometries and the molecular geometries of many covalent compounds.

Let's start by thinking of the central atom as the center of a sphere, with all the other atoms in the molecule placed on the surface of the sphere and linked to the central atom by covalent bonds. If the central atom is bonded covalently to only two other atoms, then SN = 2. How do the electron pairs in the two bonds arrange themselves to minimize their mutual repulsion? They are as far from each other as possible—on opposite sides of the sphere (**Figure 9.2a**). This gives a linear electron-pair geometry and a linear molecular geometry. The three atoms in the molecule are arranged in a straight line, and the bond angle is 180°.

If three atoms are bonded to a central atom with no lone pairs, then SN = 3. The three bonding pairs are as far apart as possible when they are located at the three corners of an equilateral triangle. The angle between each pair of bonds is 120° (**Figure 9.2b**). The name of this electron-pair and molecular geometry is trigonal planar.

With four atoms around the central atom and no lone pairs (SN = 4), we have the first case in which the atoms are not all in the same plane. Instead, the atoms bonded to the central atom occupy the four vertices of a tetrahedron, which is a four-sided pyramid (*tetra* is Greek, meaning "four"). The bonding pairs form bond angles of 109.5° with each other, as shown in **Figure 9.2c**. The electron-pair geometry and molecular geometry are both tetrahedral.

When five atoms are bonded to a central atom with no lone pairs, SN = 5 and the atoms occupy the five corners of two triangular pyramids that share the same base. The central atom of the molecule is in the center of the sphere at the common center of the two bases, as shown in **Figure 9.2d**. One bond points to the tip of the top pyramid, one points to the tip of the bottom pyramid, and the other three point to the three vertices of the shared triangular base. These three vertices lie along the equator of the sphere, so the atoms that occupy these sites and the bonds that connect them to the central atom are called *equatorial* atoms and bonds, which are highlighted in orange in Figure 9.2d. The bond angles between the three equatorial bonds are 120° (just as in the triangle of the trigonal planar geometry in Figure 9.2b). The bond angle between an equatorial bond and either vertical, or *axial*, bond (highlighted in green) is 90°, and the angle between the two axial bonds is 180°. A molecule in which the atoms are arranged this way is said to have a trigonal bipyramidal electron-pair and molecular geometry.

For SN = 6, picture two pyramids that have a square base (**Figure 9.2e**). Put them together, base to base, and you form a shape in which all six positions around the sphere are equivalent. We can think of the six bonds as three sets of two bonds each. The two pairs in each set are oriented at 180° to each other and at 90° to the other two sets, just like the axes of an x–y–z coordinate system. Four equatorial atoms lie at the four vertices of the common square base and are 90° apart, another atom lies at the tip of the top pyramid, and a sixth lies at the tip of the bottom pyramid. This arrangement defines octahedral electron-pair and molecular geometries.

To demonstrate a real-world analogy to the bond orientations in Figure 9.2, we start with a batch of fully inflated yellow balloons. We tie them together in clusters of two, three, four, five, and six balloons (**Figure 9.3**). Assume that all the balloons have acquired a static electrical charge, so they repel each other. If the tie points of the clusters represent the central atom in our balloon models, then the opposite ends of the balloons represent the atoms that are bonded to the central atom. Note how our clusters of two, three, four, five, and six balloons produce the same orientations that resulted from selecting points on a sphere that were as far apart as possible. The long axes of the balloons in Figure 9.3 provide an accurate representation of the bond directions in Figure 9.2.

CONNECTION We learned in Chapter 8 that some molecules have central atoms that do not have an octet of electrons. The boron atom in BF_3 shares only three pairs of electrons.

Now let’s look at five simple molecules that have no lone pairs about the central atom and apply VSEPR theory and the concept of steric number to predict their electron-pair and molecular geometries. To do so, we follow these three steps:

1. Draw the Lewis structure, including any equivalent resonance structures.
2. Determine the steric number of the central atom.
3. Use the steric number to predict the electron-pair and molecular geometries by using the images in Figure 9.2.

Example I: Carbon Dioxide (CO_2)

1. Lewis structure: 
---

2. The central carbon atom has two atoms bonded to it and no lone pairs, so the steric number is 2.
3. Because SN = 2, the O—C—O bond angle is 180° (see Figure 9.2a) and the electron-pair and molecular geometries are both linear.

Example II: Boron Trifluoride (BF_3)

1. Lewis structure: 
---

2. Three fluorine atoms are bonded to the central boron atom, and there are no lone pairs on boron. Therefore, SN = 3.
3. Because SN = 3, all four atoms lie in the same plane, forming a triangle with F—B—F bond angles of 120°. The electron-

pair and molecular geometries are trigonal planar (**Figure 9.4**).

Example III: Carbon Tetrachloride (CCl_4)

1. Lewis structure: 2. Four chlorine atoms are bonded to the central carbon atom, which gives carbon a full octet. Therefore, SN = 4.
3. Because SN = 4, the chlorine atoms are located at the vertices of a tetrahedron and all four Cl—C—Cl bond angles are 109.5°, producing tetrahedral electron-pair and molecular geometries (**Figure 9.5**).

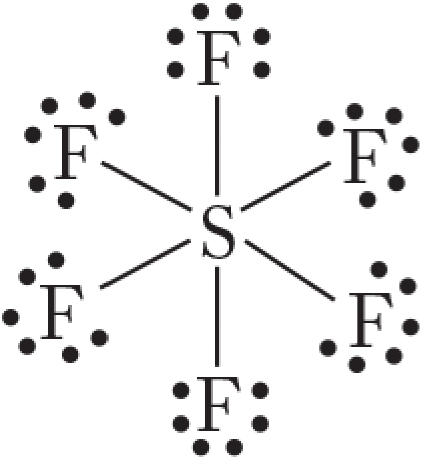
Before we explore any more molecular geometries, you need to understand the conventions used in drawing three-dimensional structures in two dimensions. To convey the three-dimensional structure of a molecule, we use a solid wedge  to indicate a bond that comes out of the page toward the viewer. The solid wedge in the CCl_4 structure in Figure 9.5, for example, means that the chlorine in that position projects out of the plane of the page and toward the viewer at a downward angle. A dashed wedge  indicates a bond that goes behind the plane of the page and away from the viewer at a downward angle. Solid lines are used for bonds that lie in the plane of the page. We typically orient a structure so that the maximum number of bonds lie in the plane of the page.

Example IV: Phosphorus Pentafluoride (PF_5)

1. Lewis structure: 
2. Five fluorine atoms are bonded to the central phosphorus atom, which has no lone pairs. Therefore, SN = 5.
3. Because SN = 5, the fluorine atoms are located at the five vertices of a trigonal bipyramid, and the electron-pair geometry and molecular geometry are trigonal bipyramidal (**Figure 9.6**).

Example V: Sulfur Hexafluoride (SF_6)

1. Lewis structure:



2. Six fluorine atoms are bonded to the central sulfur atom, which has no lone pairs. Therefore, SN = 6.
3. Because SN = 6, the fluorine atoms are located at the vertices of an octahedron and the electron-pair and molecular geometries are octahedral (**Figure 9.7**).

SAMPLE EXERCISE 9.1 Using VSEPR Theory to Predict Geometry I LO1

Formaldehyde (CH_2O) is a gas at room temperature (boiling point −21°C). Aqueous solutions of formaldehyde are used to preserve biological samples. It is also a product of the incomplete combustion of hydrocarbons, and it was the first polyatomic molecule to be detected in interstellar space. Use VSEPR theory to predict the molecular geometry of formaldehyde.

Collect and Organize We are given the molecular formula of formaldehyde. The solution requires (1) drawing the Lewis structure, (2) determining the steric number, and (3) identifying the molecular geometry by using Figure 9.2.

Analyze Carbon is the likely central atom of the molecule because it has a bonding capacity of 4 and is less electronegative than oxygen, whose bonding capacity is 2. If there are no lone pairs of electrons, then SN = 3 and the three atoms bonded to C are as far from each other as possible.

Solve Using the five-step procedure developed in Section 8.2 for drawing Lewis structures, we obtain the following for formaldehyde:

As predicted, SN = 3 and there are no lone pairs of electrons on the central atom. According to Figure 9.2, the molecular geometry is trigonal planar.

Think About It The key to predicting the correct molecular geometry of a molecule with no lone pairs on its central atom is to determine the steric number, which is simply a matter of counting the number of atoms bonded to the central atom.

Practice Exercise Use VSEPR to determine the molecular geometry of the chloroform molecule ($CHCl_3$) and draw the molecule by using the solid-wedge, dashed-wedge convention.

(Answers to Practice Exercises are in the back of the book.)

Measurements of the bond angles in formaldehyde show that the H—C—H bond angle is slightly smaller than the 120° predicted for trigonal planar geometry (Figure 9.2b). The C=O double bond consists of two pairs of bonding electrons (four electrons) and exerts greater repulsion than a single bond would. This greater repulsion decreases the H—C—H bond angle. VSEPR theory does not enable us to predict the actual values of the bond angles in molecules containing double bonds to the central atom, but it does allow us to correctly predict how the presence of a double bond causes a bond angle to deviate from the ideal value.

CONCEPT TEST

Rank the following bond angles from largest to smallest:

1. The O—C—O bond angle in CO_2

2. The H—C—H bond angles in CH_4
3. The H—C—H bond angle in CH_2O

Central Atoms with Lone Pairs

We now explore what happens when a central atom has one or more lone pairs. As we do, keep in mind that the impact of these lone pairs will be to create molecular geometries with names that are not the same as the molecules’ electron pair geometries. For SN = 2, the only bonding pattern possible is two atoms bound to a central atom. If we replace one bonding pair with a lone pair, we have a molecule with only two atoms, which means there is no central atom and no bond angle. Because it takes three atoms to define a bond angle, we begin the discussion of molecules containing lone pairs with SN = 3.

Sulfur dioxide, one of the gases produced when high-sulfur coal is burned, has the following distribution of electrons in its two resonance structures:

To calculate the steric number of the central S atom we need to add up the number of atoms and lone pairs of electrons that surround it. In both resonance structures, the central S atom is bonded to two atoms and has one lone pair of electrons. Therefore, its SN value in either resonance structure is 2 + 1 = 3. When SN = 3, the arrangement of atoms and lone pairs about the sulfur atom is trigonal planar (Figure 9.2b). This means that the electron-pair geometry, which considers both the atoms and the nonbonding pairs of electrons around the central atom, is trigonal planar (as shown in **Figure 9.8a**). The molecular geometry, though, describes the relative position of only the atoms in the molecule. With SN = 3 and two atoms attached to the central S atom, the SO_2 molecule has the bent (or angular) molecular geometry shown in **Figure 9.8b**.

Experimental measurements establish that SO_2 is indeed a bent molecule, but the O—S—O bond angle is a little smaller than 120°. We explain the smaller angle with VSEPR theory by comparing the space occupied by bonding electrons with the space occupied by electrons in a lone pair. Because the bonding electrons are attracted to two nuclei, they have a high probability of being located between the two atomic centers that share them. In contrast, the lone pair is *not* shared with a second atom and is spread out around the sulfur atom, as shown in **Figure 9.9**. This puts the lone pair of electrons closer to the bonding pairs and produces greater repulsion. As a result, the lone pair pushes the bonding pairs closer together, thereby reducing the bond angle. In general:

- Repulsion between lone pairs and bonding pairs is greater than the repulsion between bonding pairs.
- Repulsion caused by a lone pair is greater than that caused by a double bond.
- Repulsion caused by a double bond is greater than that caused by a single bond.
- Two lone pairs of electrons on a central atom exert a greater repulsive force on the atom's bonding pairs than does one lone pair.

SAMPLE EXERCISE 9.2 Predicting Relative Sizes of Bond Angles LO1

Rank NH_3, CH_4, and H_2O in order of decreasing bond angles in their molecular structures.

Collect and Organize We are asked to predict the relative sizes of the bond angles in three molecules, given their molecular formulas. The information in Figure 9.2 links steric numbers to electron-pair geometries and bond angles. The presence of double bonds and lone pairs of electrons on the central atom also influences bond angles.

Analyze We need to determine the steric numbers of the central atoms in these three molecules. To do that we first need to translate the molecular formulas into Lewis structures and determine how many lone pairs or bonds to other atoms surround the central atom.

Solve Using the method for drawing Lewis structures from Chapter

8, we obtain the following:

In each of these structures, the central atom has a steric number of 4: bonds to 3 atoms + 1 lone pair for NH_3, bonds to 4 atoms + 0 lone pairs for CH_4, and bonds to 2 atoms + 2 lone pairs for H_2O.

According to Figure 9.2, the electron-pair geometry for SN = 4 is tetrahedral. In a molecule such as CH_4, in which all four tetrahedral electron pairs are equivalent bonding pairs, all bond angles are 109.5°. In NH_3 and H_2O, however, repulsion from the lone pairs of electrons squeezes their bonds together, reducing the bond angles. The two lone pairs on the O atom in H_2O exert a greater repulsive force on its bonding pairs than the single lone pair on the N atom exerts on the bonding pairs in NH_3. Therefore, the bond angle in H_2O should be less than the bond angles in NH_3. Ranking the three molecules in order of decreasing bond angle, we have:

$CH_4 > NH_3 > H_2O$

Think About It The logic used in answering this problem is supported by experimental evidence: the bond angles in molecules of CH_4, NH_3, and H_2O are 109.5°, 107.0°, and 104.5°, respectively.

Practice Exercise Are the O—S—O bond angles greater in SO_2 or SO_3?

As we saw in Sample Exercise 9.2, three combinations of atoms and lone pairs are possible about a central atom with a steric number of 4: four atoms and no lone pairs, three atoms and one lone pair, and two atoms and two lone pairs. The first case is illustrated by the molecular structure of methane (CH_4) in which a tetrahedral electron-pair geometry translates into a tetrahedral molecular geometry. A molecule of ammonia (NH_3) has only three bonding pairs and one lone pair. This means that the Lewis structure in **Figure 9.10a** translates into a tetrahedral electron-pair geometry in which one of the vertices is the lone pair on the N atom (**Figure**

9.10b). The resulting molecular geometry, which is essentially a flattened tetrahedron, is called trigonal pyramidal (**Figure 9.10c**). The strong repulsion produced by the diffuse lone pair of electrons on the N atom pushes the N—H bonds closer together in NH_3 and reduces the angles between them from the 109.5° of the H—C—H bond angles in CH_4 to 107.0°.

The central O atom in a molecule of H_2O has a steric number of 4 because it is bonded to two atoms and has two lone pairs of electrons. The result is a tetrahedral electron-pair geometry (**Figure 9.11**). However, the presence of the two lone pairs means that two of the four tetrahedral vertices are not occupied by atoms, which leaves us with a bent (or angular) molecular geometry. Therefore, the H—O—H bond angle in water is reduced from 109.5° to 104.5° because of repulsion between the two lone pairs and each bonding pair.

Molecules with trigonal bipyramidal electron-pair geometry have four possible molecular geometries, depending on the number of lone pairs per molecule (**Table 9.1**). These options are possible because of the different axial and equatorial vertices in a trigonal bipyramid (Figure 9.2d). VSEPR theory enables us to predict which vertices are occupied by atoms and which are occupied by lone pairs. The key to these predictions is the fact that the repulsions between pairs of electrons decrease as the angle between them increases—that is, two electron pairs at 90° experience a greater mutual repulsion than two at 120°, which have a greater repulsion than two at 180°. To minimize repulsions involving lone pairs, VSEPR theory predicts that they preferentially occupy equatorial rather than axial vertices. Why? Because an equatorial lone pair has *two* 90° repulsions with the two axial electron pairs (**Figure 9.12a**), but an axial lone pair has *three* 90° repulsions with the three equatorial electron pairs (**Figure 9.12b**).

When we assign one, two, or three lone pairs of valence electrons to equatorial vertices, we get three of the molecular geometries for SN = 5 in Table 9.1. When a single lone pair occupies an equatorial site, we get a molecular geometry called seesaw (**Figure 9.13**) because its shape, when rotated 90° clockwise, resembles a playground seesaw. (The formal name for this shape is *disphenoidal*.)

TABLE 9.1 Electron-Pair Geometries and Molecular Geometries

Electron-Pair Geometry	Number of Bonded Atoms	Number of Lone Pairs	Molecular Geometry	Theoretical Bond Angles	Example
Trigonal planar	3	0	Trigonal planar	120°	CH_2O
Trigonal planar	2	1	Bent (angular)	< 120°	SO_2
SN = 4					
Tetrahedral	4	0	Tetrahedral	109.5°	CCl_4
Tetrahedral	3	1	Trigonal pyramidal	< 109.5°	NH_3
Tetrahedral	2	2	Bent (angular)	< 109.5°	H_2O
SN = 5					
Trigonal bipyramidal	5	0	Trigonal bipyramidal	90°, 120°, 180°	PF_3Cl_2
Trigonal bipyramidal	4	1	Seesaw	< 90°, < 120°, < 180°	SCl_4
Trigonal bipyramidal	3	2	T-shaped	< 90°, < 180°	BrF_3
Trigonal bipyramidal	2	3	Linear	180°	XeF_2
SN = 6					
Octahedral	6	0	Octahedral	90°, 180°	SF_6
Octahedral	5	1	Square pyramidal	< 90°, < 180°	IF_5
Octahedral	4	2	Square planar	90°, 180°	XeF_4
Octahedral	3	3	Although these geometries are possible, we will not encounter any molecules with them		
Octahedral	2	4			

When two lone pairs occupy equatorial sites (**Figure 9.14a**), the molecular geometry that results is called T-shaped. This designation becomes more apparent in **Figure 9.14b**, where the structure in Figure 9.14a has been rotated 90° counterclockwise. Lone-pair repulsions result in bond angles in T-shaped molecules that are slightly less than the 90° and 180° angles we would expect from a perfectly shaped "T" geometry. Finally, a SN = 5 molecule with three lone pairs and two bonded atoms has a linear geometry because all three lone pairs occupy equatorial sites, and the bonding pairs are in the two axial positions (**Figure 9.15**).

CONCEPT TEST

The bond angles in a trigonal bipyramidal molecular structure are 90°, 120°, and 180°. Are the corresponding bond angles in a seesaw structure likely to be larger than, the same as, or smaller than these values? Why?

Molecules that have a central atom with a steric number of 6 have an octahedral electron-pair geometry (Figure 9.2e) and the molecular geometries listed in Table 9.1. With one lone pair of electrons, there is only one possible molecular geometry because all the sites in an octahedron are equivalent (**Figure 9.16**). That one molecular geometry is called square pyramidal: a pyramid with a square base, four triangular sides, and the central atom “embedded” in the base.

Because of stronger repulsion between lone pairs and bonding pairs, we predict the bond angles in a square pyramidal molecule to be slightly less than the ideal angle of 90°. The molecule BrF_5, for example, has a square pyramidal molecular geometry, and the angles between its equatorial and axial bonds are 85°.

When two lone pairs are present at the central atom in a molecule with octahedral electron-pair geometry, they occupy vertices on opposite sides of the octahedron to minimize the interactions between them. The resultant molecular geometry is called square planar because the molecule is shaped like a square and all five atoms reside in the same plane (**Figure 9.17**). Because the two lone pairs are on opposite sides of the bonding pairs, the presence of the lone pairs does not distort the bond angles: they are all 90°.

SAMPLE EXERCISE 9.3 Using VSEPR Theory to Predict Geometry II LO1

The Lewis structure of sulfur tetrafluoride (SF_4) is

What is its molecular geometry and what are the angles between the S—F bonds?

Collect and Organize We are given the Lewis structure of SF_4. From it we can determine the steric number of the central atom in the molecule and its electron-pair geometry.

Analyze Four atoms are bonded to the central S atom, which also has one lone pair of electrons, so SN = 5.

Solve With a steric number of 5 for its central atom, the electron-pair geometry of SF_4 is trigonal bipyramidal. The presence of one lone pair of electrons on the S atom means that its molecular geometry is not the same as its electron-pair geometry. According to Table 9.1, a seesaw molecular geometry results when a lone pair occupies one of the three equatorial positions in a trigonal bipyramidal electron-pair geometry:

The equatorial lone pair slightly reduces the bond angles from their normal values of 90° between the axial and equatorial bonds, 120° between the two equatorial bonds, and 180° between the two axial bonds.

Think About It Any molecule with SN = 5 and one lone pair should have the same geometry as SF_4.

Practice Exercise What are the molecular geometries and the bond angles of (a) SO_2Cl_2, (b) ClF_3, and (c) XeF_4?

Glossary

valence-shell electron-pair repulsion (VSEPR) theory
: a model predicting that the arrangement of valence electron pairs around a central atom minimizes their mutual repulsion to produce the lowest-energy orientations.

electron-pair geometry
: the three-dimensional arrangement of bonding pairs and lone pairs of electrons about a central atom.

molecular geometry
: the three-dimensional arrangement of the atoms in a molecule.

steric number (SN)
: the sum of both the number of atoms bonded to a central atom and the number of lone pairs of electrons on the central atom.

linear
: the molecular geometry about a central atom with a steric number of 2 and no lone pairs of electrons; the bond angle is 180°.

trigonal planar
: the molecular geometry about a central atom with a steric number of 3 and no lone pairs of electrons; the bond angles are all 120°.

tetrahedral
: the molecular geometry about a central atom with a steric number of 4 and no lone pairs of electrons; the bond angles are all 109.5°.

trigonal bipyramidal
: the molecular geometry about a central atom with a steric number of 5 and no lone pairs of electrons; three atoms occupy equatorial sites (bond angles 120°) and two other atoms occupy axial sites (bond angle 180°) above and below the equatorial plane; the bond angle between the axial and equatorial bonds is 90°.

octahedral
: the molecular geometry about a central atom with a steric number of 6 and no lone pairs of electrons, in which all six sites are equivalent.

trigonal pyramidal

the molecular geometry about a central atom with a steric number of 4 and one lone pair of electrons.

seesaw

the molecular geometry about a central atom with a steric number of 5 and one lone pair of electrons in an equatorial position.

T-shaped

the molecular geometry about a central atom with a steric number of 5 and two lone pairs of electrons that occupy equatorial positions; the outer atoms occupy two axial sites and one equatorial site.

square pyramidal

the molecular geometry about a central atom with a steric number of 6 and one lone pair of electrons; as typically drawn, the atoms occupy four equatorial and one axial site.

square planar

the molecular geometry about a central atom with a steric number of 6 and two lone pairs of electrons that occupy axial sites; the atoms occupy four equatorial positions.

bent (or angular)

the molecular geometry about a central atom with a steric number of 3 (bonds to two atoms + one lone pair) or a steric number of 4 (bonds to two atoms + two lone pairs).

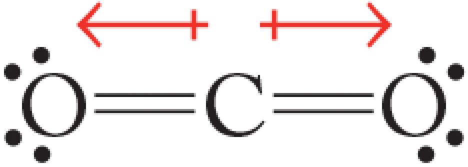
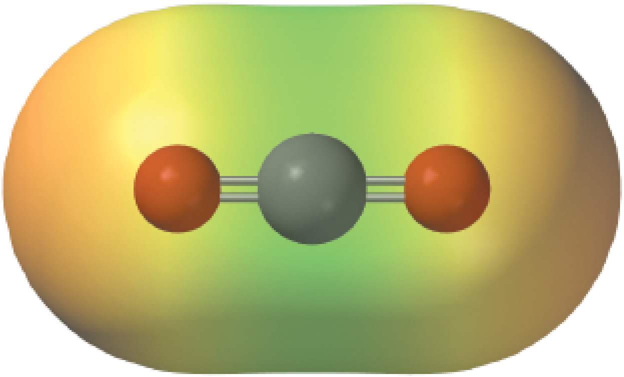
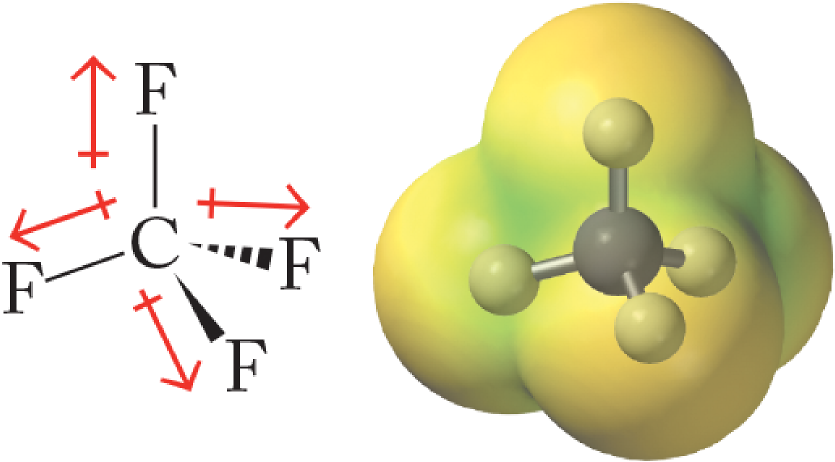
FIGURE 9.18 Gaseous HF molecules are randomly oriented in the absence of an electric field but align themselves when an electric field is applied to two metal plates. The negative (fluorine) end of each molecule is directed toward the positively charged plate, whereas the positive (hydrogen) end is directed toward the negative plate.







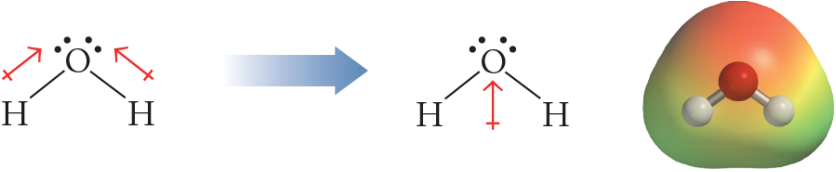


FIGURE 9.19 Water is a polar substance because the dipoles of the O–H bonds in its molecules are angled in such a way that they only partially offset one another with greater electron density around the O atom and lower electron density around the H atoms as shown in the electron density model on the right.

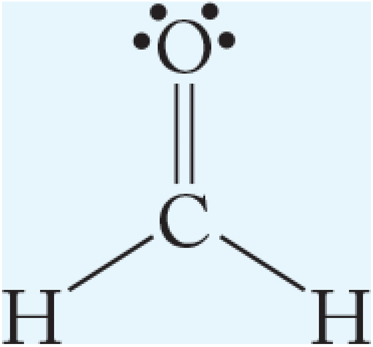


9.3 Polar Bonds and Polar Molecules

In Chapter 8 we learned that differences in the electronegativities of the elements can cause the shared electrons in covalent bonds between their atoms to be distributed unevenly, with a higher density of the electrons toward the end of the bond that is occupied by the more electronegative atom. This unequal distribution of bonding electrons produces a partial negative charge in one region of the bond and a partial positive charge in the other. This charge separation creates a bond dipole.

CONNECTION See Figure 8.7 to review the use of arrows to indicate bond polarity and Figure 8.8 to review the use of electron-density surfaces to indicate bond polarity.

CONNECTION In Section 8.3 we introduced electronegativity and the unequal distribution of electrons in polar covalent bonds. See Figures 8.9 and 8.10 to review the Pauling electronegativity values and their periodic trends.

In diatomic molecules with polar bonds, such as HF, unequal sharing of bonding electrons means the entire molecule is polar (see Figure 8.8). In other words, the H—F bond dipole gives a molecule of HF a permanent dipole moment (μ), which is a measure of the uneven distribution of electron density over the entire molecule. The value of μ can be determined experimentally by measuring the degree to which molecules align with a strong electric field between parallel plates that have positive $(+)$ and negative $(-)$ charges (**Figure 9.18**). Polar molecules align with the field so that their negative regions are oriented toward the positive plate and their positive regions are oriented toward the negative plate. Molecules with larger dipole moments align more strongly with the field. Dipole moments are usually expressed in units of *debyes* (D), where $1\ \text{D} = 3.34 \times 10^{-30}$ coulomb-meter.

In molecules with multiple polar bonds around a center atom, the bond dipoles *may* combine to give the molecule an overall polarity. Such a molecule is said to have a *permanent dipole*. Whether a molecule has a permanent dipole depends on the strengths of its bond dipoles and how the dipoles are oriented with respect to one another. Determining how they are oriented starts with drawing the Lewis structure of the molecule, determining the steric number of the central atom, and then using this SN value and VSEPR to predict the geometry of the molecule and the orientation of its bonds and their dipoles.

Consider, for example, a molecule of CO_2. Its Lewis structure tells us that the steric number of the carbon atom is 2, which means it is a linear molecule with its two C□O bonds (and their bond dipoles) 180° from each other:

The color-coded distribution pattern of valence electrons in the molecular model tells us that the electron density is lower around the central C atom than around the two O atoms, but the electron densities around the two ends of the molecules are the same. This means the molecule has no overall polarity. The two bond dipoles, oriented in opposite directions, exactly offset each other. The result is no permanent dipole and a dipole moment of zero. In other words, carbon dioxide is a nonpolar substance.

Similarly, CF_4 is a nonpolar substance even though its molecules contain four polar C—F bonds. To understand why this is so, we again start with the Lewis structure of CF_4, which tells us that the carbon atom has a steric number of 4. According to VSEPR, the four C—F bonds (and their bond dipoles) are oriented toward the four corners of a tetrahedron. This means the angles between all the bonds (and bond dipoles) are exactly the same (109.5°), which makes the molecule and the orientation of its bond dipoles perfectly symmetric in three-dimensional space:

Molecular symmetry is a key characteristic of all nonpolar substances because symmetric orientation of their bond dipoles means the dipoles completely offset one another, producing dipole moments of zero.

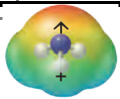
On the other hand, molecules of water are not symmetrical. The presence of two lone pairs of electrons in the valence shell of the O atom means that their tetrahedral electron-pair geometry translates into a bent molecular geometry as shown in **Figure 9.19**. Therefore, the dipoles of the two O—H bonds do *not completely* offset each other, giving the molecule a permanent dipole with a positive pole centered between the H atoms and negative pole in the O atom. The presence of this permanent dipole means that water is a polar substance. In Chapter 10 we discuss the considerable impact of the polarity of water on its physical properties.

The dipole moments of several polar substances are listed in **Table 9.2**. Let's examine their molecular structures to determine how their bond dipoles combine to give them permanent dipoles. It is not surprising that most (though not all) of these polar molecules contain polar bonds. Differences in electronegativity between the atoms in the bonds in these molecules range from $\Delta EN = 1.9$ for H—F, 1.4 for H—O, 0.9 for H—N and P—Cl, to 0.0 for the O—O bonds in ozone.

The polar bonds in HF and the other hydrogen halides make all these compounds polar. We have also discussed how the asymmetric shape of water molecules means the dipoles of their O—H bonds are oriented in such a way that they do not completely offset each other, giving H_2O molecules permanent dipoles. Similarly, the lone pair of electrons on the nitrogen atom in a molecule of ammonia gives the molecule the asymmetric shape of a trigonal pyramid. When viewed with the lone pair at the top, as in Table 9.2, the horizontal components of the N—H bond dipoles are arranged symmetrically around the N atom, which means they offset each other. However, all the vertical components are directed upward toward the N atom's side of the molecule, giving it a permanent dipole and a dipole moment only slightly smaller than that of water.

TABLE 9.2 Dipole Moments of Several Polar Molecules

Polar Molecule	Bond Dipoles	Molecular Dipole	Dipole Moment (debyes)
HF			1.91
H_2O			1.85
NH_3			1.47

PCl_3			0.97
O_3			0.53

Molecules of PCl_3 are also trigonal pyramidal, but the P—Cl dipoles point toward the Cl atoms and away from the less electronegative (P) central atom. As in ammonia, the horizontal components of the three bond dipoles cancel out, but the vertical components do not. They combine to form a permanent dipole pointed downward through the center of the molecule as it is drawn in Table 9.2.

The last molecule in the table is ozone. There are no bond dipoles in O_3, just as there are none in O_2, but O_3 has a permanent dipole, whereas O_2 does not. Why? Once again, the key is symmetry: O_2 molecules are symmetrical because both O atoms are double bonded to the other O atom and have two lone pairs of electrons. However, we learned in Chapter 8 that ozone contains two equivalent O—O bonds that equally share a total of three bonding pairs of electrons. The steric number of the central O atom is 3 because it is bonded to the other two O atoms and it has one lone pair of valence-shell electrons. This SN value means that the molecule has a trigonal planar electron-pair geometry and a bent molecular geometry, which makes it asymmetric.

CONCEPT TEST

NCl_3 and $AlCl_3$ both contain polar bonds, yet NCl_3 is a polar molecule, whereas $AlCl_3$ is a nonpolar molecule. Explain how this is possible. (*Hint*: Begin by drawing their Lewis structures.)

SAMPLE EXERCISE 9.4 Predicting the Polarity of a Substance LO2

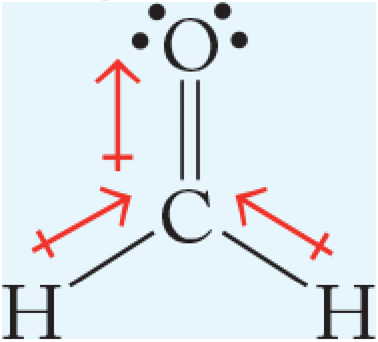
Does either of these molecules have a permanent dipole: (a) CH_2O (formaldehyde); (b) CH_2Cl_2 (dichloromethane, an organic solvent)?

Collect and Organize To predict whether a molecule has a permanent dipole, we need to determine whether there is asymmetry in its structure, particularly in the way polar bonds in the molecule are oriented relative to one another. Bond polarity depends on the difference in the electronegativity of the bonded pair of atoms. In Sample Exercise 9.1 we determined that formaldehyde has a trigonal planar structure:

Analyze The electronegativities of the atoms in formaldehyde are H = 2.1, C = 2.5, and O = 3.5, and the electronegativity of the chlorine atoms in dichloromethane is 3.0 (Figure 8.9). Therefore, bonding electrons will be drawn toward the O end of a C—O bond and the Cl end of a C—Cl bond. There is little polarity in C—H bonds (ΔEN = 0.4); however, the presence of both C—H and C—O bonds in molecules of formaldehyde and C—H and C—Cl bonds in molecules of dichloromethane increases the probability that the bond dipoles in these molecules will not offset each other, at least not completely, and that the molecules will have permanent dipoles.

Solve

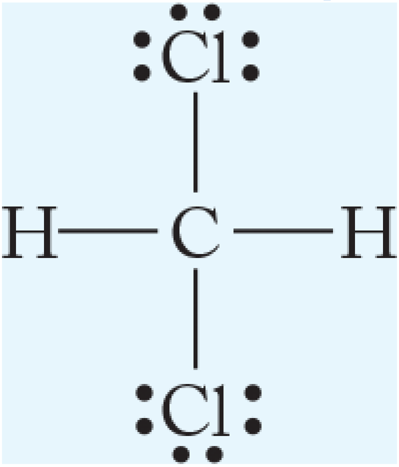
1. The hydrogen atoms are the least electronegative atoms in a molecule of formaldehyde and the oxygen atom is the most electronegative, so each of the bonds in the molecule has a bond dipole directed toward the oxygen atom:



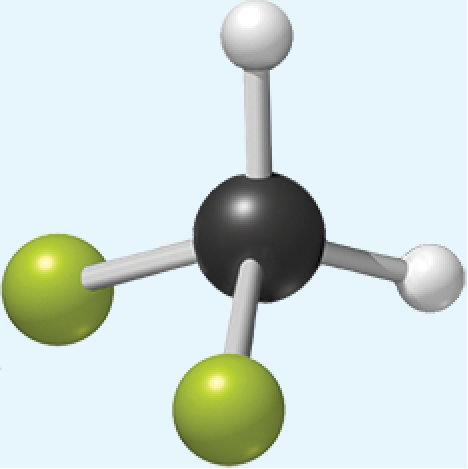
This alignment of the bond dipoles means that the formaldehyde molecule has a permanent dipole moment.

2. To assess the symmetry of dichloromethane we need to draw its Lewis structure and determine the orientation of its bonds and their dipoles. Using the procedure for drawing Lewis structures that we learned in Chapter 8 yields this one for

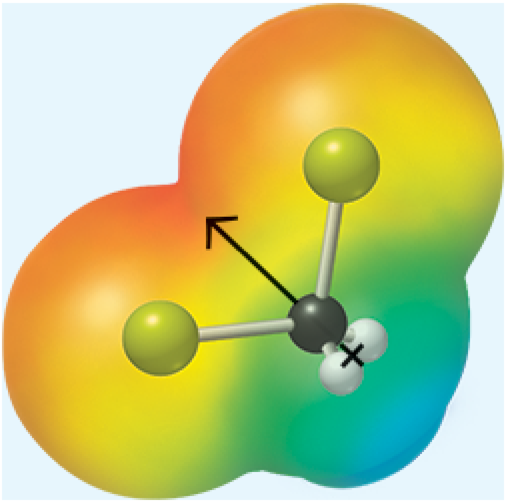
CH_2Cl_2:



There are four atoms bonded to the central carbon atom and no lone pairs of electrons, so the SN value of the carbon atom is 4 and the molecular geometry is tetrahedral. One way to assess the symmetry of two C—H and two C—Cl bonds in three-dimensional space is to consult a ball-and-stick model of the molecule:



The model shows that the C—H and C—Cl bonds are arranged asymmetrically in three-dimensional space: the molecule has a hydrogen region (toward the right in this photo) that should have low electron density and a chlorine region (toward the left) that should have high electron density. Therefore, CH_2Cl_2 should have a permanent dipole oriented from lower right to upper left, which it does:



Think About It Molecular polarity cannot always be determined solely from a Lewis structure, but using a Lewis structure along with VSEPR helps us determine molecular shape and symmetry. Also, the presence of atoms of two or more elements bonded to the central atom of a molecule makes it likely that the molecule has a permanent dipole.

Practice Exercise Does carbon disulfide (CS_2), a gas present in small amounts in crude petroleum, have a dipole moment? Does dimethyl ether, $H_3C—O—CH_3$, have a permanent dipole moment? Explain your answers.

CONCEPT TEST

Water and hydrogen sulfide both have a bent molecular geometry with dipole moments of 1.85 D and 0.98 D, respectively. Why is the dipole moment of H_2S less than that of H_2O?

Glossary

bond dipole	the separation of electrical charge created when atoms with different electronegativities form a covalent bond.
dipole moment (μ)	a measure of the degree to which a molecule aligns itself in a strong electric field; a quantitative expression of the polarity of a molecule.

9.4 Valence Bond Theory

Drawing Lewis structures and applying VSEPR theory enable us to predict the geometry of many molecules reliably. However, we have yet to make a connection between molecular geometry and the arrangement of electrons in atoms in atomic orbitals as described in Chapter 7. The search for a connection between the electronic structure of atoms and the electronic structure of molecules led to the development of bonding theories that use atomic orbitals to account for the molecular geometries predicted by VSEPR theory. We explore one of these theories—called *valence bond theory*—next.

Bonds from Orbital Overlap

Valence bond theory arose in the late 1920s, largely because of the genius and efforts of Linus Pauling, who developed this theory of molecular bonding based on quantum mechanics. Valence bond theory incorporates the assumption that (a) a chemical bond between two atoms results from overlap of the atoms' atomic orbitals, and (b) the greater the overlap, the stronger and more stable the bond.

Shared electrons in a chemical bond are located between the nuclei of two atoms and are attracted to both. This attraction leads to lower potential energy and greater chemical stability than if the atoms were completely independent of one another (see Figure 8.2). This view of chemical bonding is especially useful for analyzing the physical and chemical properties of covalent substances because it provides a model of where the electrons are in a molecule. Just as the locations of electrons in atoms define atomic properties, the locations of electrons in molecules define the properties of those molecules.

Let's begin by applying Pauling's valence bond theory to H_2, the simplest diatomic molecule. A single H atom has one electron in a 1*s* atomic orbital. According to valence bond theory, the overlap between two H atoms, each with a half-filled 1*s* orbital, produces a single H—H bond (**Figure 9.20**). Overlapping two orbitals from two atoms in this way increases electron density along the axis connecting the two nuclei. Whenever the region of high electron density lies along the bond axis, the resulting covalent bond is called a sigma (σ) bond.

SAMPLE EXERCISE 9.5 Identifying Overlapping Orbitals in a Molecule LO3

Identify the atomic orbitals responsible for the covalent bond in gaseous HCl.

Collect, Organize, and Analyze First we must determine the number of valence electrons in each atom and then draw Lewis structures for the molecule. Next, we must identify which atomic orbitals are half-filled; these are the orbitals that form the covalent bond between H and Cl.

Solve Atoms from group 17 (halogens) all have seven valence electrons, and hydrogen has one valence electron, so the Lewis structure for HCl is

---

The electron configurations of H and Cl atoms are

H: $1s^1$ and Cl:[Ne]$3s^23p^5$

The covalent bond between H and Cl in HCl results from overlap between the half-filled hydrogen 1*s* orbital and a half-filled chlorine 3*p* atomic orbital.

Think About It The σ bond between hydrogen and chlorine in HCl that arises from overlap of two atomic orbitals is consistent with the prediction from its Lewis structure.

Practice Exercise The halogens (group 17 elements) form a series of interhalogen compounds such as IBr. Identify the atomic orbitals that overlap to form the σ bond in IBr.

Hybridization

In molecules other than simple ones such as H_2, an inconsistency arises between the atomic orbital shapes and orientations described in Chapter 7 and the molecular geometries we predict from VSEPR theory that are supported by experimental data. Methane, for example, has a carbon atom at its center. We established in Chapter 7 that carbon atoms have the electron configuration $[He]2s^22p^2$, that the 2*s* orbital is spherical, and the three 2*p* orbitals (i.e., p_x, p_y, and p_z) are oriented at 90° to one another (**Figure 9.21**). We also learned in Chapter 8 that carbon atoms form four covalent bonds oriented at 109.5° to one another in a tetrahedral arrangement. How can this be explained from the overlap of a filled 2*s* orbital and two partly filled 2*p* orbitals? Furthermore, how can there be two double bonds 180° apart in a molecule of CO_2, or one double bond and two single bonds 120° apart in a molecule of CH_2O?

To account for shapes of these and many other molecules, valence bond theory describes atomic orbitals of different shapes and energies as being mixed in a process called hybridization to form hybrid atomic orbitals. Covalent bonds then result either from overlap of a hybrid orbital on one atom with an unhybridized orbital on another atom, from overlap of two hybrid orbitals on two atoms, or from overlap of two unhybridized orbitals on two atoms. Let's examine the types of hybrid orbitals that form on carbon and other elements and how these orbitals account for observed molecular geometries.

Tetrahedral Geometry: *sp*^{3} Hybrid Orbitals

Methane has a tetrahedral molecular geometry with H—C—H bond angles of 109.5°. To account for this geometry by using orbital hybridization, we start with a single carbon atom with its $2s^22p^2$ valence-shell electron configuration (**Figure 9.22a**). We then promote one electron from the 2*s* orbital to the empty 2*p* orbital. Promotion raises the energy of the 2*s* electron; this gain in energy is balanced, however, by a slight decrease in the energies of the three *p* orbitals. We now have four orbitals of equal energy on the carbon atom, each containing one electron.

These four orbitals have been *hybridized* (mixed and averaged) to make a set of four equivalent hybrid orbitals, each containing one electron. An atom's steric number always indicates how many of its orbitals must be mixed to generate the hybrid set, and the number of hybrid orbitals in a set is always equal to the number of atomic orbitals mixed. The carbon atom in methane has SN = 4, so four atomic orbitals on carbon are mixed to form four hybrid orbitals.

The four orbitals are called sp^3 hybrid orbitals because they result from the mixing of one *s* and three *p* orbitals. Their energy level is the weighted average of the energies of the *s* and *p* orbitals that formed them. They are oriented 109.5° from one another and point toward the vertices of a tetrahedron (**Figure 9.22b**). Now four hydrogen atoms can form σ bonds with the sp^3 hybridized orbitals on carbon and form a methane molecule that has the observed tetrahedral geometry.

The sp^3 hybrid orbitals in Figure 9.22b are shown as having one lobe each, but in fact every sp^3 hybrid orbital consists of a major lobe and a minor lobe (**Figure 9.23a**). Because the minor lobe is not involved in bonding, we ignore it in this chapter. It becomes important in the discussion of chemical reactions that are beyond the scope of this book. Also, to better show the orientation of bonds formed by hybrid orbitals, we elongate the major lobe in illustrations (**Figure 9.23b**).

According to valence bond theory, any atom with a set of four equivalent sp^3 hybrid orbitals has a tetrahedral orientation of its valence electrons. This includes atoms in which one or more hybrid orbitals are filled before any bonding takes place. For example, sp^3 hybridization of the valence electrons on the nitrogen atom in ammonia produces three hybrid orbitals that are half-filled and one hybrid orbital that is filled (**Figure 9.24a**). The three half-filled orbitals form the three σ bonds in ammonia by overlapping with the 1*s* orbitals of three hydrogen atoms. The one filled hybrid orbital of N contains the lone pair of electrons. Similarly, the oxygen atom in water has four sp^3 hybrid orbitals in its valence shell, two filled before any bonding takes place and two half-filled and available for bond formation (**Figure 9.24b**). The two half-filled orbitals overlap with 1*s* orbitals from hydrogen atoms and form the two σ bonds in H_2O. Thus, a carbon atom forming four σ bonds, a nitrogen atom with three σ bonds and one lone pair of electrons, and an oxygen atom with two σ bonds and two lone pairs of electrons all have SN = 4 and all are sp^3 hybridized atoms. As we will see, the steric number of an atom and its hybridization are closely related in other electron-pair geometries as well.

Trigonal Planar Geometry: sp^2 Hybrid Orbitals

Formaldehyde has a trigonal planar molecular geometry (**Figure 9.25**). A hybridization scheme other than sp^3 must be used to generate an orbital array with this molecular geometry because of the double bond. The VSEPR model defines SN = 3 for the carbon atom in a molecule of formaldehyde, so three atomic orbitals must be mixed to make three hybrid orbitals. To produce a trigonal planar geometry, the 2*s* orbital on carbon is mixed with two of the carbon 2*p* orbitals, and the third 2*p* orbital is left unhybridized (**Figure 9.26a**). This is the common hybridization scheme for all carbonyl ($C{=}O$) groups in organic molecules.

Mixing and averaging one *s* and two *p* orbitals generates three hybrid orbitals called sp^2 hybrid orbitals. The energy level of sp^2 orbitals is slightly lower than that of sp^3 orbitals because only two *p* orbitals are mixed with an *s* orbital in a set of sp^2 orbitals. The orbitals in an sp^2 hybridized atom all lie in the same plane and are 120° apart. The two lobes of the unhybridized *p* orbital lie above and below the plane of the triangle defined by the sp^2 hybrid orbitals. An sp^2 hybridized carbon atom forms three σ bonds with its three hybridized orbitals.

Valence electrons in *s* and *p* orbitals in other atoms can also be sp^2

hybridized. To complete the valence bond picture of formaldehyde or any carbonyl-containing compound, the oxygen atom must be sp^2 hybridized as well (**Figure 9.26b**). That both the carbon and the oxygen atoms in formaldehyde are hybridized points out another difference between VSEPR theory, which considers only the central atom in a molecule, and valence bond theory, which considers all the atoms in the molecule.

The valence bond view of the bonding in formaldehyde shows the 1*s* orbitals of two hydrogen atoms overlapping with two carbon sp^2 hybrid orbitals and the third carbon sp^2 hybrid orbital overlapping with one oxygen sp^2 hybrid orbital (**Figure 9.26c**). These overlapping orbitals constitute the σ-bonding framework of the molecule. The unhybridized carbon 2*p* orbital is parallel to the unhybridized oxygen 2*p* orbital, and the overlap of these two orbitals above and below the plane of the σ-bonding framework forms a pi (π) bond. The widths of the lobes on the *p* orbitals and the distances between atoms are not drawn to scale in this and similar figures. The lobes are much closer together than they appear, and they do overlap.

Pi bonds have their greatest electron density above and below the internuclear axis (or in front of and behind the internuclear axis). They can be formed only by the overlap of partially filled *p* orbitals that are parallel to each other and perpendicular to the σ bond joining the atoms. Pi bonds are inherently weaker than σ bonds because the side-on overlap of *p* orbitals is less efficient than the head-on overlap of σ bonds.

The lone pairs of electrons on the oxygen atom are in the two oxygen sp^2 hybrid orbitals not involved in the bonding with carbon. These two orbitals are oriented at an angle of about 120° in the plane of the molecule. A nitrogen atom can also form sp^2 hybrid orbitals (**Figure 9.27**). When it does, its lone pair occupies one of the three hybrid orbitals, the other two are half-filled and available to form two σ bonds, and the unhybridized half-filled *p* orbital is available to form one π bond. This combination of one lone pair plus the capacity to form two σ bonds to two other atoms gives N a steric number of 3, the same SN value as sp^2 hybridized C and O atoms. As a result, central atoms with a trigonal planar electron-pair geometry are sp^2 hybridized.

Linear Geometry: *sp* Hybrid Orbitals

In the linear alkyne acetylene (C_2H_2), both carbon atoms have SN = 2 according to VSEPR theory. Because steric number indicates the number of hybrid orbitals that must be created, two atomic orbitals mix to make two hybrid orbitals on each carbon atom.

The results of mixing one 2*s* and one 2*p* orbital on carbon and leaving the other two 2*p* orbitals unhybridized are shown in **Figure 9.28a**. The two *sp* hybrid orbitals have major lobes that are on opposite sides of the carbon atom. One set of the unhybridized *p* orbitals has lobes above and below the axis of the *sp* hybrid orbitals; the second set is in front and behind the plane of the hybrid orbitals.

The valence bond view of C_2H_2 shows a σ-bonding framework in which a hydrogen 1*s* orbital overlaps with one *sp* hybrid orbital on each carbon atom. Each carbon atom's other *sp* hybrid orbital overlaps with one *sp* hybrid orbital on the other carbon atom (**Figure 9.28b**). This arrangement brings the two sets of unhybridized *p* orbitals on the two carbon atoms into parallel alignment with each other. They then overlap to form two π bonds between the two carbon atoms, so that the one σ bond and the two π bonds form the triple bond in HC≡

Figure 9.29 summarizes the differences in electron distributions for single, double, and triple bonds for the carbon atoms in alkanes, alkenes, and alkynes as described by valence bond theory. The structures of these molecules determine their physical and chemical properties, but "structure" in this sense refers to more than just the location of the atoms. The distribution of electrons in three-dimensional space also greatly influences these properties. For reactions to take place, particles must interact, and the location of the valence electrons in molecules influences which bonds will break in reactions and which new bonds will form. According to valence bond theory, the electron density in the carbon–carbon σ bonds in alkanes lies on the axis directly between the two atomic centers (Figure 9.29a). In contrast, the electron density in the π bonds in alkenes and alkynes is largest not between the two carbon atoms, but above and below or in front of and behind the bonding axis (Figure 9.29b, c). The electrons in these π bonds more easily interact with those on other molecules, which is one reason why alkenes and alkynes are more reactive than alkanes, which have only σ bonds.

The link between SN = 2 and *sp* hybridization applies to atoms other than carbon—for example, the nitrogen atoms in N_2. A lone pair occupies one of the two *sp* orbitals on each nitrogen atom and the other *sp* hybrid orbital forms the σ bond (**Figure 9.30**).

A summary of the shapes associated with all the hybridization schemes we have discussed is provided in **Table 9.3**.

SAMPLE EXERCISE 9.6 Describing Bonding in a Molecule LO3

Use valence bond theory to account for the linear molecular geometry of CO_2, to determine the hybridization of carbon and oxygen in this molecule, and to describe the orbitals that overlap to form the bonds. Draw the molecule, showing the orbitals that overlap to form the bonds.

Collect and Organize We know that CO_2 is linear and that the Lewis structure of the molecule is

Analyze Each double bond is composed of one σ bond and one π bond. Therefore, the carbon atom forms two σ bonds and two π bonds. It has no lone pairs and so SN = 2. Each oxygen atom forms one σ bond and one π bond.

Solve The carbon atom must be *sp* hybridized because half-filled *sp* hybrid orbitals have the capacity to form two σ bonds, leaving two half-filled unhybridized *p* orbitals available to form two π bonds (**Figure 9.31**). The lobes of *sp* hybrid orbitals are at an angle of 180°, which is consistent with the linear molecular geometry of CO_2. The oxygen atoms must be sp^2 hybridized because that hybridization leaves them with one unhybridized *p* orbital to form a π bond. The σ bonds form when each *sp* orbital on the carbon atom overlaps with one sp^2 orbital on an oxygen atom.

The two unhybridized *p* orbitals of carbon are oriented 90° to each other and the plane containing the three sp^2 orbitals of one oxygen atom is rotated 90° with respect to the plane containing the three sp^2 orbitals of the other oxygen atom. This orientation is necessary for the formation of the two π bonds because the two unhybridized *p* orbitals that overlap to form a π bond must be parallel. The unshared pairs of electrons on each oxygen atom and the σ bond to carbon lie in a trigonal plane 120° apart. The sp^2 hybridization of the oxygen accounts for all these features.

Think About It The *sp* hybridization of the carbon atom is consistent with its steric number (SN = 2), its capacity to form two σ and two π bonds, and the linear geometry of the molecule.

Practice Exercise In which of the following molecules does the central atom have sp^3 hybrid orbitals? (a) CCl_4; (b) HCN; (c) SO_2; (d) PH_3

CONCEPT TEST

Why can’t a carbon atom with sp^3 hybrid orbitals form π bonds?

Glossary

valence bond theory

a quantum mechanics–based theory of bonding that incorporates the assumption that covalent bonds form when half-filled orbitals on different atoms overlap or occupy the same region in space.

overlap

the degree to which atomic orbitals on adjoining atoms occupy the same region of space.

sigma (σ) bond

a covalent bond in which the highest electron density lies between the two atoms along the bond axis.

hybridization

in valence bond theory, the mixing of atomic orbitals to generate new sets of orbitals that are then available to form covalent bonds with other atoms.

hybrid atomic orbital

in valence bond theory, one of a set of equivalent orbitals about an atom created when specific atomic orbitals are mixed.

pi (π) bond

a covalent bond in which electron density is greatest around—not along—the bonding axis; it forms from side-on overlap of two parallel *p* orbitals.

sp^3 hybrid orbitals

a set of four hybrid orbitals with a tetrahedral orientation, formed by mixing one *s* and three *p* atomic orbitals.

sp^2 hybrid orbitals

three hybrid orbitals in a trigonal planar orientation, formed by mixing one *s* and two *p* atomic orbitals.

*sp*hybrid orbitals

two hybrid orbitals oriented 180° from one another, formed by mixing one *s* and one *p* orbital.

9.5 Shape, Large Molecules, and Molecular Recognition

Most of the molecules we have considered so far have small molar masses or a single central atom bonded to two or more atoms. Because we will see more examples of larger molecules (i.e., molecules with more than just one central atom) in this chapter and throughout the text, we need to learn some of the ways that chemists have developed to represent such structures in addition to Lewis structures. Then we can apply the concepts that we have discussed about valence bond theory to these larger molecules. It is important to learn how to represent larger molecules with more than one central atom because molecular shape is an important factor in determining the physical, chemical, and biological properties of all substances.

Drawing Larger Molecules

Figure 9.32a shows the Lewis structures for both pentane and butanone. Pentane is a member of the alkane family that we discussed in Section 6.9, whereas butanone contains the functional group known as a ketone. In a ketone, the carbon of the carbonyl group is bonded to two other carbon atoms. A Lewis structure shows all the bonds in the molecule as well as all the lone pairs on the atoms, but it does not convey the three-dimensional shape of the molecule. Structural formulas of organic molecules that show all the bonds with lines, but omit lone pairs, are called *Kekulé structures* (**Figure 9.32b**) after August Kekulé (1829–1896), who first used this method for illustrating molecules. Alkanes do not have lone pairs on any atoms, so there is no difference between the Lewis structure and the Kekulé structure for pentane, but there is for butanone because the lone pairs on the oxygen atom are omitted in its Kekulé structure.

CONNECTION Kekulé structures are the same as the structural formulas we have been drawing throughout the text since Chapter 1.

Writing Lewis or Kekulé structures for larger and larger organic molecules gets tedious quickly. For this reason, chemists use even shorter notations called *condensed structures* (**Figure 9.32c**) to represent molecules. Condensed structures do not show most of the individual bonds between atoms as Lewis and Kekulé structures do. They use subscripts to indicate the number of times a subgroup is repeated. For example, the condensed structure of pentane can be written as $CH_3CH_2CH_2CH_2CH_3$ or as $CH_3(CH_2)_3CH_3$. The numerical subscript after the CH_2 group in parentheses means that three of these groups connect the terminal $–CH_3$ groups in this compound. Note that the subscript indicating the number of CH_2 groups comes *after* the closing parenthesis. The subscript 2 inside the parentheses is for the two H atoms bonded to each C atom of each CH_2 group.

CONNECTION We saw methyl groups ($–CH_3$) and methylene groups ($–CH_2–$) when we investigated alkanes in Section 6.9. We also classified alkanes as straight-chain or branched-chain hydrocarbons.

The most minimal notation, shown in **Figure 9.32d**, is the *skeletal structure* of a molecule, which has no element symbols for carbon and hydrogen atoms. Atoms other than C and H, such as the oxygen in butanone, are shown in skeletal structures. **Figure 9.33** shows how to create a skeletal structure for octane (C_8H_{18}). Short line segments are drawn at angles to one another in a “zigzag” manner, and each line segment symbolizes one carbon–carbon bond in the molecule. The angles represent the bond angle between the two carbon atoms (109.5° for sp^3 hybridized carbon atoms in alkanes). There is a $–CH_3$ group at each end of the zigzag line, and there is either a $–CH_2–$ group (as is the case in pentane) or a functional group (as is the case for butanone) at each vertex formed by the intersection of two line segments. Skeletal structures are assumed to contain the appropriate number of hydrogen atoms so that each carbon atom has a steric number of 4. Hydrogen atoms are not shown in a skeletal structure because all carbon atoms are known to make four bonds, and any bonds not shown are understood to be C—H bonds.

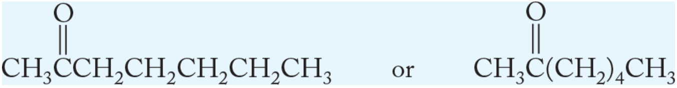
SAMPLE EXERCISE 9.7 Drawing Condensed and Skeletal Structures LO4

The Kekulé structure of a compound that contributes to the distinctive aroma of Gorgonzola cheese is shown in **Figure 9.34**. (a) Write a condensed structure and (b) draw the skeletal structure for this ketone.

Collect, Organize, and Analyze Figure 9.32 summarizes the differences between Kekulé, condensed, and skeletal structures. Condensed structures show the symbol for each element in a molecule with subscripts indicating the numbers of atoms of each element, but they do not show C—H or C—C single bonds. We can group all $–CH_2–$ groups by using parentheses followed by a subscript to show the number of $–CH_2–$ groups. Skeletal structures use short line segments to represent the carbon–carbon bonds in molecules. Intersections of these segments represent carbon atoms.

Solve

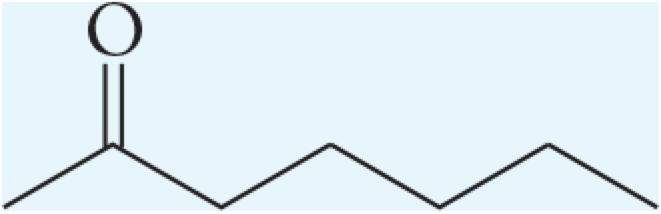
1. The condensed structure comes from its Kekulé structure, where we write each carbon followed by H plus a subscript showing the number of H atoms bonded to that carbon atom. The ketone functional group is written as C□O, with the carbonyl carbon atom bonded to two other carbon atoms. There must be two $CH_3–$ groups at the ends with a ketone functional group and four $–CH_2–$ groups between them:



$$CH_3\overset{\overset{\displaystyle O}{\|}}{C}CH_2CH_2CH_2CH_2CH_3 \quad \text{or} \quad CH_3\overset{\overset{\displaystyle O}{\|}}{C}(CH_2)_4CH_3$$

2. To draw the skeletal structure, first draw a short line slanted upward to the right; this represents the bond between the first carbon atom and the carbonyl carbon. Then without

removing your pencil from the paper, draw a short line slanted downward to the right to represent the bond between the carbonyl carbon and the third carbon atom. Continue until you have drawn seven carbon atoms (including the carbonyl carbon).



Think About It Condensed structures and skeletal structures both represent the same number of atoms and the same number of bonds, even though the bonds are not shown in the condensed structure and not all the atoms are shown in the skeletal structure.

Practice Exercise Draw the skeletal structure of hexane, $CH_3(CH_2)_4CH_3$, and a condensed structure of heptane:

Molecules with More than One Functional Group

Now let’s consider a biologically active molecule with three “central” atoms and more than one functional group. Acrolein is one of the components of barbeque smoke that contributes to the distinctive odor of a cookout. It is also a possible cancer-causing compound. The Lewis structure of acrolein is

Each molecule contains a C□O double bond, which is part of an aldehyde functional group, and a C□C double bond, which is an alkene functional group. Both double bonds are formed by trigonal planar, sp^2 hybridized carbon atoms.

Benzene (C_6H_6) is another molecule in barbeque smoke. As we saw in Section 8.4, each benzene molecule is a hexagon of six carbon atoms, each bonded to one hydrogen atom. The Lewis structure of benzene shows three C□C bonds. Resonance structures for benzene are shown in **Figure 9.35**, along with a view of the π bonds located above and below the plane of the ring. Each carbon in benzene has a trigonal planar geometry and forms sp^2 hybrid orbitals. The carbon ring is made of σ bonds formed by overlapping sp^2 hybrid orbitals on adjacent carbon atoms. The C—H bonds are formed by the overlap of carbon sp^2 hybrid orbitals with hydrogen 1*s* orbitals.

The two resonance forms of benzene shown in Figure 9.35a correspond to shifts in the locations of the π bonds formed by the overlap of carbon 2*p* orbitals. However, because all the carbon 2*p* orbitals are identical, they are all equally likely to overlap with their neighbors, so the electrons in the π bonds are *delocalized* over all six carbon atoms rather than fixed between alternating pairs of carbon atoms, as depicted in the computer-generated view in Figure 9.35b.

CONNECTION We described delocalized electrons in Section 8.1 with respect to metallic bonds, but delocalization occurs in molecules and ions as well.

Delocalization reduces the potential energy of the electrons in π bonds and lowers the energy of the entire molecule, a phenomenon known as resonance stabilization.

CONNECTION We mentioned aromatic compounds in Section 8.4 when we discussed resonance in Lewis structures.

As shown in Figure 8.16b, the presence of delocalized π electrons in benzene is often represented by a circle drawn in the middle of the hexagon of carbon atoms in the structural formula, corresponding to continuous rings of π electrons above and below the plane of the molecule. The skeletal structure of benzene is a simple hexagon with a circle in it.

CONCEPT TEST

In which of the molecules and polyatomic ions in **Figure 9.36** are the electrons in the π bonds delocalized?

The molecular structures of many other compounds in addition to benzene contain carbon rings with delocalized π electrons above and below the plane of the ring. They are called aromatic compounds. An important class of these compounds, known as *polycyclic aromatic hydrocarbons* (PAHs), consists of molecules containing several benzene rings joined together (**Figure 9.37a**). PAHs are formed any time coal, oil, gas, and most hydrocarbon fuels are burned, and they are also found in cigarette smoke. In 2004 they were discovered in interstellar space.

The shape of PAH molecules gives rise to a significant health hazard. After we inhale or ingest them, some PAHs may bind to the DNA in our cells in a process called *intercalation*. Because PAHs are flat, they can slide into the double helix that DNA forms (**Figure 9.37b**). Once there, they may alter or prevent DNA replication and thereby damage or kill cells. Intercalation in DNA is one step in the process by which PAHs induce cancer.

Chirality and Molecular Recognition

Living things respond to molecules that interact with regions in their tissues called *receptors* or *active sites*. The process by which these molecules and sites interact is known as molecular recognition. This recognition does not usually involve covalent bond formation. Instead, these noncovalent interactions require that the biologically active molecules and the receptors that respond to them fit tightly together, which means that they must have complementary three-dimensional shapes. Slight differences in these shapes can result in different biological responses, such as cilantro having the taste of a fresh herb to some people, but soap to other people.

Another example of molecular recognition is the role of the gaseous hydrocarbon ethylene, C_2H_4 (**Figure 9.38**), in speeding up the ripening of many fruits and vegetables, including the green tomatoes in **Figure 9.39**. Each of the carbon atoms in a molecule of ethylene is bonded to three other atoms and has no lone pairs of electrons. This means SN = 3, in which case the geometry around each carbon atom is trigonal planar and the atom is sp^2 hybridized (see Table 9.3). These three hybrid orbitals form three σ bonds with two hydrogen atoms and the other carbon atom. Side-on overlap of their unhybridized 2*p* orbitals forms a π bond between the carbon atoms. Taken together, the two trigonal planar carbon atoms produce an overall planar geometry for ethylene, which means that all six atoms lie in the same plane.

SAMPLE EXERCISE 9.8 Comparing Structures by Using Valence Bond Theory LO3

Use valence bond theory to describe the bonding and molecular geometry of ethane (CH_3–CH_3) and compare them with the bonding and molecular geometry of ethylene.

Collect, Organize, and Analyze We are given the condensed structure of ethane and can use it to draw its Lewis structure and then use the Lewis structure and VSEPR theory to determine its molecular geometry and the hybridization of its carbon atoms. These can be compared to the molecular structure of ethylene in Figure 9.38.

Solve Each carbon atom in ethane has four single bonds and no lone pairs, which means each carbon has SN = 4, tetrahedral geometry, and sp^3 hybridization. Comparing the overall molecular structures of ethane and ethylene (**Figure 9.40**), we see the distinctive three-dimensionality of tetrahedral environments: only two of the six C–H bonds in ethane are in the plane of the page, whereas all the bonds in ethylene are coplanar.

Think About It Remember the analogy at the beginning of the chapter about how molecules fit receptors like hands fit gloves. Based on their structures, ethylene and ethane would fit into very different gloves.

Practice Exercise Diazene (N_2H_2) and hydrazine (NH_2NH_2) are reactive nitrogen compounds. Draw the Lewis structures of these compounds and use valence bond theory to describe the differences in their molecular structures.

As Sample Exercise 9.8 illustrates, ethane (an alkane) and ethylene (an alkene) have similar formulas and molar masses, but very different molecular geometries. Ethane does not trigger the ripening process because its shape does not allow it to fit the receptor in plant tissue that binds the planar molecule ethylene. This structural difference is important in larger molecules, where planar regions caused by the presence of sp^2 hybridized carbon atoms and double bonds produce overall molecular shapes that are very different from those associated with sp^3 hybridized carbon atoms.

Before ending our exploration of molecular shapes, we need to address the subject of handedness introduced at the beginning of the chapter. There we described how two molecules with the same molecular formula and Lewis structure can interact differently with receptors in our nasal membranes. As a result, one produces the smell of caraway seeds, and the other, spearmint leaves. You may find these different odors surprising when you consider the molecular structures of these two compounds (**Figure 9.41**). At first glance they may seem identical but look closely at the bonding pattern around the carbon atoms circled in red. The H atom bonded directly to the bottom carbon atom is on the front side of the ring in the spearmint compound (the C—H bond is shown as a solid wedge), but it is on the back side in the caraway compound (the C—H bond is shown as a dashed wedge). This minor difference in bond orientation creates a difference in molecular shape that is easily recognized by receptors in our noses.

The structures in Figure 9.41 are called *optical isomers*. The term “optical” refers to the ways these compounds interact with a special kind of light called *plane-polarized* light. We explore this topic in more detail in Chapter 20, but it is enough now for you to know that when plane-polarized light passes through a solution of the caraway compound, the light twists in one direction. When the light passes through a solution of the spearmint compound, it twists in the *opposite* direction.

Optical isomerism has another name: chirality. Many molecules of biological importance, including the proteins and carbohydrates that we consume each day, are composed of chiral compounds. Chirality comes from the Greek word *chier*, meaning "hand," and is quite correctly called "handedness." Although several features within molecules can lead to chirality, the most common is the presence of a carbon atom that has four different atoms or groups of atoms attached to it.

To see how chirality works, let's consider the molecular structure of bromochlorofluoromethane (CHBrClF; **Figure 9.42a**), which is used in fire extinguishers on airplanes. It contains a central carbon atom bonded to *four* different atoms. We will compare its molecular structure with that of dibromochloromethane ($CHBr_2Cl$), a compound that may form during the purification of municipal water supplies with chlorine and that has only *three* different atoms bonded to its central carbon atom (**Figure 9.42b**). First, we generate mirror images of both molecules, and then we rotate the mirror images 180° to superimpose each mirror image on its original image. If the reflected, rotated image is superimposable on the original image, then the substance is *not* chiral. Scientists call it *achiral*. The molecular images of $CHBr_2Cl$ can be superimposed in this way, so it is achiral. The images of CHBrClF, on the other hand, can*not* be superimposed. For example, when we superimpose the F, C, and H atoms of the two images in Figure 9.42a, the Br and Cl atoms are not aligned. This means that CHBrClF *is* a chiral compound.

Any structure like CHBrClF that has four different atoms or groups attached to an sp^3 hybridized carbon atom is chiral. It has two optical isomers that are mirror images of each other and are distinctly different compounds. Where is the chiral carbon atom in the molecules of the caraway and spearmint compounds? If you guessed the circled carbon atoms, you were right. Two of the four different groups consist of a hydrogen atom and this group:

The other two “groups” on the bottom carbon atom are really the two sides of the ring. The left side contains a C□C double bond, whereas the right side contains a C□O double bond. These differences mean that the two sides are not equivalent, so the carbon atom is attached to four different groups. This makes it a chiral carbon atom, and the two compounds are optical isomers of each other.

CONCEPT TEST

Identify the molecules in **Figure 9.43** that are chiral.

Glossary

ketone
: organic molecule containing a carbonyl group in which the carbonyl carbon is bonded to two other carbon atoms.

resonance stabilization
: the stability of a molecular structure due to delocalization of its electrons.

aromatic compound
: a cyclic, planar compound with delocalized π (pi) electrons above and below the plane of the molecule.

molecular recognition
: the process by which molecules interact with other molecules in living tissues to produce a biological effect.

chirality
: a property of a molecule that is not superimposable on its mirror image.

Learning Objectives

- Draw condensed and skeletal structures of organic compounds **Return to Sample Exercise 9.7**
- Use atomic orbital hybridization and valence bond theory to explain orbital overlap, bond angles, and molecular shapes **Return to Sample Exercises 9.5, 9.6, 9.8**

9.6 Molecular Orbital Theory

Lewis structures and valence bond theory help us understand the bonding patterns in molecules and molecular ions; VSEPR theory and valence bond theory account for molecular shapes. Other phenomena, though, cannot be explained by any of these models. For example, none of these models explains why O_2 is attracted to a magnetic field whereas N_2 is slightly repelled by one, or how molecules and ions in Earth’s upper atmosphere produce the shimmering, colorful displays known as *auroras* (**Figure 9.44**). To explain these phenomena, we need molecular orbital (MO) theory, another model that describes covalent bonding.

Like valence bond theory, molecular orbital theory invokes the mixing of atomic orbitals. In valence bond theory, the mixing results in hybrid atomic orbitals, whereas molecular orbital theory is based on the formation of molecular orbitals. A key difference between the two types of orbitals is that hybrid atomic orbitals are associated with a single atom in a molecule, but molecular orbitals are spread out over two or more atoms in a molecule.

Molecular orbitals represent discrete energy states in molecules, just as atomic orbitals represent allowed energy states in single atoms. As with atomic orbitals, electrons fill the lowest-energy MOs first; higher-energy MOs are filled as more electrons are added. Electrons in molecules can move to higher-energy MOs when molecules absorb quanta of electromagnetic radiation. When the electrons return to lower-energy MOs, distinctive wavelengths of UV and visible radiation are emitted, including some of the shimmering colors in an aurora.

The colors of an aurora are caused by collisions between atoms, molecules, and molecular ions in the atmosphere with electrons and positive particles in the solar wind that are attracted to Earth's magnetic poles. These collisions produce excited-state species. As they return to their ground states, these species emit characteristic colors of light. We discussed in Chapter 7 how excited-state atoms emit characteristic atomic spectra. In this section we use MO theory to explore how excited-state molecules and molecular ions, such as N_2 and $N_2{}^+$, do the same thing.

CONNECTION In Chapter 7 we discussed the role of atomic emission and absorption spectra in the development of quantum mechanics.

Unlike atomic orbitals, including hybrid atomic orbitals, MOs are not linked to single atoms but rather belong to all the atoms in a molecule. As a result, any valence electron in a molecule could be anywhere in the molecule. This delocalized view of covalent bonding is particularly effective at describing the bonding in molecules such as benzene, in which the electrons in the p bonds of a molecular orbital are spread out over all six carbon atoms.

In MO theory, molecular orbitals are formed by combining atomic orbitals from each of the atoms in the molecule. In this book, we limit our discussion of MO theory to simple molecules in which MOs are formed from the atomic orbitals of only a few atoms. Some MOs have lobes of high electron density that lie *between* bonded pairs of atoms; they are called bonding orbitals. The energies of bonding MOs are lower than the energies of the atomic orbitals that combined to form them, so populating them with electrons (each MO can hold two electrons, just like an atomic orbital) stabilizes the molecule and contributes to the strength of the bonds holding its atoms together.

There are other MOs with lobes of high electron density that are not located between the bonded atoms. They are antibonding orbitals and have energies that are higher than the atomic orbitals that combined to form them. When electrons are in antibonding orbitals, they destabilize the molecule. If a molecule were to have the same number of electrons in its bonding and antibonding orbitals, then there would be no net energy holding the molecule together, and it would never have formed.

Another key point is that the *total number of molecular orbitals must match the number of atomic orbitals involved in forming them*. For example, combining two atomic orbitals, one from each of two atoms, produces one low-energy bonding orbital and one high-energy antibonding orbital. To further explore the distinction between bonding and antibonding molecular orbitals, let’s apply MO theory to the simplest molecular compounds: hydrogen and helium.

CONCEPT TEST

In your own words, describe one way in which hybrid orbitals and molecular orbitals are similar and one way in which they are different.

Molecular Orbitals of Hydrogen and Helium

According to MO theory, a hydrogen molecule is formed when the 1*s* atomic orbitals on two hydrogen atoms combine to form two molecular orbitals (**Figure 9.45a**). Molecular orbital theory also stipulates that these two orbitals represent two different energy states (**Figure 9.45b**).

The lower-energy bonding molecular orbital is oval and spans the two atomic centers. Its shape corresponds to enhanced electron density between the two atoms that donated their atomic orbitals. This enhanced electron density is a covalent bond. When two electrons occupy a bonding MO, a single bond is formed. When the region of highest density lies along the bond axis, as it does in the bonding MO in H_2, the MO is designated a sigma (σ) molecular orbital and the covalent bond is a σ bond. The bonding molecular orbital in H_2 is labeled σ_{1s} in Figure 9.45a because it is formed by mixing two 1*s* atomic orbitals.

The higher-energy (less stable) antibonding molecular orbital formed from two hydrogen atomic orbitals is designated $\sigma^*{}_{1s}$ (pronounced “sigma star”). This antibonding orbital has two separate lobes of electron density and a region of zero electron density (a node) between the two hydrogen atoms (Figure 9.45a).

Figure 9.45b is a molecular orbital diagram, analogous to an energy-level diagram for atomic orbitals. It shows that the σ_{1s} MO is lower in energy and therefore more stable than the 1*s* atomic orbitals by nearly the same amount that the $\sigma^*{}_{1s}$ MO is higher in energy than the 1*s* atomic orbitals. Therefore, the formation of the two MOs does not significantly change the total energy of the system. A hydrogen molecule has two valence electrons, one from each H atom, both residing in the lower-energy σ_{1s} orbital because that is the lowest-energy orbital available. As in atomic orbitals, these two σ_{1s} electrons must have opposite spins. The electron configuration that corresponds to the molecular orbital diagram in Figure 9.45b is written $(\sigma_{1s})^2$, where the superscript indicates that there are two electrons in the σ_{1s} molecular orbital. Because the energy of the electrons in a $(\sigma_{1s})^2$ configuration is lower than the energy of the electrons in two isolated hydrogen atoms, MO theory explains why hydrogen is a diatomic gas—namely, H_2 molecules are lower in energy, so they are more stable than H atoms.

CONNECTION We used energy-level diagrams in Chapter 7 to show the electron transitions between energy levels as atoms absorb and emit electromagnetic radiation.

Hydrogen is a diatomic gas, but helium exists as free atoms and not as molecular He_2. MO theory explains why. One helium atom has two valence electrons in a 1*s* atomic orbital. Mixing two He 1*s* orbitals yields the same set of molecular orbitals we generated for H_2, as shown in **Figure 9.46**. Unlike H_2, the two helium atoms have a total of four valence electrons. Each molecular orbital in Figure 9.46—the bonding orbital and the antibonding orbital—has a maximum capacity of two electrons. Adding four valence electrons to the orbitals in Figure 9.46 means filling both orbitals and the two electrons in the σ^*_{1s} orbital cancel the stability gained from having two electrons in the σ_{1s} orbital. Because there is no net gain in stability, He_2 does not exist.

Another way to compare the bonding in H_2 and He_2 is to look at the *bond order* in each. We previously defined bond order as the number of bonds between two atoms: a bond order of 1 for X—X, 2 for X□X, and 3 for X≡

A molecule of H_2 has two electrons in the bonding MO and none in the antibonding MO, so

For He_2, the bond order is 0 because an equal number of electrons reside in bonding and antibonding orbitals:

CONNECTION We first defined bond order in Section 8.7 when we related the length and strength of bonds to the number of electron pairs shared by two atoms.

A bond order of 0 means that He_2 is not a stable molecule and does not exist. In general, the greater the bond order, the stronger the bond and the more stable the molecule.

SAMPLE EXERCISE 9.9 Using MO Diagrams to Predict Bond Order I LO7

Draw the MO diagram for the molecular ion H_2^-, determine the bond order of the ion, and predict whether the ion is stable.

Collect and Organize We are asked to draw the MO diagram for the molecular ion H_2^- and then determine bond order by using Equation 9.2. If the value of the bond order is greater than 0, the ion may be stable.

Analyze We should be able to base the MO diagram for H_2^- on the MO diagram for H_2 (Figure 9.45b) because the H_2^- ion has only one more electron than H_2 and the empty $\sigma^*{}_{1s}$ orbital in H_2 can accommodate up to two more electrons.

Solve The σ_{1s} orbital is filled in H_2, so the third electron goes into the $\sigma^*{}_{1s}$ orbital. The resulting MO diagram is shown in **Figure 9.47**. The notation for this electron configuration is $(\sigma_{1s})^2(\sigma^*{}_{1s})^1$ (listing the molecular orbitals in order of increasing energy). The bond order is

We predict that the H_2^- ion is less stable than H_2 but more stable than He_2.

Think About It We encountered the idea of fractional bonds in Chapter 8 in the discussion of resonance, and we encounter it again here in the MO treatment of H_2^-. A bond order of 0.5 in MO theory means that the bond between the two atoms in H_2^- is weaker than the single bond in H_2, making H_2^- a less stable species.

Practice Exercise Use MO theory to predict whether the H_2^+ ion can exist.

Molecular Orbitals of Homonuclear Diatomic Molecules

Molecular orbital diagrams for homonuclear (same atom) diatomic molecules such as N_2 and O_2 are more complex than that of H_2 because of the greater number and variety of atomic orbitals in N_2 and O_2. Not all combinations of atomic orbitals result in effective bonding, but there are some general guidelines for constructing the molecular orbital diagram for any molecule:

1. The number of molecular orbitals equals the number of atomic orbitals used to create them.
2. Atomic orbitals with similar energy and orientation mix more effectively than do those that have different energies and orientations. For example, an *s* atomic orbital mixes more effectively with another *s* atomic orbital than with a *p* orbital. The 1*s* and 2*s* orbitals have different sizes and energies, resulting in less effective mixing than two 1*s* or two 2*s* orbitals.
3. Better mixing leads to a larger energy difference between bonding and antibonding orbitals and thus greater stabilization of the bonding MOs.
4. A molecular orbital can accommodate a maximum of two electrons; two electrons in the same MO have opposite spins.
5. Electrons in ground-state molecules occupy the lowest-energy molecular orbitals available, following the aufbau principle and Hund’s rule.

When mixing atomic orbitals to create molecular orbitals, we consider *only the valence electrons* on the atoms because core electrons do not participate in bonding. Focusing on N_2 and O_2 as examples, we first mix their 2*s* orbitals. The mixing process is analogous to the one we used for H_2, except that the resulting MOs are designated σ_{2s} and σ^*_{2s}.

CONNECTION The aufbau principle (Section 7.8) states that the most stable atomic structures are those in which the electrons are in the lowest-energy orbitals available. Hund’s rule (also Section 7.8) states that the lowest-energy electron configuration of a set of degenerate orbitals is the one with the maximum number of unpaired electrons, all having the same spin.

Next, we mix the three pairs of 2*p* orbitals, producing a total of six MOs. The different spatial orientations of the $2p_x$, $2p_y$, and $2p_z$ atomic orbitals result in different kinds of MOs (**Figure 9.48**). The $2p_z$ atomic orbitals point toward each other. When they mix, two molecular orbitals form, a $\sigma_{2\mathrm{p}}$ bonding orbital and a $\sigma^*{}_{2p}$ antibonding orbital. The lobes of the $2p_y$ and $2p_x$ atomic orbitals are oriented at 90° to the bonding axis and at 90° to each other. When the $2p_x$ orbitals mix, and when the $2p_y$ orbitals mix, they do so around the bonding axis instead of along it. This mixing produces two pi (π) molecular orbitals and two π* molecular orbitals. When electrons occupy a π orbital, they form a π bond.

The relative energies of σ and π molecular orbitals for N_2 and O_2 are shown in **Figure 9.49**. In each molecule, the energies of the MOs derived from two 2*s* atomic orbitals (σ_{2s} and $\sigma^*{}_{2s}$) are lower than the energy of the σ_{2p} MO for the same reason that a 2*s* atomic orbital is lower in energy than a 2*p* atomic orbital.

Now let’s consider the relative energies of the MOs formed by mixing the 2*p* orbitals in N_2 and O_2. We begin with O_2 (Figure 9.49b) because it is representative of most homonuclear diatomic molecules, including all the halogens. In order of increasing energy, the MOs are σ_{2p}, π_{2p}, $\pi^*{}_{2p}$, and $\sigma^*{}_{2p}$. Keep in mind that there are groups of two π_{2p} and two $\pi^*{}_{2p}$ orbitals. This means that each group of two can hold four electrons. Adding 12 valence electrons (six from each O atom) in the O_2 molecule into these MOs, starting with the lowest-energy MO first and working our way up, we get the following valence electron configuration:

O_2: $(\sigma_{2s})^2(\sigma^*{}_{2s})^2(\sigma_{2p})^2(\pi_{2p})^4(\pi^*{}_{2p})^2$

The distribution of electrons in the MO diagram follows this sequence. The two $\pi^*{}_{2p}$ orbitals are degenerate (equivalent in energy), so each contains a single electron, in accordance with Hund’s rule.

According to the MO diagram, there are two unpaired electrons in a molecule of O_2. This finding contradicts the representation of bonding obtained from the Lewis structure of O_2, from VSEPR theory, and from valence bond theory, all of which predict that the valence electrons are paired. We will return to this point shortly, but for now let's consider the MO diagram for N_2.

The MO diagrams of N_2 and O_2 can be compared in Figure 9.49. There is a difference in the relative energies of two of their MOs—namely, the π_{2p} molecular orbital is lower in energy than the σ_{2p} orbital in N_2. These energy levels are switched from their relative positions in O_2 and many other diatomic molecules. As the atomic number increases from left to right, the energy difference between the 2*s* and 2*p* orbitals increases and there is no mixing of the 2*s* and 2*p*. In N_2, the 2*s* orbital does mix with the 2*p* orbital to a small extent. This proximity of energies has the effect of lowering the energy of the σ_{2s} molecular orbital and raising the energy of the σ_{2p} orbital—enough to put it above π_{2p}. Adding ten valence electrons to this stack of MOs in N_2, lowest energy first, produces the following electron configuration:

N_2: $(\sigma_{2s})^2(\sigma^*_{2s})^2(\pi_{2p})^4(\sigma_{2p})^2$

The distribution of electrons in the MO diagram in Figure 9.49a reflects this electron configuration. There are a total of eight electrons in bonding MOs and two in antibonding MOs. Using Equation 9.2 to calculate the bond order for N_2, we get

In O_2, eight electrons occupy bonding orbitals and four electrons occupy antibonding orbitals, so

CONNECTION The spin magnetic quantum number (m_s; Section 7.6) has a value of either $+\frac{1}{2}$ or $-\frac{1}{2}$ and defines the orientation of an electron in a magnetic field.

Based on their Lewis structures (Section 8.2), we predicted a triple bond in N_2 and a double bond in O_2, and molecular orbital theory leads to the same predictions.

One of the strengths of MO theory is that it enables us to explain properties of molecular compounds that cannot be explained by other bonding theories. The magnetic behavior of homonuclear diatomic molecules is a case in point. Electrons in atoms have two possible spin orientations, depending on the value of their spin magnetic quantum number m_s. **Figure 9.50** shows the MO-based electron configurations in diatomic molecules of the row 2 elements. In most of these molecules, all the electrons are paired so that their spins cancel out. The molecules that make up most substances contain only paired electrons. This complete electron pairing means that these substances are repelled slightly by a magnetic field. These substances are said to be diamagnetic. If a substance's molecules contain unpaired electrons, as do those of B_2 and O_2, then it is attracted by a magnetic field, as shown in **Figure 9.51** for O_2, and is paramagnetic. The more unpaired electrons in a molecule, the greater its paramagnetism. Only MO theory accounts for the magnetic behavior of oxygen and of many other substances as well.

CONCEPT TEST

Can liquid N_2 and O_2 be separated from each other with a magnet? Explain your answer.

Figure 9.50 enables us to make several predictions about diatomic molecules of the second-row elements. First, Be_2 and Ne_2 do not exist for the same reason that He_2 does not exist: both Be_2 and Ne_2 have the same number of antibonding electrons as they have bonding electrons, so they have a net bond order of 0. Second, Li_2, B_2, and F_2 have a bond order of 1, whereas C_2 has a bond order of 2. Like O_2, B_2 is paramagnetic, whereas Li_2, C_2, N_2, and F_2 are diamagnetic. (We have not discussed C_2 molecules before, but they do exist in electric arcs and in comets, and they are responsible for the blue light of flames.)

SAMPLE EXERCISE 9.10 Using MO Diagrams to Predict Bond Order II LO7

In which of the molecules in Figure 9.50 does the bond order increase when one electron is removed from the molecule? You may exclude nonexistent Be_2 and Ne_2 from this analysis.

Collect, Organize, and Analyze Equation 9.2 relates bond order to the difference in the numbers of electrons in bonding and antibonding orbitals. Removing an electron from Li_2, B_2, C_2, N_2, O_2, and F_2 results in the molecular ions $Li_2{}^+$, $B_2{}^+$, $C_2{}^+$, $N_2{}^+$, $O_2{}^+$, and $F_2{}^+$, respectively. We may assume that the molecular ions have MO diagrams with orbital energies in the same order as their parent molecules. Thus, the MO diagrams for the molecular ions are the same as those in Figure 9.50, but with one electron removed from the highest-energy orbital.

Solve Removing one electron from each MO diagram in Figure 9.50 gives us

Electron Configuration	Bond Order
	$\frac{1}{2}(1 - 0) = 0.5$
	$\frac{1}{2}(3 - 2) = 0.5$
	$\frac{1}{2}(5 - 2) = 1.5$
	$\frac{1}{2}(7 - 2) = 2.5$
	$\frac{1}{2}(8 - 3) = 2.5$
	$\frac{1}{2}(8 - 5) = 1.5$

Comparing these values with the bond orders listed in Figure 9.50, we see that bond order increases for only $O_2{}^+$ and $F_2{}^+$.

Think About It Removing an electron from O_2 or F_2 reduces the number of electrons in antibonding molecular orbitals while leaving the number of electrons in bonding molecular orbitals unchanged. The result is an increase in bond order. In the other four homonuclear diatomic molecules, removing an electron reduces the number of electrons in bonding molecular orbitals while leaving the number of electrons in antibonding orbitals unchanged. The result is a decrease in bond order for Li_2^+, B_2^+, C_2^+, and N_2^+.

Practice Exercise In which molecules in Figure 9.50 does the bond order increase when one electron is *added* to the molecule?

Molecular Orbitals of Heteronuclear Diatomic Molecules

Molecular orbital theory also enables us to account for the bonding in *heteronuclear* diatomic molecules, which are molecules containing two different atoms. The bonding in some of these molecules is difficult to explain using other bonding theories. For example, it is often difficult to draw a single Lewis structure for an odd-electron molecule such as nitrogen monoxide (NO). In Chapter 8 we considered two arrangements of its valence electrons:

We predicted that oxygen was more likely to have a complete octet of valence electrons because it is the more electronegative element. In addition, experimental evidence allows us to rule out structures with unpaired electrons on the oxygen atom. Our preferred structure was therefore the one shown in red. However, the bond length in NO (115 pm) is considerably shorter than the value in Table 8.3 for an average N=O double bond (122 pm). Molecular orbital theory is useful for explaining both the bonding in NO and the deviation from the expected bond length.

Let’s consider the bonding first. The MO diagram for NO is different from the diagrams of homonuclear diatomic gases. Nitrogen and oxygen atoms have different numbers of protons and electrons, and the difference in effective nuclear charge in N and O atoms means that their atomic orbitals have different energies, as shown in **Figure 9.52** for their 2*s* and 2*p* orbitals.

For constructing the MO diagram for NO, the guidelines described previously still apply. The number of MOs formed must equal the number of atomic orbitals combined, and the energy and orientation of the atomic orbitals being mixed must be considered. One additional factor influences the energies of the MOs in heteronuclear diatomic molecules: *bonding* MOs tend to be closer in energy to the atomic orbitals of the *more* electronegative atom, whereas *antibonding* MOs tend to be closer in energy to the atomic orbitals of the *less* electronegative atom. In Figure 9.52, the energy of the bonding σ_{2s} orbital is closer to that of the 2*s* orbital of O (the more electronegative atom), whereas the energy of the antibonding σ^*_{2s} orbital is closer to that of the 2*s* orbital of N (the less electronegative atom). Similarly, the π_{2p} MOs in NO are closer in energy to the 2*p* orbitals of oxygen, whereas the π^*_{2p} MOs are closer in energy to the 2*p* orbitals of nitrogen. The proximity of the nitrogen 2*p* atomic orbitals to the π^*_{2p} MOs means that the single electron in the π^*_{2p} MO is more likely to be on nitrogen than on oxygen. This prediction is consistent with our Lewis structure in which the odd electron in NO is on the nitrogen atom.

Molecular orbital theory also enables us to rationalize the relatively short bond length in NO. Using Equation 9.2, we obtain a bond order of $\frac{1}{2}(8 - 3) = 2.5$. This is about halfway between the bond orders for N□O and N≡

SAMPLE EXERCISE 9.11 Using MO Diagrams for Heteronuclear Diatomic Molecules LO7

Nitrogen monoxide reacts with many transition metals, including the iron in our blood. In these compounds, NO is sometimes present as NO^+ and at other times as NO^-. Use Figure 9.52 to predict the bond order of NO^+ and NO^-.

Collect and Organize We are asked to predict the bond order of two diatomic ions based on the MO diagram of their parent molecule (Figure 9.52). Equation 9.2 relates bond order to the numbers of electrons in bonding and antibonding orbitals.

Analyze NO has 11 valence electrons. We can remove one electron from the MO diagram for NO to get the diagram for NO^+ and add one electron to get the diagram for NO^-.

Solve To generate NO^+, we remove the highest-energy electron in NO, which is the one in the π^*_{2p} molecular orbital. This gives NO^+ the electron configuration

NO^+: $(\sigma_{2s})^2(\sigma^*_{2s})^2(\sigma_{2p})^2(\pi_{2p})^4$

Adding an electron to the lowest-energy MO available in NO (also π^*_{2p}) yields NO^- with the valence electron configuration

NO^-: $(\sigma_{2s})^2(\sigma^*_{2s})^2(\sigma_{2p})^2(\pi_{2p})^4(\pi^*_{2p})^2$

The bond orders of the two ions are

Think About It The calculated bond orders make sense given the NO bond order of 2.5: NO^+ has one fewer electron in an antibonding orbital than NO, which increases its bond order by 0.5 to 3.0, whereas NO^- has one more electron in an antibonding orbital than NO, which decreases its bond order by 0.5 to 2.0.

Practice Exercise Using Figure 9.52 as a guide, draw the MO diagram for carbon monoxide, and determine the bond order of the carbon–oxygen bond.

Molecular Orbitals of N_2^+ and Spectra of

Auroras

In addition to predicting the magnetic properties of molecules, MO theory is particularly useful for predicting their spectroscopic properties—and the colors of auroras. In Chapter 7 we learned that the light emitted by excited free atoms is quantized and can be related to the movement of electrons between atomic orbitals. Broadly speaking, the same is true in molecules—that is, electrons can move from one molecular orbital to another by absorbing or emitting light.

How, then, are the colors of the aurora produced? The principal chemical species involved are listed in **Table 9.4**. An asterisk indicates a molecule or molecular ion in an excited state. Excited N_2 molecules (i.e., N_2*) produce deep crimson red (650–680 nm) light, and excited $N_2{}^+$ ions (i.e., $N_2{}^{+*}$) produce blue-violet (391–470 nm) light. The MO diagrams for these species are shown in **Figure 9.53**. Comparing the MO diagrams of N_2* and N_2 in Figure 9.53a, we find that one of the two electrons originally in the σ_{2p} MO in N_2 has been raised to a $\pi^*{}_{2p}$ orbital in N_2*, leaving an unpaired σ_{2p} electron behind. Figure 9.53b shows us that $N_2{}^{+*}$ also has one electron in a $\pi^*{}_{2p}$ orbital, but its σ_{2p} orbital is empty because the other σ_{2p} electron originally in the N_2 molecule was lost when it was ionized to $N_2{}^+$. As $\pi^*{}_{2p}$ electrons return from their antibonding, excited-state orbitals to the bonding σ_{2p} orbital in the ground state, the distinctive blue-violet and crimson emissions of $N_2{}^+$ and N_2 appear, as shown in the photograph in Figure 9.44.

TABLE 9.4 Origins of Colors in the Aurora

Chemical Species	Wavelength (nm)	Color
N_2*	650–680	Deep red
O*	630	Red
O*	558	Green
$N_2{}^{+*}$	391–470	Blue-violet

CONCEPT TEST

Are the bond orders of the excited-state species in Figure 9.53 the same as the ground-state species?

Using MO Theory to Explain Fractional Bond Orders and Resonance

In Chapter 8 our attempts to draw the Lewis structure of ozone led to the conclusion that molecules of O_3 are held together by two O—O single bonds plus a shared pair of electrons distributed equally across both bonds. The concept of resonance was used to describe the delocalization of the second bonding pair and the equivalency of the bonds in O_3, which are shorter and stronger than O—O single bonds but not as short or strong as O□O double bonds. In this chapter we have learned how VSEPR theory explains the bent shape of O_3 molecules, and how valence bond theory and the formation of sp^2 hybrid orbitals help us visualize the trigonal planar orientation of bonding and lone pairs of electrons that account for ozone's molecular shape.

Now let's explore how MO theory provides another perspective on the delocalized bonding in O_3—one that does not require drawing resonance structures that do not accurately convey where all the bonding and lone pairs of electrons really are. MO theory is great at explaining bonding pair delocalization because MOs are spread across several atoms or even entire molecules, not isolated between pairs of atoms. We begin with three O atoms that are connected by two single (σ) bonds and that have a total of five lone pairs of valence electrons (**Figure 9.54**). This trigonal planar pattern of electron pairs is what we would expect if each of the O atoms had sp^2 hybridized atomic orbitals. There are 14 valence electrons in Figure 9.54 (5 lone pairs + 2 σ bonds = 10 + 4 = 14), leaving $(3 \times 6) - 14 = 4$ electrons unaccounted for. Let's distribute the four electrons among a set of molecular orbitals formed by mixing the three unhybridized *p* orbitals of the three O atoms.

In MO theory, mixing three *p* orbitals with lobes above and below the bonding plane produces three molecular orbitals. One of them is a low-energy π MO, and another is a high-energy π* MO, but what about the third? It turns out that the third orbital is neither bonding nor antibonding. Instead, it is a *nonbonding* (*n*) molecular orbital. Electrons in nonbonding MOs neither lower the energy of a molecular structure, which would stabilize it, nor do they raise its energy and destabilize it. Rather, nonbonding MOs have the same energy as the atomic orbitals from which they formed, as shown in the partial MO diagram of ozone in **Figure 9.55**. Adding four electrons to these three molecular orbitals puts two electrons in the π orbital, two in the nonbonding orbital, and zero in π*. Therefore, there is $\frac{1}{2}(2 - 0) = 1$ π bond distributed across the entire molecule. The overall bond order of 2 σ bonds + 1 π bond = 3 is divided equally between the two pairs of atoms, giving an average bond order for ozone of 1.5. The pair of nonbonding electrons is also delocalized. Each of the two terminal O atoms gets half ownership of this nonbonding pair for a total of 2.5 lone pairs of electrons each, which is the average of two lone pairs on one terminal O atom and three on the other in the resonance structures of O_3:

A Bonding Theory for SN > 4

In Chapter 8 we noted that the central atoms in some molecules form more than four bonds, as shown in these Lewis structures of PCl_5 and SF_6:

Until recently, a popular explanation for how atoms such as phosphorus and sulfur can form more than four bonds was based on their using valence shell *d* orbitals to form hybrid sets of orbitals that expanded their capacities to form bonds and have more than an octet of valence electrons. Here we explore another way to explain the capacity of atoms to form more than four bonds, or, more generally, to have a steric number (consisting of bonds, lone pairs, or both) of more than four without expanding their octets.

Let’s begin by examining the bonding in molecules of a noble gas compound, XeF_2, whose synthesis was first reported in 1962. The Lewis symbol of xenon is  $:\ddot{\underset{\cdot\cdot}{Xe}}:$, which shows that the atom has a full octet in its valence shell. It has no unpaired electrons, and, theoretically, no capacity to form covalent bonds. One way to explain the existence of XeF_2 begins by hybridizing the 5*s* and two of the 5*p* orbitals in xenon’s valence shell, which yields a set of three sp^2 hybrid orbitals and one unhybridized *p* orbital as shown in **Figure 9.56a**.

Now, we assume that the two lobes of xenon’s unhybridized 5*p* orbital (which already contains two electrons) overlap with the half-filled 2*p* orbitals of two F atoms *and* that this overlap results in the formation of two Xe—F bonds as shown in **Figure 9.56b**. According to MO theory, these assumptions are valid: the three overlapping atomic orbitals can mix together, and when they do they form a set of three molecular orbitals: one bonding (σ), one antibonding (σ*), and one that is nonbonding (*n*), as shown in **Figure 9.57**.

There are a total of four electrons in the three molecular orbitals, and they preferentially fill the lowest-energy bonding and nonbonding MOs, leaving the antibonding orbital empty. Electrons in the nonbonding orbital do not influence bond order, so the presence of two electrons in the bonding orbital together with the absence of any electrons in the antibonding orbital produces a bond order of $(2 - 0)/2 = 1$. This bond order of 1 is delocalized over both Xe—F bonds, leaving each one with an effective bond order of only $\frac{1}{2}$ (the two nonbonding electrons are located on the F atoms).

Thus, MO theory predicts that XeF_2 should exist, which it has since 1962. In addition, using xenon’s unhybridized *p* orbital to make the two Xe—F bonds means that the molecule should be linear, which it is. This molecular shape is reinforced by offsetting interactions between the bonding electrons and the three lone pairs of electrons in xenon's sp^2 hybrid orbitals, which are evenly distributed in lobes that are all 120° from each other in the equatorial plane of the molecule and 90° from the axial bonding orbitals. This arrangement means that the electron-pair geometry of the molecule is trigonal bipyramidal, as is expected with a central atom that has three lone pairs of valence electrons and that is bonded to two other atoms.

The bonding pattern in a molecule of PCl_5 resembles the pattern in XeF_2 because PCl_5 has trigonal bipyramidal electron-pair geometry, too. As with the Xe atom in XeF_2, the valence shell orbitals of the P atom in PCl_5 are sp^2 hybridized, but before they are, one of the 3*s* electrons is promoted to a 3*p* orbital so that, after hybridization, the valence shell contains three half-filled sp^2 hybrid orbitals and one full *p* orbital (**Figure 9.58a**).

As in XeF_2, the two lobes of the P atom's full 3*p* orbital overlap with those of the half-filled 2*p* orbitals of two Cl atoms (**Figure 9.58b**), leading to the formation of two axial P—Cl bonds that each have a bond order of $\frac{1}{2}$. The half-filled sp^2 hybrid orbitals of the P atom overlap with the half-filled 2*p* orbitals of three Cl atoms to produce three equatorial P—Cl bonds that each have a bond order of 1. Because of their lower bond order, the axial bonds are weaker and longer than the equatorial single bonds: the equatorial bonds are 202 pm long and the axial bonds are 214 pm. There are no lone pairs of electrons in the valence shell of the P atom, so the molecular shape of PCl_5 matches its electron-pair geometry: trigonal bipyramidal, as predicted by VSEPR theory for $SN = 5$.

Finally, let's consider the bonding in a molecule of SF_6. How might we model an expansion of the bonding capacity of a sulfur atom from 2—as predicted by its Lewis symbol—to 6 using only the four orbitals in its 3*s* and 3*p* subshells? One such model uses the four lobes of two of sulfur's 3*p* orbitals to make a total of four S—F bonds.

The two lobes of each of the S atom's two full 3*p* orbitals (shown in blue in **Figure 9.59**) overlap with the half-filled 2*p* orbitals of the four F atoms to form four S—F bonds: two oriented above and below the S atom in the figure and two oriented behind and in front of the S atom. Each of these four bonds, according to MO theory, has a bond order of $\frac{1}{2}$. The two half-filled *sp* hybrid orbitals of the S atom (shown in purple) overlap with the half-filled 2*p* orbitals of two F atoms to produce the two S—F bonds to the left and right of the S atom. These bonds each have a bond order of 1. The six S—F bonds are all oriented 90° from each other and give the molecule an octahedral shape, as predicted for SN = 6.

Because of their different bond orders, you might expect two of the S—F bonds to be shorter than the other four. Actually, they are all the same length because all six bonds are directed toward equivalent fluorine atoms at the corners of an octahedron and all the bonding electrons are evenly distributed over the entire molecule. Thus, any differences between hybridized *sp* and unhybridized *p* orbitals in the valence shell of the S atom disappear once the molecule forms, and each of the equivalent S—F bonds in SF_6 has a bond order of:

Metallic Bonds and Conduction Bands

We introduced metallic bonding in Section 8.1 where we described the atoms in metals as “floating” in seas of mobile bonding electrons shared by all the atoms in a sample. In this section we use a more sophisticated bonding model to describe the forces that hold the densely packed atoms in metallic solids tightly in place. Dense packing means that the valence orbitals of these atoms overlap with the orbitals of many other nearby atoms. Many interactions between each atom and its nearest neighbors make metals strong but sharing a limited number of valence electrons per atom with many bonding partners makes the bond linking any two metal atoms relatively weak.

To understand this point, consider the bond that would result if two Cu atoms came together and formed a molecule of Cu_2. Copper atoms have the electron configuration [Ar]$3d^{10}4s^1$. When the partially filled 4*s* orbitals of the two atoms overlap, they form a diatomic molecule held together by a single covalent bond (**Figure 9.60a**). However, the Cu atoms in solid copper are each surrounded by a total of 12 other Cu atoms and each is bonded to all 12 of its neighbors (**Figure 9.60b**). This means that each Cu atom must share its 4*s* electron with 12 other atoms, not just one. Inevitably, this dispersion of bonding electrons weakens the Cu—Cu bond between each pair of Cu atoms.

Metallic elements have low ionization energies, which reflects the diffuse nature of this bonding. Many metallic atoms emit photoelectrons when illuminated by photons of ultraviolet radiation or even lower-energy visible light.

CONNECTION The photoelectric effect is described in Chapter 7.

We can also use an extension of MO theory called band theory to explain the bonding in metals and other solids. For example, when the 4*s* atomic orbitals on two Cu atoms overlap to form Cu_2, the atomic orbitals combine to form two molecular orbitals with different energies, equally spaced above and below the initial energy value (**Figure 9.61a**). This is analogous to the formation of low-energy bonding and high-energy antibonding molecular orbitals. If another two Cu atoms join the first two to form a molecule of Cu_4, the 4*s* atomic orbitals of four Cu atoms combine to form four molecular orbitals. If we add another four atoms to make Cu_8, a total of eight copper 4*s* atomic orbitals combine to form eight molecular orbitals. In all these molecules the lower-energy orbitals are filled with the available 4*s* electrons and the upper orbitals are empty (**Figure 9.61b**). If we apply this model to the enormous number of atoms in a piece of copper wire, an equally enormous number of molecular orbitals is created. The lower-energy half of them is occupied by electrons, whereas the higher-energy half is empty. There are so many of these orbitals that they form a continuous *band* of energies with no gap between the occupied lower half and the empty upper half. Because this band of MOs was formed by combining valence-shell orbitals, it is called a valence band.

Band theory explains the conductivity of copper and many other metals by incorporating the assumption that essentially no gap exists between the energy of the occupied lower portion of the valence band and the empty upper portion. As a result, valence electrons can move easily from the filled lower portion to the empty upper portion, where they are free to move from one empty orbital to the next and thus flow throughout the solid.

The model of a partially filled valence shell explains the conductivity of many metals, but not all. Zinc, for example, which is copper's neighbor in the periodic table, has an electron configuration of [Ar]$3d^{10}4s^2$. All its valence-shell electrons reside in filled orbitals, which means the valence band in solid zinc is filled (**Figure 9.62**). With no empty space in the valence band to accommodate additional electrons, it might seem that the valence-shell electrons in Zn would be immobile, making Zn a poor electrical conductor. However, electrons in the valence band of Zn *do* migrate through the solid, making zinc a good conductor of electricity. Band theory allows for *all* atomic orbitals of comparable shape and energy, including the empty 4*p* orbitals on zinc, to combine and form additional energy bands. The energy band produced by combining empty 4*p* orbitals, called a conduction band, is also empty and is broad enough to overlap the valence band. This overlap makes it possible for electrons from the valence band to move to the conduction band, where they are free to migrate from atom to atom in solid zinc, thereby conducting electricity.

CONCEPT TEST

Is the electrical conductivity of magnesium metal best explained in terms of overlapping conduction and valence bands or in terms of a partially filled valence band? Explain your answer.

Semiconductors

To the right of the metals in the periodic table is a "staircase" of elements that tend to have the physical properties of metals and the chemical properties of nonmetals. These metalloids are not as good at conducting electricity as metals, but they are much better at it than nonmetals. We can use band theory to explain this intermediate behavior. In metalloids, the conduction and valence bands do *not* overlap but instead are separated by an energy gap. In silicon, the most abundant metalloid, band theory predicts an energy gap, or band gap (E_g), of 107 kJ/mol at 298 K (**Figure 9.63a**).

Generally, only a few valence-band electrons in Si have sufficient energy to move to the conduction band, which limits silicon's ability to conduct electricity and makes it a semiconductor. However, we can enhance the conductivity of solid Si, or of any other elemental metalloid, by replacing some of the Si atoms with atoms of an element of similar atomic radius but with a different number of valence electrons. The replacement process is called *doping*, and the added element is called a *dopant*. Suppose the dopant is a group 15 element such as phosphorus. Each P atom has one more electron than the atom of Si (group 14) that it replaced. The energy of these additional electrons is different from the energy of the silicon electrons. They populate a narrow band located in the silicon band gap (**Figure 9.63b**). This arrangement effectively reduces the size of the energy gap and increases electrical conductivity because electrons can move more easily across the remaining gaps between the valence and conduction bands. Phosphorus-doped silicon is an example of an n-type semiconductor because the dopant contributes extra negative charges (electrons) to the structure of the host element.

The conductivity of solid silicon can also be enhanced by replacing some Si atoms with atoms of a group 13 element such as gallium (**Figure 9.63c**). Because Ga atoms have one fewer valence electron than Si atoms, substituting them in the Si structure means fewer valence electrons in the solid. The result is the creation of a narrow Ga conduction band (*acceptor band*, **Figure 9.63d**) in the Si band gap. Because the gap between the Si valence band and the acceptor band is smaller than the band gap in pure Si, electrons from the valence band move more easily to the acceptor band, increasing electrical conductivity. This array of bands makes Si doped with Ga a p-type semiconductor because a reduction in the number of negatively charged electrons in the valence band is equivalent to the presence of positively charged “holes” as shown in Figure 9.63d. The semiconductors used in solid-state electronics are combinations of n-type and p-type.

Doping is not the only way to change the conductivity of semimetals. Compounds prepared from combinations of group 13 and group 15 elements also may behave as semiconductors. For example, gallium arsenide (GaAs) is a semiconductor that emits infrared radiation ($\lambda = 874$ nm) when connected to an electrical circuit. This emission is used in devices such as bar-code readers and DVD players. Like silicon, solid gallium arsenide has both a valence band and a conduction band separated by a characteristic band gap. The energy of each photon of light corresponds to the energy gap between the valence band and the conduction band. When electrical energy is applied to the material, electrons are raised to the conduction band. When they fall back to the valence band, they emit radiation. If some aluminum is substituted for gallium in GaAs, the band gap increases, and the wavelength of emitted light decreases. For example, a material with the empirical formula $AlGaAs_2$ emits orange-red light ($\lambda = 620$ nm). Many of the multicolored indicator lights in electronic devices use $AlGaAs_2$ semiconductors.

CONNECTION We introduced the metalloids in Section 2.5 when we described the structure of the periodic table.

CONNECTION Emission spectra obtained from gas discharge tubes are discussed in Chapter 7.

SAMPLE EXERCISE 9.12 Distinguishing p- and n-Type Semiconductors LO8

Which kind of semiconductor—n-type or p-type—is created when germanium is doped with arsenic?

Collect and Organize We are asked to determine the type of semiconductor formed when germanium (Ge, group 14) is doped with arsenic (As, group 15). Figure 9.63 helps us distinguish between n- and p-type semiconductors.

Analyze When the dopant has *more* valence electrons than the host semimetal, the two form an n-type semiconductor (Figure 9.63b). If the dopant has *fewer* valence electrons than the host, the result is a p-type semiconductor (Figure 9.63c).

Solve Atoms of arsenic have one more valence electron than do the atoms of Ge, so As-doped Ge is an n-type semiconductor.

Think About It Other group 15 elements might also be used as dopants for making germanium-based, n-type semiconductors, but arsenic is a particularly good candidate because As atoms are nearly the same size as Ge atoms and fit easily into the structure of solid Ge.

Practice Exercise Gallium arsenide (GaAs) is a semiconductor used in optical scanners in retail stores. GaAs can be made an n-type or a p-type semiconductor by replacing some of the As atoms with another element. Which element—Se or Sn—would form an n-type semiconductor with GaAs?

In Chapter 8 and in this chapter we have presented several theories of chemical bonding. Each theory has its strengths and weaknesses. The best one to apply in a given situation depends on the questions being asked and on the level of sophistication required in the answer. If our focus is on how the atoms in the second row of elements in the periodic table bond together in molecules, Lewis structures usually suffice. If we are also interested in visualizing the shapes of molecules, then VSEPR theory and valence bond theory can be useful tools. However, if we want to explain the magnetic properties of molecular compounds and their ability to absorb and emit UV radiation and visible light, then molecular orbital theory is our most powerful model. Molecular orbital theory may provide the most complete picture of covalent bonding, but it is also the most difficult to apply to large molecules.

Although we have focused primarily on the small molecules found in the atmosphere—nitrogen, oxygen, water, carbon dioxide, methane, ozone—and somewhat larger molecules found in living systems, the principles described in this chapter apply to larger and more complex molecules and ions. We return to the importance of molecular shape, particularly in defining the biological activity of both large and small molecules, in later chapters of this book.

SAMPLE EXERCISE 9.13 Integrating Concepts: Insect Pheromones

Social insects such as bees, wasps, and ants communicate with one another by secreting and detecting molecules called pheromones. Small differences in the structure of these compounds, including chiral carbon atoms, lead to differences in shape that signal for either finding a mate or avoiding a predator. This molecular recognition is the basis of traps used to capture destructive pests such as the Japanese beetle (**Figure 9.64**).

The sex pheromone for the Japanese beetle used in these traps is called japonilure. The condensed structure for this compound is

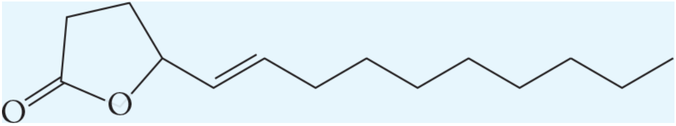
---

1. Draw the skeletal structure of japonilure.
2. Determine the molecular geometry at the carbonyl carbon atom in the ring. What hybridization best explains this geometry? Identify two other atoms in japonilure that also have this hybridization.
3. How many π bonds are in this molecule? Do these contain delocalized π electrons?
4. Identify the chiral carbon atom in japonilure.

Collect, Organize, and Analyze We are given the condensed structure of japonilure. The molecule consists of a five-atom ring and a long hydrocarbon chain. Section 9.5 provides guidelines on how to draw skeletal structures and their relationship to condensed structures. The atoms at each vertex in the ring are carbon atoms. Sections 9.2 and 9.4 provide guidelines for determining the molecular geometry of an atom and for assessing the hybrid orbitals that are consistent with those geometries, including the formation of σ and π bonds. Section 9.5 also explains why carbon atoms bonded to four different groups are chiral.

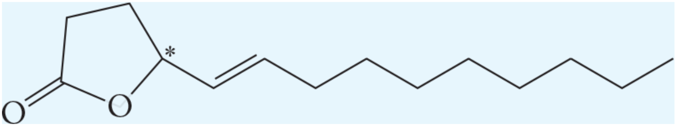
Solve

1. The hydrocarbon chain attached to the ring can be drawn using the zigzag lines of a skeletal structure. There are 10 carbon atoms in the chain. There is a double bond between the first and second carbon atom in the chain, followed by seven methylene groups and ending with a methyl group:

2. The carbon atom in the C□O carbonyl group has a steric number of 3 because it has the double bond to oxygen as well as single bonds to a carbon atom and a second oxygen atom. According to Table 9.1, the molecular geometry at the carbonyl carbon atom is trigonal planar. The carbonyl carbon is sp^2 hybridized. It forms three σ bonds: one to the adjacent carbon and one to each of the two oxygen atoms. The remaining *p* orbital is used to form a π bond to the oxygen atom that is part of the carbonyl group. The two carbon atoms in the hydrocarbon chain connected by a double bond are sp^2 hybridized, too.
3. As discussed in the solution to part (b), the carbonyl group contains a π bond. The double bond between the two carbon atoms in the hydrocarbon chain consists of one σ bond and one π bond. Therefore, there are two π bonds in the molecule, neither of which contains delocalized electrons because they are separated by more than one carbon atom.
4. A chiral carbon atom is bonded to four different groups. A carbon atom in a methylene ($-CH_2-$) or methyl ($-CH_3$) group cannot be chiral because it is bonded to multiple hydrogen atoms. Therefore, none of the carbon atoms in the hydrocarbon chain can be the chiral atom in japonilure. That leaves us with the four carbon atoms in the ring. The

carbonyl carbon has SN = 3, so it is not bonded to four groups and therefore cannot be chiral. The carbon atom adjacent to the carbonyl atom (and the next carbon atom) are both (–CH_2–) groups. (In skeletal structures, hydrogen atoms are not explicitly drawn, and carbon atoms are assumed to be bonded to enough hydrogen atoms to have an octet.) That leaves us with the carbon atom in the ring to which the hydrocarbon chain is attached; it is marked with a *:



Think About It Japonilure contains one chiral carbon atom, which means that two optical isomers exist. One isomer is a sex attractant for a mate, whereas the other detects the sex attractant released by a predator. This important chiral carbon atom makes the difference between life and death for a Japanese beetle.

Glossary

molecular orbital (MO) theory	A bonding theory based on the mixing of atomic orbitals of similar shapes and energies to form molecular.
molecular orbital	a region of characteristic shape and energy where electrons in a molecule are delocalized over two or more atoms in a molecule.
bonding orbital	a molecular orbital in which electron density is highest in the region between atom centers.
antibonding orbital	a molecular orbital in which electron density is highest outside the region between atom centers.
sigma (σ) molecular orbital	a molecular orbital in which the greatest electron density is concentrated along an imaginary line drawn through the bonded atom centers.

molecular orbital diagram

an energy-level diagram showing the relative energies and electron occupancy of the molecular orbitals for a molecule.

pi (π) molecular orbitals

molecular orbitals formed by the mixing of atomic orbitals oriented above and below, or in front of and behind, the bonding axis

diamagnetic

a substance with no unpaired electrons that is weakly repelled by a magnetic field.

paramagnetic

a substance with one or more unpaired electrons that is attracted to a magnetic field.

band theory

an extension of molecular orbital theory that describes bonding in solids.

valence band

a band of orbitals that are filled or partially filled by valence electrons.

conduction band

in metals, an unoccupied band higher in energy than a valence band, in which electrons are free to migrate.

band gap (E_g)

the energy gap between the valence and conduction bands.

semiconductor

a metalloid with electrical conductivity between that of metals and insulators that can be chemically altered to increase its electrical conductivity.

n-type semiconductor

a semiconductor containing electron-rich dopant atoms that contribute excess electrons.

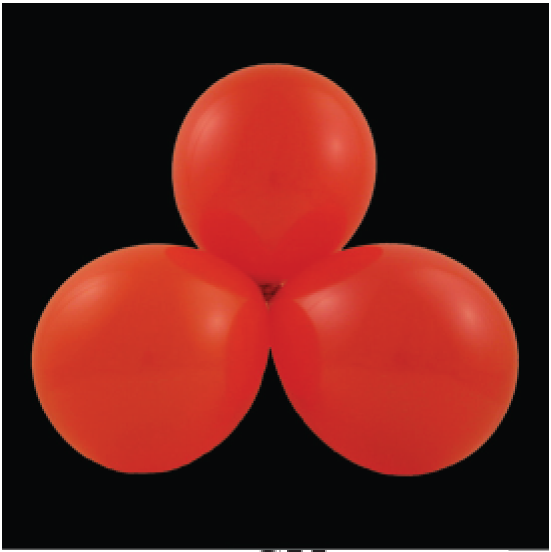
p-type semiconductor

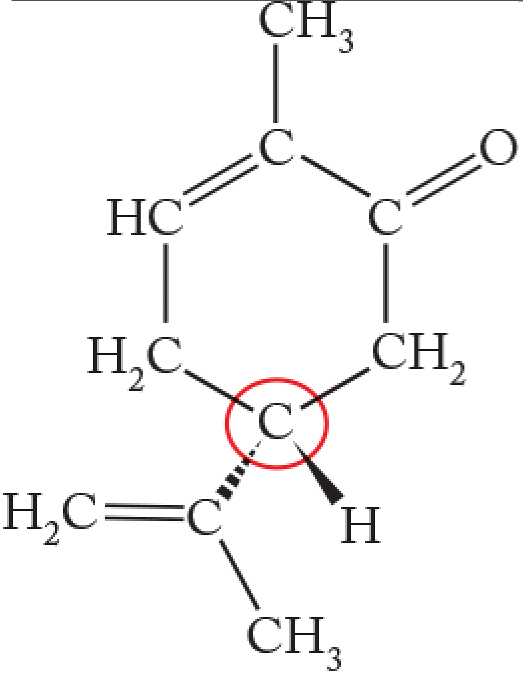
a semiconductor containing electron-poor dopant atoms that cause a reduction in the number of electrons, which is equivalent to the presence of positively charged holes.

Learning Objectives

- Draw molecular orbital (MO) diagrams of diatomic molecules and use MO theory to predict bond order and to explain magnetic properties and spectra **Return to Sample Exercises 9.9, 9.10, 9.11**

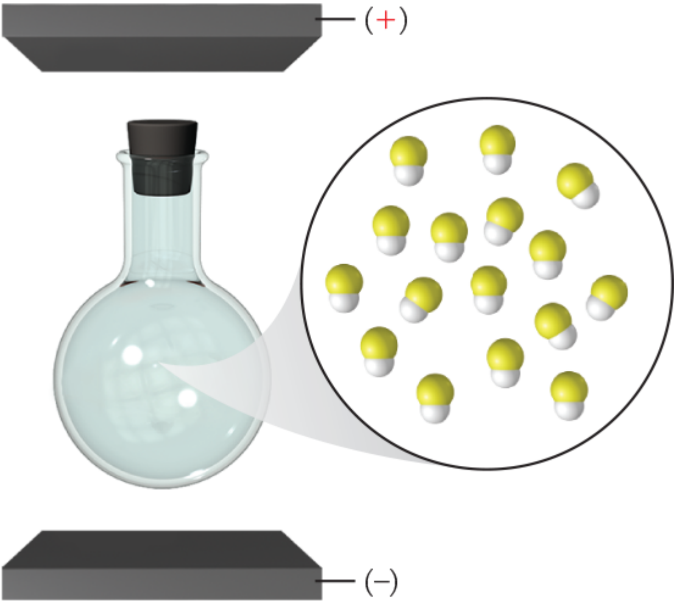
- Draw molecular orbital (MO) diagrams of diatomic molecules and use MO theory to predict bond order and to explain magnetic properties and spectra **Return to Sample Exercises 9.9, 9.10, 9.11**
- Draw molecular orbital (MO) diagrams of diatomic molecules and use MO theory to predict bond order and to explain magnetic properties and spectra **Return to Sample Exercises 9.9, 9.10, 9.11**
- Use MO theory to describe metallic bonding and the properties of doped and undoped semiconductors **Return to Sample Exercise 9.12**





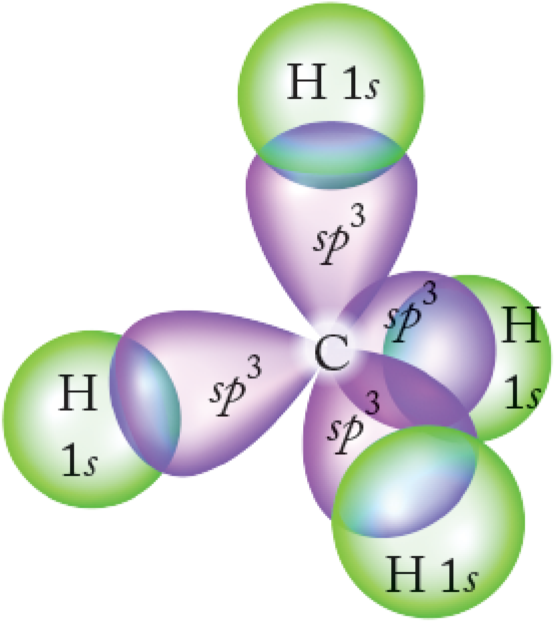
SUMMARY

LO1 The shape of a molecule reflects the arrangement of the atoms in three-dimensional space and is determined largely by characteristic bond angles. Minimizing repulsion between pairs of valence electrons (the VSEPR model) results in the lowest-energy orientations of bonding and nonbonding electron pairs and accounts for the observed molecular geometries of molecules. The shape of a molecule can be determined by its steric number (the sum of the number of bonded atoms and lone pairs around a central atom) and the electron-pair geometry (the arrangement of its atoms and lone pairs). Molecules with SN $=$ 2 and no lone pairs on the central atom have a linear electron-pair geometry and linear molecular geometry, while the electron-pair geometries of molecules with steric numbers 3 to 6 are trigonal planar, tetrahedral, trigonal bipyramidal, and octahedral, respectively. The presence of lone pairs of electrons in molecules with the preceding electron-pair geometries produce the following additional *molecular* geometries: angular (bent), trigonal pyramidal, seesaw, T-shaped, square pyramidal, and square planar. The observed bond angles in molecules deviate from the ideal values because of unequal repulsions between lone pairs and bonding pairs of electrons. (Sections 9.1 and 9.2)



Electric field on

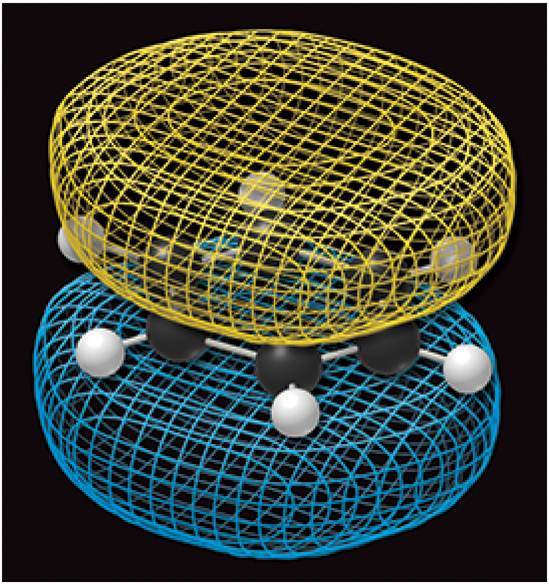
- LO2 Two covalently bonded atoms with different electronegativities have partial electrical charges of opposite sign, creating a bond dipole. If the individual bond dipoles in a molecule do not offset each other, the molecule is polar. If they do offset each other, the molecule is nonpolar. A polar molecule has a permanent dipole moment (μ), which is a quantitative measure of the polarity of the molecule. (Section 9.3)



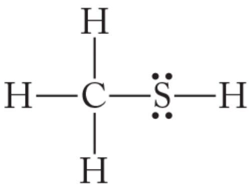
CH_4

- LO3 In valence bond theory, the overlap of half-filled atomic orbitals results in covalent bonds between pairs of atoms in molecules. Molecular geometry is explained by the mixing, or hybridization, of atomic orbitals to create hybrid atomic orbitals. Mixing one *s* and three *p* orbitals forms four sp^3 hybrid orbitals. Overlap between sp^3 orbitals and other atomic or hybrid orbitals results in up to four sigma (σ) bonds and a tetrahedral orientation of valence electrons. Mixing one *s* and two *p* orbitals forms three sp^2 hybrid orbitals. Overlap between sp^2 orbitals and other atomic or hybrid orbitals results in up to three σ bonds and a trigonal planar orientation of valence electrons. Mixing one *s* and one *p* orbital forms two *sp* hybrid orbitals. Overlap between two *sp* hybrid orbitals results in up to two σ bonds oriented linearly to one another. Covalent bonds in which the electron density is greatest either above and below or in front of and behind the bonding axis are pi (π) bonds. The shape of a molecule with more than one central atom is a result of overlapping geometries around the atoms. (Section 9.4)

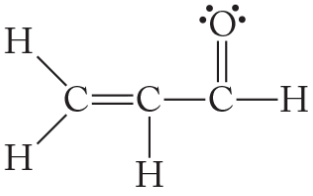
- LO4 Chemists use multiple representations to draw larger organic molecules, including condensed structures and skeletal structures. (Section 9.5)



- LO5 Molecules with only sp^2 hybridized central atoms have extended planar geometries. The molecules of aromatic compounds contain planar rings of six sp^2 hybridized carbon atoms with alternating π bonds whose electrons are delocalized over the entire ring system. Molecules with alternating single and double bonds are stabilized by electron delocalization over the system. (Section 9.5)



Methyl mercaptan



Acrolein

- LO6 Chiral molecules exist in left- and right-handed forms that have different properties. Many contain an sp^3 hybridized carbon atom bonded to four different atoms or groups of atoms. (Section 9.5)

- LO7 Molecular orbital (MO) theory is based on the formation of molecular orbitals, which are orbitals delocalized over two or more atoms in a molecule. MO theory does not explain shape, but it does explain the magnetic and spectroscopic properties of molecules in ways that valence bond theory cannot. Mixing two atomic orbitals creates one bonding orbital and one antibonding orbital. The region of highest electron density lies along the bond axis in a sigma (σ) molecular orbital. Electrons in σ bonding orbitals form σ bonds. The regions of highest electron density of pi (π) molecular orbitals are above and below or behind and in front of the bonding axis. Electrons occupying π bonding orbitals form π bonds. A molecular orbital diagram shows relative energies of the molecular orbitals in a molecule. MO electron configurations use the designations σ, σ*, π, and π* to describe the type of molecular orbitals occupied by electrons; subscripts to identify the atomic orbitals that combined to form the MOs; and superscripts to indicate the number of electrons in each MO. Atoms, ions, and molecules with no unpaired electrons are diamagnetic and are slightly repelled by an applied magnetic field. Atoms, ions, and molecules containing at least one unpaired electron are paramagnetic and are attracted by an external magnetic field. The bonding in molecules with more than an octet of valence electrons around a central atom is best explained using MO diagrams. (Section 9.6)
- LO8 MO theory is useful to describe metallic bonding and semiconductors. The electrical conductivity of metals can be explained by band theory as the ease with which valence electrons can gain mobility by moving into empty energy levels in multiatom structures. Metalloids are semiconductors, intermediate in electrical conducting ability between metals and nonmetals. In semiconductors, the filled valence band and empty conduction band are separated by a band gap (E_g). Substituting electron-rich atoms into a semiconductor results in n-type semiconductors. Substituting electron-poor atoms results in p-type semiconductors. Both types of substitution increase the conductivity of the semiconductor by decreasing its band gap. (Section 9.6)

PARTICULATE PREVIEW WRAP-UP

The Lewis structures of methyl mercaptan and acrolein are shown here. Lewis structures do not include shape information (bond angles), but they tell us, for example, that the steric numbers of the carbon atom and the sulfur atom in methyl mercaptan are both four, which means they have tetrahedral electron-pair geometries and bond angles near 109°, which means the molecule is *not* planar. The steric number of all three carbon atoms in acrolein is three, which gives all three atoms trigonal planar electron-pair and molecular geometries and bond angles near 120°. These linked planar molecular geometries make the entire molecule planar.

PROBLEM-SOLVING SUMMARY

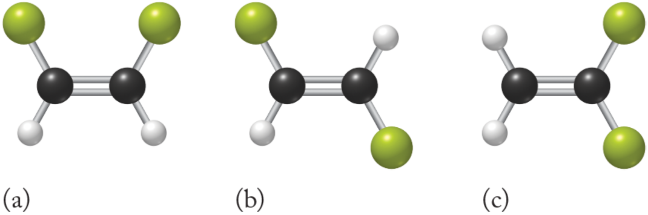
Type of Problem	Concepts and Equations	Sample Exercises
Predicting molecular geometry	Draw the Lewis structure for the molecule. Determine the steric number (SN) of the central atom, where $$\text{SN} = \begin{pmatrix}\text{number of atoms}\\ \text{bonded to central atom}\end{pmatrix} + \begin{pmatrix}\text{number of lone pairs}\\ \text{on central atom}\end{pmatrix} \quad (9.1)$$ Choose a geometry that minimizes repulsion between electron pairs.	9.1, 9.3
Predicting relative sizes of bond angles	Lone pairs on a central atom push bonded atoms closer together, decreasing bond angles.	9.2
Predicting the polarity of a substance	Assign the direction of polarity to each bond dipole and use molecular geometry to determine whether the dipoles offset each other.	9.4
Identifying overlapping orbitals in a molecule	Identify the partially filled orbitals on the bonded atoms.	9.5
Describing bonding in molecules and the shape of molecules by using hybrid orbitals	Identify the hybrid orbitals that result from mixing different numbers of *s* and *p* orbitals that result in the observed molecular geometry: $s+p =$ two *sp* hybrid orbitals $s+$ two $p =$ three sp^2 hybrid orbitals $s+$ three $p =$ four sp^3 hybrid orbitals	9.6, 9.8
Drawing larger molecules	Write condensed structures and draw skeletal structures.	9.7
Using MO diagrams to predict bond order	$$\text{Bond order} = \frac{1}{2}\left(\begin{matrix}\text{number of}\\ \text{bonding electrons}\end{matrix} - \begin{matrix}\text{number of}\\ \text{antibonding electrons}\end{matrix}\right) \quad (9.2)$$	9.9, 9.10, 9.11
Describing n- and p-type semiconductors	Adding electron-rich dopants creates an n-type semiconductor.	9.12

Adding electron-poor dopants creates a p-type semiconductor.

VISUAL PROBLEMS

(Answers to boldface end-of-chapter questions and problems are in the back of the book.)

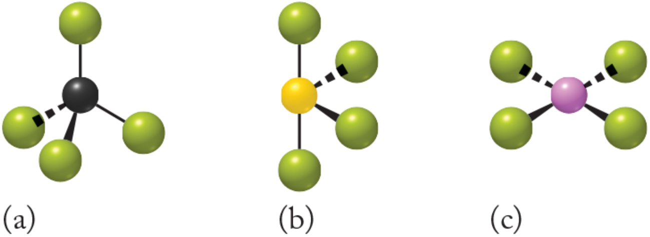
The three compounds with the molecular structures shown in Figure P9.1 have the same molecular formula: $C_2H_2Cl_2$. Which, if any, of the molecules has a dipole moment of zero?



(a) (b) (c)

FIGURE P9.1

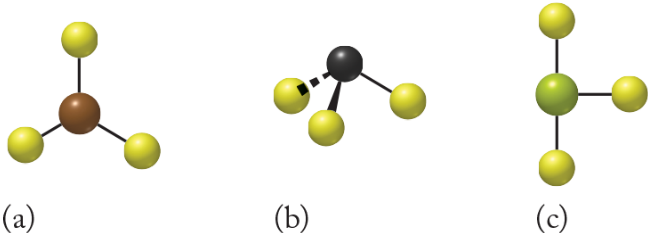
Figure P9.2 shows the molecular structures of (a) CCl_4, (b) SF_4, and (c) $XeCl_4$. What is the electron-pair geometry and the molecular geometry of each molecule?



(a) (b) (c)

FIGURE P9.2

Figure P9.3 shows the molecular structures of (a) BF_3, (b) NF_3, and (c) ClF_3. What is the electron-pair geometry and the molecular geometry of each molecule?



(a) (b) (c)

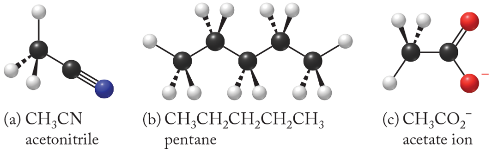
FIGURE P9.3

Which molecules in Figure P9.2 have polar bonds? Which molecules in Figure P9.2 have no dipole moment?

Which molecules in Figure P9.3 have polar bonds? Which molecules in Figure P9.3 have a permanent dipole?

Regarding the structures in Figure P9.6:

1. Which, if any, of the structures contains π electrons?
2. Which, if any, of the structures contains delocalized π electrons?



(a) CH_3CN acetonitrile (b) $CH_3CH_2CH_2CH_2CH_3$ pentane (c) $CH_3CO_2^-$ acetate ion

FIGURE P9.6

Regarding the molecular shape in Figure P9.7:

1. Which two electron-pair geometries could correspond to this molecular geometry?
2. For each of the two electron-pair geometries that could correspond to the shape in Figure P9.7, identify the hybridization of the central atom.
3. Explain why the hybridization of the central atom must be different for the two electron-pair geometries.

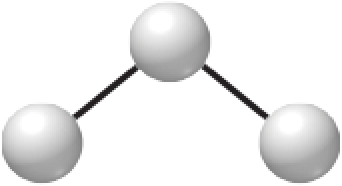


FIGURE P9.7

Could you distinguish between the two structures of N_2H_2 shown in Figure P9.8 by the magnitude of their dipole moments?

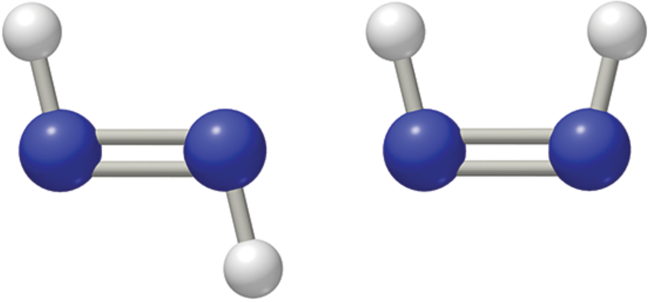

FIGURE P9.8

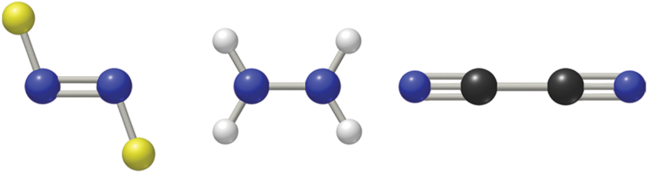
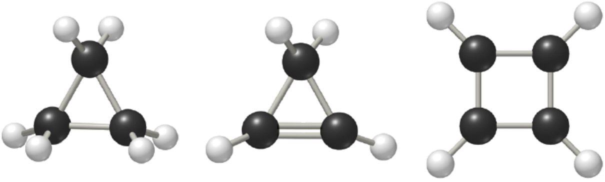
Which of the molecules shown in Figure P9.9 are planar—that is, all atoms are in a single plane? Are there delocalized π electrons in any of these molecules?



N_2F_2 H_2NNH_2 NCCN

FIGURE P9.9

Which of the molecules shown in Figure P9.10 is *not* planar? Are there delocalized π electrons in any of these molecules?



C_3H_6 C_3H_4 C_4H_4

QUESTIONS AND PROBLEMS

Biological Activity and Molecular Shape; Valence-Shell Electron-Pair Repulsion (VSEPR) Theory

Concept Review

Why is the shape of a molecule determined by repulsions between electron pairs and not by repulsions between nuclei?

Do all resonance forms of a molecule have the same molecular geometry? Explain your answer.

In a molecule of ammonia, why is the repulsion between the lone pair and a bonding pair of electrons on nitrogen greater than the repulsion between two N—H bonding pairs?

Why is it important to draw a correct Lewis structure for a molecule before predicting its geometry?

Why does the seesaw structure have lower energy than a trigonal pyramidal structure derived by removing an axial atom from a trigonal bipyramidal molecule?

Which geometry do you predict will have lower energy: a square pyramid or a trigonal bipyramid? Why?

Problems

Arrange the following molecular geometries in order of increasing bond angle: (a) trigonal planar; (b) octahedral; (c) tetrahedral.

Arrange the following molecular geometries in order of increasing bond angle: (a) square planar; (b) tetrahedral; (c) square pyramidal.

Which of the molecular geometries discussed in this chapter have more than one characteristic bond angle?

Which molecular geometries for molecules of the general formula AB_x ($x = 2$ to 6) discussed in this chapter have the same bond angles when lone pairs replace one or more atoms?

Which of the following molecular geometries does *not* lead to linear triatomic molecules after the removal of one or more atoms? (a) tetrahedral; (b) octahedral; (c) T-shaped

Which of the following molecular geometries does *not* lead to linear triatomic molecules after the removal of one or more atoms? (a) trigonal bipyramidal; (b) seesaw; (c) trigonal planar

Describe the molecular geometries that result from replacing one atom with a lone pair of electrons in an AB_7 molecule with the pentagonal bipyramidal geometry shown in

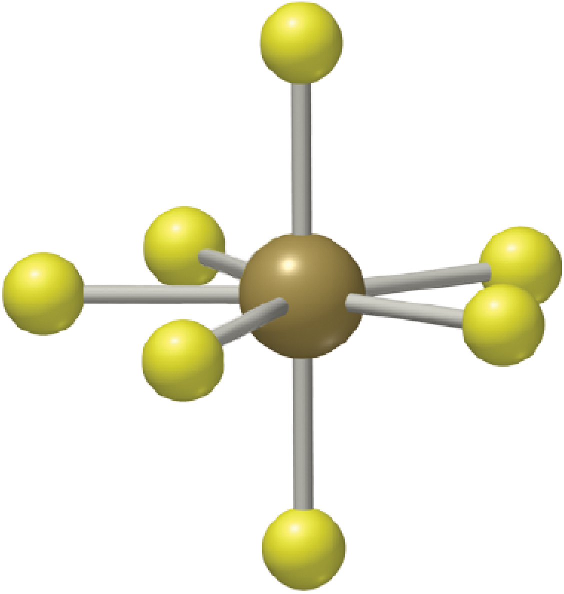

Figure P9.27.
FIGURE P9.27

Which numbered atoms would you have to remove from the cubic molecule shown in Figure P9.28 to create a geometry that approximates an octahedron?

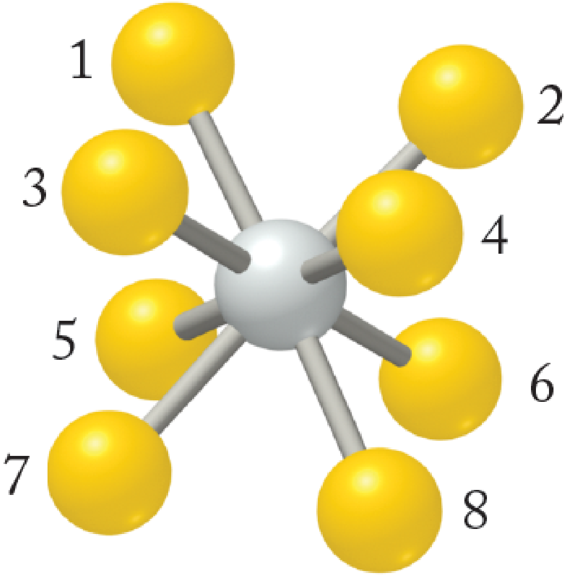

FIGURE P9.28

Determine the molecular geometries of the following molecules: (a) GeH_4; (b) PH_3; (c) H_2S; (d) $CHCl_3$.

Determine the molecular geometries of the following molecules and ions: (a) NO_3^-; (b) NO_4^{3-}; (c) S_2O; (d) NF_3.

Determine the bond angles in the following ions: (a) NH_4^+; (b) SO_3^{2-}; (c) NO_2^-; (d) XeF_5^+.

Determine the bond angles in the following ions: (a) SCN^-; (b) BF_2^+; (c) ICl_2^-; (d) PO_3^{3-}.

Determine the electron-pair and molecular geometries of the following ions: (a) $S_2O_3^{2-}$; (b) PO_4^{3-}; (c) NO_3^-; (d) NCO^-.

Determine the electron-pair and molecular geometries of the following molecules: (a) ClO_2; (b) ClO_3; (c) IF_3; (d) SF_4.

Which of the following triatomic molecules—O_3, SO_2, N_2O, S_2O, and CO_2—have the same molecular geometry?

Which of the following species—N_3^-, O_3, CO_2, SCN^-, CNO^-, and NO_2^-—have the same molecular geometry?

The anion $C(CN)_3^-$ has a trigonal planar geometry about the central carbon atom. Draw Lewis structures for $C(CN)_3^-$, including resonance forms, and determine which structure contributes the most to the bonding.

The anion $C(NO_2)_3^-$ has a trigonal planar geometry about the carbon atom. Draw Lewis structures for $C(NO_2)_3^-$, including resonance forms, and determine which structure contributes the most to the bonding.

The C—N—C bond angles in tri(methyl)amine, $N(CH_3)_3$, are approximately 109°, whereas the Si—N—Si and S—N—S bond angles in $N(SiH_3)_3$ and $N(SCF_3)_3$, respectively, are 120° as shown in Figure P9.39. Explain the difference in bond angle between $N(CH_3)_3$ and the other two compounds.

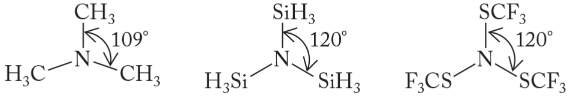

FIGURE P9.39

Complete the Lewis structures of $SCNCl_3$ in Figure P9.40. Is the geometry around nitrogen the same in both molecules?

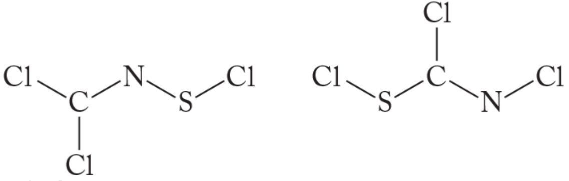

FIGURE P9.40

For many years, it was believed that the noble gases could not form covalently bonded compounds. However, xenon reacts with fluorine and oxygen. Reaction between xenon tetrafluoride and fluoride ions produces the pentafluoroxenate anion:

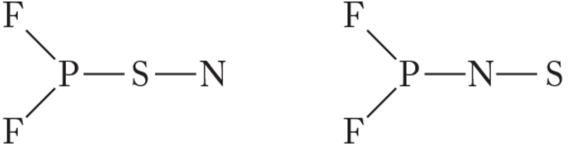
$XeF_4 + F^- \rightarrow XeF_5^-$

Draw Lewis structures for XeF_4 and XeF_5^-, and predict the geometry around xenon in XeF_4. The crystal structure of XeF_5^- compounds indicates a pentagonal bipyramidal orientation of valence pairs around Xe. Sketch the structure for XeF_5^-.

The first compound containing a xenon–sulfur bond was isolated in 1998. Draw a Lewis structure for HXeSH and determine its molecular geometry at Xe.

The Cl—O distances in ClO_2^+, ClO_2, and ClO_2^- are 131 pm, 147 pm, and 156 pm, respectively. The corresponding O—Cl—O bond angles are 122°, 118°, and 110°. Draw Lewis structures consistent with these data.

The skeletal structures of F_2PSN and F_2PNS are shown in Figure



P9.44.
FIGURE P9.44

---

1. Complete the Lewis structures for both forms of this compound such that the P—S—N and P—N—S bond angles are 120°.
2. Is the N—S bond distance the same in both molecules?

The three group 16 tetrafluorides—SF_4, SeF_4, and TeF_4—all have the seesaw structure, but their bond angles in Figure P9.45 follow the order M = S > Se > Te. Explain this trend.

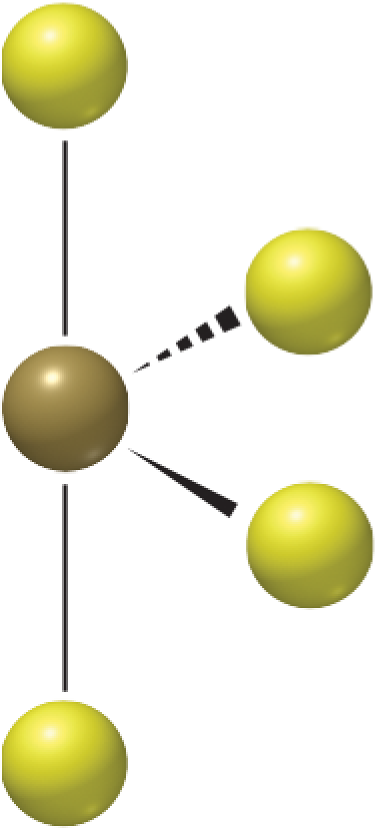


FIGURE P9.45

Two resonance forms of the $SF_4(NH_2)^+$ cation are shown in Figure P9.46. Are the bond angles likely to be the same in both? If not, which angles will be different?

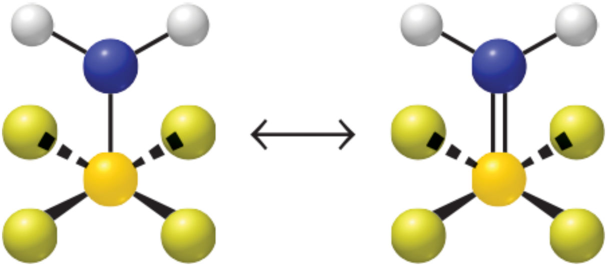

FIGURE P9.46

Polar Bonds and Polar Molecules

Concept Review

Describe the criteria for distinguishing between nonpolar covalent, polar covalent, and ionic bonds.

Describe how you would determine whether a molecule has a permanent dipole.

Can a nonpolar molecule contain polar covalent bonds?

Compare the dipole moments of CO_2 and OCS.

Problems

Consider the following molecules: (a) CCl_4; (b) $CHCl_3$; (c) CO_2; (d) H_2S; (e) SO_2.

Which1of them contain polar bonds?
Which2are polar molecules?
Which3are nonpolar molecules?

Fluorine forms compounds with B, C, N, O, and itself: BF_3, CF_4, NF_3, OF_2, and F_2. Which of these molecules are polar?

Freon Ban Compounds containing carbon, chlorine, and fluorine are known as Freons or chlorofluorocarbons (CFCs). Widespread use of these substances was banned because they destroyed the ozone layer in the upper atmosphere. Which of the following CFCs are polar and which are nonpolar? (a) Freon 11 ($CFCl_3$); (b) Freon 12 (CF_2Cl_2); (c) Freon 113 (Cl_2FCCF_2Cl)

Which of the following chlorofluorocarbons (CFCs) are polar and which are nonpolar? (a) Freon C318 (C_4F_8, cyclic structure); (b) Freon 1113 (C_2ClF_3); (c) $Cl_2HCCClF_2$

Xenon gas reacts with ClCN and BrCN to form ClXeCN and BrXeCN, respectively (Figure P9.55).

FIGURE P9.55

---

1. Are the two compounds isoelectronic?
2. Which bond is the most polar in each molecule?
3. Which molecule has the larger value of μ?

The two compounds shown in Figure P9.56 are isoelectronic.

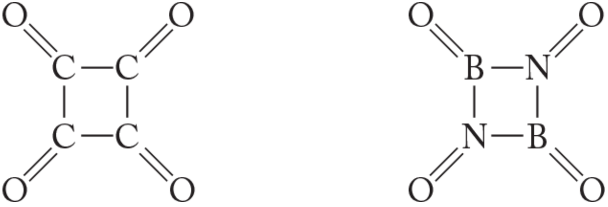

FIGURE P9.56

---

1. Why are the two molecules considered to be isoelectronic?
2. Which bond is the most polar in each molecule?
3. Which bond is the most polar overall?
4. Which molecule has the larger value of μ?

Which molecule in each of the pairs in Figure P9.57 has the larger dipole moment?

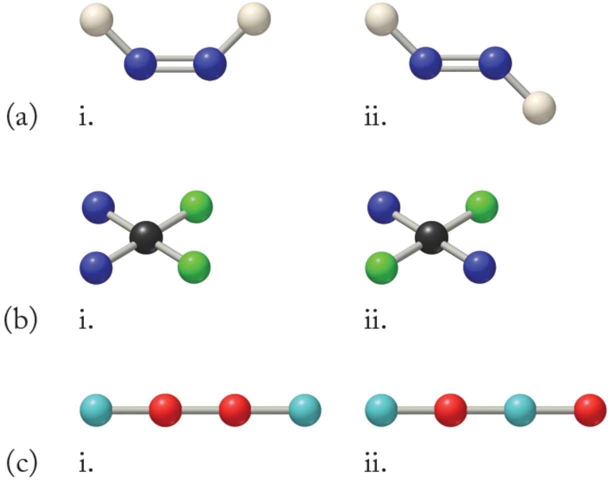

FIGURE P9.57

Which molecule in each of the following pairs has the larger dipole moment? (a) BF_3 or BCl_3; (b) BCl_2F or $BClF_2$

Aluminum chloride has the Lewis structure shown in Figure P9.59.

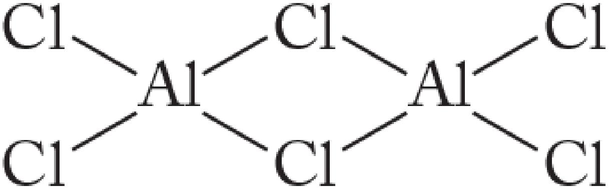

FIGURE P9.59

1. What is the geometry about the aluminum atom?
2. Is Al_2Cl_6 polar or nonpolar?

Cleaning Silicon Chips Nitrogen trifluoride (NF_3) is used in the electronics industry to clean surfaces. NF_3 is also a potent greenhouse gas.

1. Draw the Lewis structure of NF_3 and determine its molecular geometry.
2. BF_3 and NF_3 both have three covalently bonded fluorine atoms around a central atom. Do they have the same dipole moment?
3. Could BF_3 also behave as a greenhouse gas?

Valence Bond Theory

Concept Review

Why aren’t the orbitals on isolated atoms hybridized?

Can hybrid orbitals be associated with more than one atom? Explain your answer.

Describe in your own words the differences between sigma and pi bonds.

What hybridization scheme of *s* and *p* orbitals are needed to form two σ and two π bonds to a carbon atom?

Problems

Draw a valence bond diagram like the ones in Figures 9.24 and 9.26 that describes the bonding in PCl_3.

Draw a valence bond diagram like the ones in Figures 9.24 and 9.26 that describes the bonding in NO_2^-.

Airbags Azides such as sodium azide (NaN_3) are used in automobile airbags as a source of nitrogen gas. Another compound with three nitrogen atoms bonded together is N_3F. What differences are there in the arrangement of the electrons around the nitrogen atoms in the azide ion (N_3^-) and N_3F? Is there a difference in the hybridization of the central nitrogen atom?

N_3F decomposes to nitrogen and N_2F_2 by the following reaction:

$2\ N_3F \rightarrow 2\ N_2 + N_2F_2$

N_2F_2 has two possible structures, as shown in Figure P9.68. Are the differences between these structures related to differences in the hybridization of nitrogen in N_2F_2? Identify the hybrid orbitals that account for the bonding in N_2F_2. Are they the same as those in acetylene (C_2H_2)?

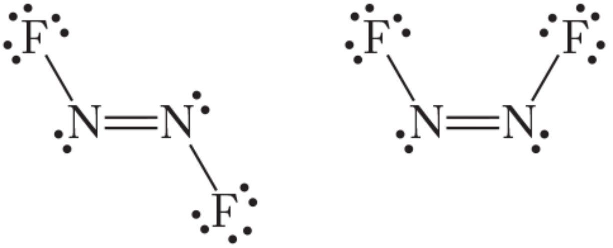

FIGURE P9.68

How does the hybridization of the sulfur atom change in the series

SF_2, SF_4, and SF_6?

How does the hybridization of the central atom change in the series CO_2, NO_2, and O_3?

Minoxidil The drug minoxidil was originally developed for treating high blood pressure but is now used primarily for treating hair loss. The Lewis structure of minoxidil is shown in Figure P9.71. Complete the Lewis structure by adding lone pairs where needed. Assign formal charges to the nitrogen and oxygen highlighted in red. Describe the bonding around the nitrogen in the N–O group.

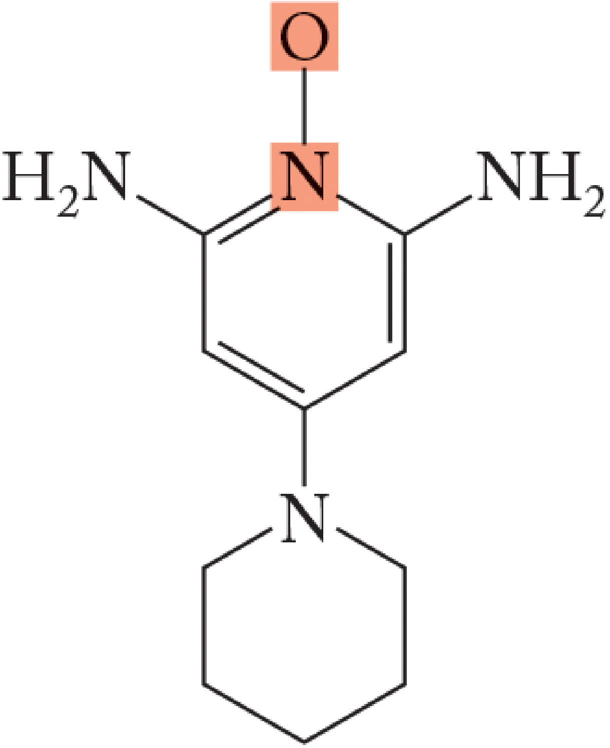

FIGURE P9.71

Treating Diabetes The drug metformin (Figure P9.72) has been used to treat type 2 diabetes for a half-century by suppressing glucose production. Metformin contains five nitrogen atoms. Determine the geometry around each nitrogen atom and describe the bonding according to valence bond theory.

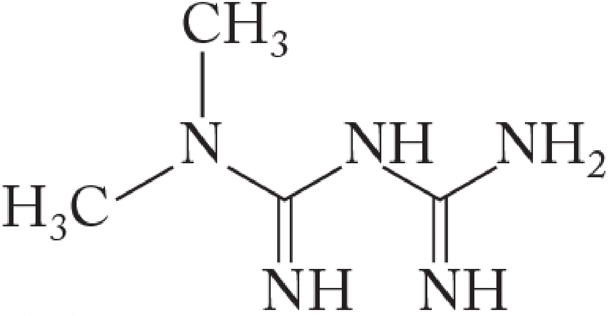

FIGURE P9.72

Draw a Lewis structure for CF_3PCF_2 where the fluorine atoms are all bonded to carbon atoms. Determine its molecular geometry at P and the hybridization of the phosphorus atom.

The Lewis structure of N_4O, with the skeletal structure O—N—N—N—N, contains one N—N single bond, one N□N double bond, and one N≡N triple bond. Is the hybridization of all the nitrogen atoms the same?

Shape, Large Molecules, and Molecular Recognition

Concept Review

What features do Lewis structures, Kekulé structures, condensed structures, and skeletal structures share? What features differentiate these four kinds of structures?

Explain why alkanes don’t have optical isomers.

Are resonance structures examples of electron delocalization? Explain your answer.

Can sp^2 and sp hybridized carbon atoms be chiral centers? Explain your answer.

Which of the following objects are chiral? (a) a baseball bat with no lettering on it; (b) a pair of scissors; (c) a boot; (d) a fork

Why is it difficult to assign a single geometry to a molecule with more than one central atom?

Problems

Bombykol is the compound synthesized by female silkworm moths to attract mates. Convert the skeletal structure in Figure P9.81 to a condensed structure.

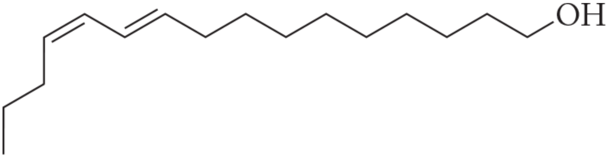

FIGURE P9.81

Fucoserratene is the compound synthesized by a brown alga to reproduce. Convert the skeletal structure in Figure P9.82 to a condensed structure.

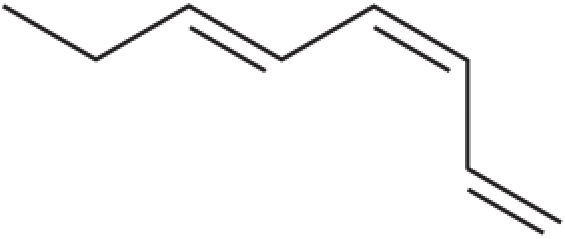

FIGURE P9.82

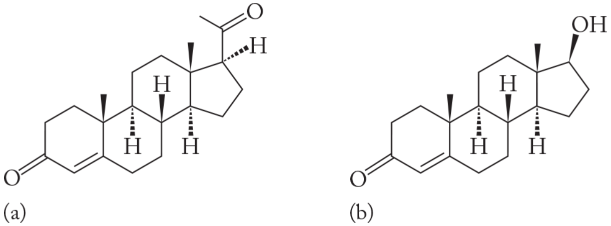
Sex Hormones Progesterone (Figure P9.83a) is a hormone involved in regulating menstrual cycles and pregnancy, whereas testosterone (Figure 9.83b) is the primary male sex



hormone.
FIGURE P9.83

1. How many carbon atoms are in each of these molecules?
2. How many sp^2 hybridized carbon atoms are in each of these molecules?
3. What functional groups do these two hormones have in common?

Steroid Hormones Cortisone (Figure P9.84) is a steroid produced by the body in response to stress. It suppresses the immune system and can be administered as a drug to reduce inflammation, pain, and swelling.

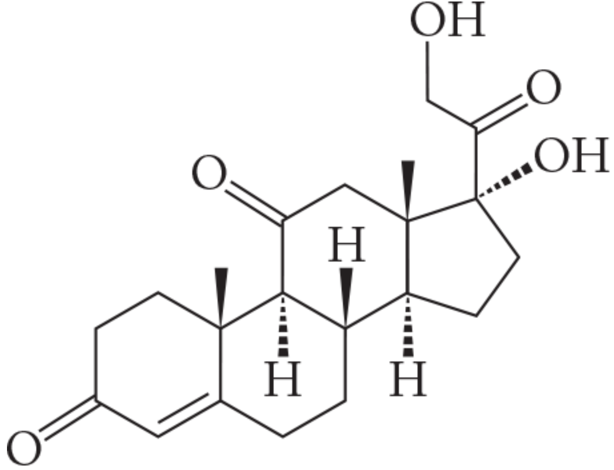


FIGURE P9.84

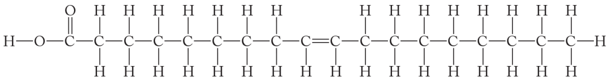
1. How many carbon atoms are in this molecule?
2. How many *sp* hybridized carbon atoms are in this molecule?
3. Identify all the functional groups in cortisone.

How many chiral carbon atoms are found in progesterone in Figure

P9.83a? In testosterone in Figure P9.83b?

How many chiral carbon atoms are found in cortisone in Figure P9.84?

Oleic acid (Figure P9.87) is a fat derived from olive oil. Write a condensed structure for oleic acid.



$$H{-}O{-}\overset{\overset{O}{\|}}{C}{-}\underset{H}{\overset{H}{C}}{-}\underset{H}{\overset{H}{C}}{-}\underset{H}{\overset{H}{C}}{-}\underset{H}{\overset{H}{C}}{-}\underset{H}{\overset{H}{C}}{-}\underset{H}{\overset{H}{C}}{-}\underset{H}{\overset{H}{C}}{-}\underset{H}{C}{=}\underset{H}{C}{-}\underset{H}{\overset{H}{C}}{-}\underset{H}{\overset{H}{C}}{-}\underset{H}{\overset{H}{C}}{-}\underset{H}{\overset{H}{C}}{-}\underset{H}{\overset{H}{C}}{-}\underset{H}{\overset{H}{C}}{-}\underset{H}{\overset{H}{C}}{-}\underset{H}{\overset{H}{C}}{-}H$$

FIGURE

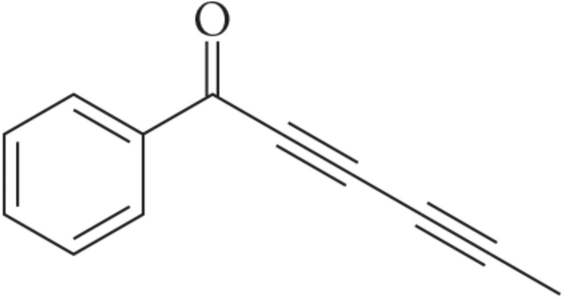
Figure P9.90 shows the skeletal structure of the antifungal compound capillin. Are there delocalized electrons in capillin? If so, identify them.



FIGURE

P9.90

Identify any chiral carbon atoms in Prozac in Figure P9.89.

Is capillin (Figure P9.90) a chiral compound?

Artificial Sweeteners Acesulfame potassium is one of many artificial sweeteners used in food. It is 200 times sweeter than sucrose (table sugar) and has the structure shown in Figure P9.93.

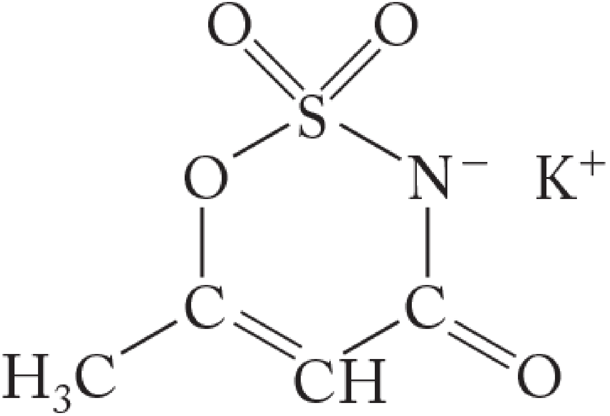


FIGURE P9.93

1. What is the geometry at each of the atoms in the six-membered ring?
2. Which atomic or hybrid orbitals overlap to form the C—O and C—N bonds?
3. In which atomic or hybrid orbital is the extra electron on N located?
4. Are there any delocalized electrons in acesulfame potassium?

First Artificial Sweetener Saccharin (Figure P9.94) was the first artificial sweetener, discovered in 1879. Like acesulfame potassium, it contains a sulfur atom adjacent to a nitrogen atom.

1. Why don't all the atoms in the five-membered ring lie in the same plane?
2. Why is it difficult to explain the bonding between S and O by

using the hybrid orbitals described in Section 9.4?
3. Are there any delocalized electrons in saccharin?

Molecular Orbital Theory

Concept Review

What is the difference between a bonding molecular orbital and an antibonding molecular orbital?

How many molecular orbitals can form from six atomic orbitals?

Are *s* atomic orbitals with different principal quantum numbers (n) as likely to overlap and form MOs as *s* atomic orbitals with the same value of n? Explain your answer.

Which atomic orbitals are more likely to mix to form a set of molecular orbitals—a $2s$ and a $3p$ orbital or a $4s$ and a $5p$ orbital?

How can molecules with even numbers of valence electrons be paramagnetic?

How does the molecular orbital diagram for a homonuclear diatomic species differ from that of a heteronuclear diatomic species?

How does the sea-of-electrons model (Chapter 8) explain the high electrical conductivity of gold? How does band theory explain this?

Some scientists believe that the solid hydrogen that forms at very low temperatures and high pressures may conduct electricity. Is this hypothesis supported by band theory?

Describe in general terms the differences in composition and conduction between n-type and p-type semiconductors.

How might doping of silicon with germanium affect the conductivity of silicon?

Problems

Make a sketch showing how two 1*s* orbitals overlap to form a σ_{1s} bonding molecular orbital and a σ^*_{1s} antibonding molecular orbital.

Make a sketch showing how two $2p_y$ orbitals overlap “side-on” to form a p_{2p} bonding molecular orbital and a π^*_{2p} antibonding molecular orbital.

Consider the following molecular ions: N_2^+, O_2^+, C_2^+, and Br_2^{2-}. Using MO theory, (a) write their orbital electron configurations; (b) predict their bond orders; (c) state whether you expect any of these species to exist.

Diatomic noble gas molecules, such as He_2 and Ne_2, do not exist.

1. Write their orbital electron configurations.
2. Does removing one electron from each of these molecules create molecular ions (He_2^+ and Ne_2^+) that are more stable than He_2 and Ne_2?

Which of the following molecular ions is expected to have one or more unpaired electrons? (a) N_2^{+}; (b) O_2^{+}; (c) C_2^{2+}; (d) Br_2^{2-}; (e) O_2^{-}; (f) O_2^{2-}; (g) N_2^{2-}; (h) F_2^{+}

Which of the following molecular ions have electrons in π antibonding orbitals? (a) O_2^{-}; (b) O_2^{2-}; (c) N_2^{2-}; (d) F_2^{+}; (e) N_2^{+}; (f) O_2^{+}; (g) C_2^{2+}; (h) Br_2^{2+}

The odd-electron molecule ClO affects the atmospheric chemistry of chlorofluorocarbons as illustrated by the reaction (where the * indicates an excited-state oxygen atom):

$CF_2Cl_2 + O^{*} \rightarrow ClO + CF_2Cl$

Draw a molecular orbital diagram for ClO. Is the odd electron in a bonding or antibonding orbital?

The elusive molecule boron monoxide (BO) can be stabilized by bonding to platinum. Draw a molecular orbital diagram for BO. Is the odd electron in a bonding or antibonding orbital?

For which of the following diatomic molecules does the bond order increase with the gain of two electrons, forming the corresponding anion with a 2− charge?

$B_2 + 2\ e^{-}$1. $\rightarrow B_2^{2-}$c. $N_2 + 2\ e^{-} \rightarrow N_2^{2-}$
$C_2 + 2\ e^{-}$2. $\rightarrow C_2^{2-}$d. $O_2 + 2\ e^{-} \rightarrow O_2^{2-}$

For which of the following diatomic molecules does the bond order increase with the loss of two electrons, forming the corresponding cation with a 2+ charge?

$B_2 \rightarrow B_2^{2+}$1. $+\ 2\ e^{-}$c. $N_2 \rightarrow N_2^{2+} + 2\ e^{-}$
$C_2 \rightarrow C_2^{2+}$2. $+\ 2\ e^{-}$d. $O_2 \rightarrow O_2^{2+} + 2\ e^{-}$

Do the 1+ cations of homonuclear diatomic molecules of the second-row elements always have shorter bond lengths than the corresponding neutral molecules?

Do any of the anions of the homonuclear diatomic molecules formed by B, C, N, O, and F have shorter bond lengths than those of the corresponding neutral molecules? Consider only the anions with 1− or 2− charge.

Thin films of doped diamond hold promise as semiconductor materials. Trace amounts of nitrogen impart a yellow color to otherwise colorless pure diamonds.

1. Are nitrogen-doped diamonds examples of semiconductors that are p-type or n-type?
2. Draw a picture of the band structure of diamond to indicate the difference between pure diamond and N-doped (nitrogen-doped) diamond.
3. N-doped diamonds absorb violet light at about 425 nm. What is the magnitude of E_g that corresponds to this wavelength?

Hope Diamond Trace amounts of boron give diamonds (including the Smithsonian's Hope Diamond) a blue color (Figure P9.120).

FIGURE P9.120

1. Are boron-doped diamonds examples of semiconductors that are p-type or n-type?
2. Draw a picture of the band structure of diamond to indicate the difference between pure diamond and B-doped diamond.
3. What is the band gap if a blue diamond absorbs red-orange light with a wavelength of 675 nm?

Additional Problems

In 1999 the ClO^+ ion, a potential contributor to stratospheric ozone depletion, was isolated in the laboratory.

1. Draw the Lewis structure for ClO^+.
2. Based on MO theory, what is the order of the Cl—O bond in ClO^+.

Arsenic-Based DNA? The waters of Mono Lake in the eastern Sierra Nevada of California (Figure P9.122) are rich in arsenate ion (AsO_4^{3-}). Some biochemists have proposed that microorganisms in this environment may incorporate arsenate into their DNA in place of the phosphate ion (PO_4^{3-}). What is the molecular geometry of the arsenate ion and the angle between its bonds?

FIGURE P9.122

Consider the molecular structure of the amino acid glycine shown in Figure P9.123. What is the angle formed by the N—C—C bonds in this structure? What are the O—C□O and C—O—H bond angles?

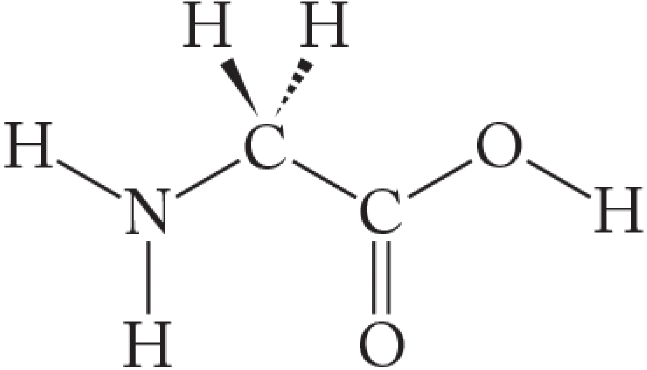

FIGURE P9.123

Thermally unstable compounds can sometimes be synthesized using matrix isolation methods in which the compounds are isolated in a nonreactive medium such as frozen argon. The reaction of boron with carbon monoxide produces compounds with the skeletal structures B—B—C—O and O—C—B—B—C—O.

1. For each of these compounds, draw the Lewis structure that minimizes formal charges.
2. Do any of your structures contain atoms with incomplete octets?
3. Predict the molecular geometries around the central boron atoms in BBCO and OCBBCO.
4. Are either of these compounds nonpolar?

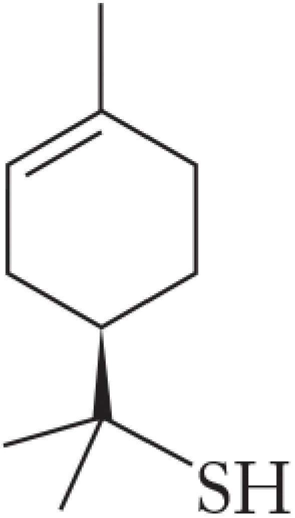
The products of the reaction between boron and NO can be trapped in solid argon matrices. Among the products is BNO. Draw the Lewis structure for BNO, including any resonance forms. Assign formal charges and predict which structure provides the best description of the bonding in this molecule. Do any of your structures contain atoms without complete octets? Predict the molecular geometry of BNO.

Compounds May Help Prevent Cancer Broccoli, cabbage, and kale contain compounds that break down in the human body to form isothiocyanates, whose presence may reduce the risk of certain types of cancer. The simplest isothiocyanate is methyl isothiocyanate (CH_3NCS). Draw the Lewis structure for CH_3NCS, including all resonance forms. Assign formal charges and determine which structure is likely to contribute the most to bonding. Predict the molecular geometry of the molecule at both carbon atoms.

Toxic to Insects and People Methyl thiocyanate (CH_3SCN) is used as an agricultural pesticide and fumigant. It is slightly water soluble and is readily absorbed through the skin; it is highly toxic if ingested. Its toxicity stems in part from its metabolism to cyanide ion. Draw three resonance structures for methyl thiocyanate. Assign formal charges and predict which structure would be the most stable. Predict the molecular geometry of the molecule at both carbon atoms.

Skunks The pungent smell of skunk spray is detected by receptors in the nose when the skunk secretes butanethiol, $CH_3(CH_2)_3SH$. Draw a skeletal structure for butanethiol.

Grapefruit Not all sulfur-containing compounds have unpleasant aromas. Figure P9.129 shows the structure of the compound primarily responsible for the aroma of grapefruit. Identify



the chiral carbon in this structure.
FIGURE P9.129

Borazine ($B_3N_3H_6$), a cyclic compound with alternating B and N atoms in the ring, is isoelectronic with benzene (C_6H_6). Are there delocalized π electrons in borazine?

Unlike O_2, sulfur monoxide (SO) is highly unstable, decomposing to a mixture of S_2O and O_2 in less than 1 second. Using the O_{2s}, O_{2p}, S_{3s}, and S_{3p} atomic orbitals, construct an approximate molecular orbital diagram for SO. Is SO diamagnetic or paramagnetic?

Ozone (O_3) has a dipole moment of 0.53 D. How can a molecule made up of only one element have a dipole moment?

A group of Finnish scientists announced the discovery of the first argon compound, HArF, in 2000. Assuming one of argon's filled 3*p* orbitals is involved in bond formation (see Figure 9.56):

1. What is the shape of the HArF molecule?
2. What is the bond order of the H—Ar and Ar—F bonds?
3. Is HArF a polar substance?

Which of the unstable nitrogen oxides—N_2O_2, N_2O_5, and N_2O_3—are polar molecules? (N_2O_2 and N_2O_3 have N—N bonds; N_2O_5 does not.)

Using an appropriate molecular orbital diagram, show that the bond order in the disulfide anion (S_2^{2-}) is equal to 1. Is S_2^{2-} diamagnetic or paramagnetic?

NO in Biology Nitrogen monoxide (NO) acts as a signaling molecule in biological processes. The products from the reaction of NO with O_2 under biological conditions have not been confirmed, but N_2O_4 is believed to be one product. Two skeletal structures for N_2O_4 are shown in Figure P9.136. Complete the Lewis structures (including resonance forms) and determine the geometry at both nitrogen atoms in each case.

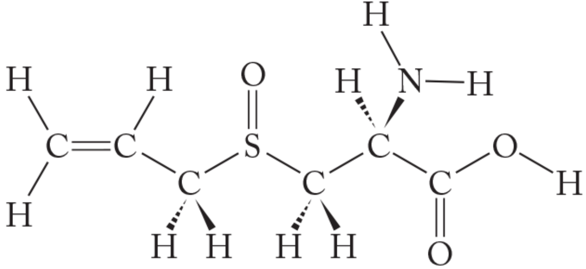
$\mathrm{O{-}N{-}O{-}O{-}N{-}O}$ $\mathrm{O_2N{-}NO_2}$ **FIGURE P9.136**

Superoxide and Peroxide Ions Some of the oxygen we breathe ends up as superoxide ion (O_2^{-}) and peroxide ion (O_2^{2-}). Cells use two classes of enzymes—superoxide dismutases and catalases—to degrade these reactive molecular ions. Use molecular orbital diagrams to determine the bond order of the O_2^{2-} and O_2^{-} ions. Are these bond order values consistent with those predicted from Lewis structures?

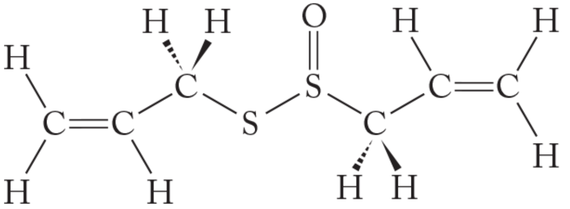
Elemental sulfur has several allotropic forms, including cyclic S_8 molecules. What is the orbital hybridization of sulfur atoms in this allotrope? The bond angles are about 108°.

The bond angle in H_2O is 104.5°, whereas the bond angles in H_2S, H_2Se, and H_2Te are very close to 90°. Which bonding theory—VSEPR, valence bond without invoking hybrid orbitals, or valence bond with hybrid orbitals—would you apply to describe the geometry in H_2S, H_2Se, and H_2Te? Why?

Garlic Garlic contains the molecule alliin (Figure P9.140). When garlic is crushed or chopped, a reaction occurs that converts alliin into the molecule allicin, which is primarily responsible for the aroma we associate with garlic.



Alliin



Allicin

FIGURE P9.140

1. Describe the molecular geometry about the sulfur atoms in both compounds.
2. Do any of the sulfur atoms in allicin have the same geometry as the sulfur atoms in the volatile sulfur compounds that cause bad breath (i.e., H_2S, $CH_3—SH$, and $CH_3—S—CH_3$)?

Glossary

bond angle

the angle (in degrees) defined by lines joining the centers of two atoms to the center of a third atom to which they are chemically bonded.

valence-shell electron-pair repulsion (VSEPR) theory

a model predicting that the arrangement of valence electron pairs around a central atom minimizes their mutual repulsion to produce the lowest-energy orientations.

molecular geometry

the three-dimensional arrangement of the atoms in a molecule.

steric number (SN)

the sum of both the number of atoms bonded to a central atom and the number of lone pairs of electrons on the central atom.

electron-pair geometry

the three-dimensional arrangement of bonding pairs and lone pairs of electrons about a central atom.

linear

the molecular geometry about a central atom with a steric number of 2 and no lone pairs of electrons; the bond angle is 180°.

trigonal planar

the molecular geometry about a central atom with a steric number of 3 and no lone pairs of electrons; the bond angles are all 120°.

tetrahedral

the molecular geometry about a central atom with a steric number of 4 and no lone pairs of electrons; the bond angles are all 109.5°.

trigonal bipyramidal

the molecular geometry about a central atom with a steric number of 5 and no lone pairs of electrons; three atoms occupy equatorial sites (bond angles 120°) and two other atoms occupy axial sites (bond angle 180°) above and below the equatorial plane; the bond angle between the axial and equatorial bonds is 90°.

octahedral

the molecular geometry about a central atom with a steric number of 6 and no lone pairs of electrons, in which all six sites are equivalent.

trigonal pyramidal

the molecular geometry about a central atom with a steric number of 4 and one lone pair of electrons.

seesaw

the molecular geometry about a central atom with a steric number of 5 and one lone pair of electrons in an equatorial position.

T-shaped

the molecular geometry about a central atom with a steric number of 5 and two lone pairs of electrons that occupy equatorial positions; the outer atoms occupy two axial sites and one equatorial site.

square pyramidal

the molecular geometry about a central atom with a steric number of 6 and one lone pair of electrons; as typically drawn, the atoms occupy four equatorial and one axial site.

square planar

the molecular geometry about a central atom with a steric number of 6 and two lone pairs of electrons that occupy axial sites; the atoms occupy four equatorial positions.

bond dipole

the separation of electrical charge created when atoms with different electronegativities form a covalent bond.

dipole moment (μ)

a measure of the degree to which a molecule aligns itself in a strong electric field; a quantitative expression of the polarity of a molecule.

valence bond theory

a quantum mechanics–based theory of bonding that incorporates the assumption that covalent bonds form when half-filled orbitals on different atoms overlap or occupy the same region in space.

overlap

the degree to which atomic orbitals on adjoining atoms occupy the same region of space.

hybridization

in valence bond theory, the mixing of atomic orbitals to generate new sets of orbitals that are then available to form covalent bonds with other atoms.

hybrid atomic orbital

in valence bond theory, one of a set of equivalent orbitals about an atom created when specific atomic orbitals are mixed.

sigma (σ) bond

a covalent bond in which the highest electron density lies between the two atoms along the bond axis.

pi (π) bond

a covalent bond in which electron density is greatest around—not along—the bonding axis; it forms from side-on overlap of two parallel *p* orbitals.

aromatic compound

a cyclic, planar compound with delocalized π (pi) electrons above and below the plane of the molecule.

chirality

a property of a molecule that is not superimposable on its mirror image.

molecular orbital (MO) theory

a bonding theory based on the mixing of atomic orbitals of similar shapes and energies to form molecular orbitals that extend across two or more atoms.

molecular orbital

a region of characteristic shape and energy where electrons in a molecule are delocalized over two or more atoms in a molecule.

bonding orbital

a molecular orbital in which electron density is highest in the region between atom centers.

antibonding orbital

a molecular orbital in which electron density is highest outside the region between atom centers.

sigma (σ) molecular orbital

a molecular orbital in which the greatest electron density is concentrated along an imaginary line drawn through the bonded atom centers.

pi (π) molecular orbitals

molecular orbitals formed by the mixing of atomic orbitals oriented above and below, or in front of and behind, the bonding axis

molecular orbital diagram

an energy-level diagram showing the relative energies and electron occupancy of the molecular orbitals for a molecule.

diamagnetic

a substance with no unpaired electrons that is weakly repelled by a magnetic field.

paramagnetic

a substance with one or more unpaired electrons that is attracted to a magnetic field.

band theory

an extension of molecular orbital theory that describes bonding in solids.

semiconductor

a metalloid with electrical conductivity between that of metals and insulators that can be chemically altered to increase its electrical conductivity.

band gap (E_g)

the energy gap between the valence and conduction bands.

n-type semiconductor

a semiconductor containing electron-rich dopant atoms that contribute excess electrons.

p-type semiconductor

a semiconductor containing electron-poor dopant atoms that cause a reduction in the number of electrons, which is equivalent to the presence of positively charged holes.

bent (or angular)

the molecular geometry about a central atom with a steric number of 3 (bonds to two atoms + one lone pair) or a steric number of 4 (bonds to two atoms + two lone pairs).

sp^3hybrid orbitals

a set of four hybrid orbitals with a tetrahedral orientation, formed by mixing one s and three p atomic orbitals.

sp^2 hybrid orbitals

three hybrid orbitals in a trigonal planar orientation, formed by mixing one s and two p atomic orbitals.

sphybrid orbitals

two hybrid orbitals oriented 180° from one another, formed by mixing one s and one p orbital.

CLEANING UP AN OIL SPILL Volunteers use dishwashing detergent to clean the oiled feathers of this pelican.

Intermolecular Forces
The Uniqueness of Water

PARTICULATE REVIEW

Polar Bonds versus Polar Molecules

In Chapter 10 we explore the connections between molecular polarity and attractive forces between molecules. Here are representations of four molecules: carbon dioxide, oxygen, water, and ozone.

- Label the polar covalent bonds in these molecules with partial charges ($\delta+$ and $\delta-$).
- Which molecule is nonpolar despite containing polar bonds?
- Which molecule is polar and contains polar bonds?
- Which molecule is polar even though it contains nonpolar bonds?

  (Review Section 9.3 if you need help.)

(Answers to Particulate Review questions are in the back of the book.)

PARTICULATE PREVIEW

One Formula, Two Structures

The physical and chemical properties of a compound depend on its structure. Here are ball-and-stick models of two compounds that have the same molecular formula. One compound is a liquid at room temperature, whereas the other is a gas. As you read this chapter, look for ideas that will help you answer these questions:

- What intermolecular forces exist between molecules of ethanol?
- What intermolecular forces exist between molecules of dimethyl ether?
- Compare the relative strength of these intermolecular forces to determine which substance is a liquid at room temperature and which is a gas.

Learning Outcomes

- LO1 Describe the types of intermolecular forces and explain how they and their strengths are related to the sizes of atoms and to the sizes, shapes, and dipole moments of molecules

  Sample Exercise 10.1

- LO2 Explain the effect of intermolecular forces on the physical properties of molecular substances, including their vapor pressures and boiling points

  Sample Exercises 10.1, 10.2

- LO3 Use the Clausius–Clapeyron equation to relate the vapor pressure of a liquid to its enthalpy of vaporization and temperature

  Sample Exercise 10.3

- LO4 Identify the regions of a phase diagram and explain the effect of temperature and pressure on phase stability and phase changes

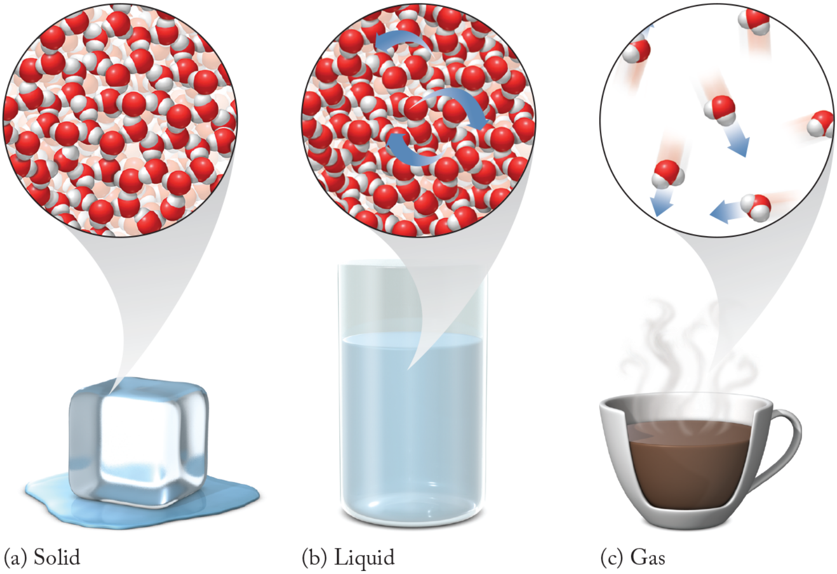
  Sample Exercise 10.4

- LO5 Relate the unique physical properties of water to the hydrogen bonds between its molecules
- LO6 Use intermolecular forces to explain and predict the relative solubilities of compounds in water and other solvents

  Sample Exercises 10.5, 10.6

- LO7 Explain how temperature, pressure, and intermolecular forces influence the solubilities of gases in liquids and use Henry’s law to calculate those solubilities

  Sample Exercise 10.7



(a) Solid (b) Liquid (c) Gas

FIGURE 10.1 (a) The molecules of H_2O in solid ice are locked in place by the strength of intermolecular attractions. (b) In liquid water, molecules of H_2O have more energy and flow past one another. (c) In water vapor above a steaming cup of coffee, the molecules have enough energy to overcome nearly all intermolecular attractions and move freely throughout the space they occupy.

10.1 Intramolecular Forces versus Intermolecular Forces

In Chapters 8 and 9 we examined the nature of the chemical bonds in molecules and showed how attractive and repulsive electrical forces between pairs of electrons determine molecular shape. We refer to these interactions *within* a molecule as *intramolecular forces*. In this chapter we begin the study of the forces that act *between* molecules and *between* molecules and ions. These *intermolecular forces* are also electrostatic in nature, but they are weaker than chemical bonds. Nevertheless, intermolecular forces strongly influence the physical properties of all substances, including their physical state (**Figure 10.1**) in the world around us.

CONNECTION The flow of energy accompanying the phase changes of water (solid ice ⇌ liquid water ⇌ water vapor) was observed in Chapter 6 in terms of the changes in kinetic and potential energies of the molecules.

Substances that are solids, for example, consist of particles that are so strongly attracted to one another that they have limited ability to overcome those forces of attraction. Consequently, these particles have the same nearest neighbors over time, and their kinetic energy is principally vibrational energy. The particles in liquids have enough kinetic energy to overcome some of the attractive forces between them. They experience more freedom of motion, including the ability to flow past one another. In gases, the average kinetic energy of the particles is enough to overcome essentially all the attractive forces between them, imparting nearly complete freedom of motion to these widely separated particles.

The stronger the attractive forces among the particles in a solid, the greater the amount of energy needed to overcome those forces to cause melting or sublimation. Thus, a substance made of particles that interact relatively strongly has high melting and boiling points, which means the substance is likely to be a solid at room temperature and normal atmospheric pressure. Under the same conditions, a substance with somewhat weaker particle–particle interactions has a lower melting point and is more likely to be a liquid. A substance with very weak particle–particle interactions has even lower melting and boiling points and is more likely to be a gas. We begin our study of intermolecular forces by examining those that are experienced by all particles from individual atoms to small polar and nonpolar molecules to biological and synthetic molecules composed of thousands or even millions of atoms bonded together.

10.2 Dispersion Forces

TABLE 10.1 Boiling Points of Noble Gases

Noble Gas		Atomic Number	Boiling Point (K)
He		2	4
Ne		10	27
Ar		18	87
Kr		36	120
Xe		54	165
Rn		86	211

The macroscopic properties of substances such as their melting points and boiling points are related to microscopic interactions between the particles that make up those substances. Let's see how this happens starting with the simplest of particles: the single atoms that make up the noble gases. **Table 10.1** lists their atomic numbers (*Z*) and their boiling points. Notice that the boiling points increase as the atomic numbers increase. To understand why this correlation exists, think about what happens at the particle level when a liquid vaporizes. As we discussed above, the particles in liquids (and solids) are in direct contact with each other. When a liquid vaporizes, however, the contacts are broken: the gas-phase particles become essentially independent. Separating liquid-phase particles that are attracted to each other requires energy, and the stronger the particles' attractions for each other, the greater the amount of energy needed to separate them. In turn, the greater the energy required to separate these particles, the higher the boiling points.

Why do single atoms interact more strongly as their atomic number increases? For that matter, *how* do atoms that are not bonded to each other interact? German-American physicist Fritz London (1900–1954) proposed one explanation for these interactions in 1930. It was based on the notion that when atoms approach each other (**Figure 10.2a**), they interact in ways that are like the electrostatic interactions involved in covalent bond formation. In other words, one atom's positive nucleus is attracted to the other atom's negative electrons, and vice versa, even as their electron clouds repel each other. These competing interactions can cause the electrons around each atom to be distributed unevenly, producing temporary induced dipoles of partial electrical charge (**Figure 10.2b**) that are attracted to regions of opposite partial charge on the adjacent atom. (This attraction is represented by the red dotted line in Figure 10.2b.) In Chapter 8 we used different colors to represent the partial electrical charges created by uneven sharing of bonding pairs of electrons. In this chapter we use those same colors (**Figure 10.2c**) to show partial electrical charges caused by uneven distributions of electrons in neutral atoms and over entire molecules.

The presence of temporary dipoles in atoms and molecules creates a way for them to interact with other atoms and molecules that are called dispersion forces (represented by ●●●●●), also referred to as London forces in honor of Fritz London's pioneering work. The strengths of the interactions increase as the numbers of electrons in atoms and molecules increase. Because all atoms and molecules have electrons, all atoms and molecules experience London forces to some degree. The larger the cloud of electrons surrounding a nucleus in an atom or multiple nuclei in a molecule, the more likely those electrons are to be distributed unevenly or *polarized*. Electrons in larger atoms are held less tightly by the nucleus because of their greater average distance from the nucleus as well as the screening of the nuclear charge by electrons in lower-energy orbitals. Consequently, they are polarized more easily than electrons in smaller atoms or molecules. Greater polarizability leads to stronger temporary dipoles and stronger intermolecular interactions, so dispersion forces become stronger as atoms and molecules become larger. This trend in polarizability accounts for the correlation between the boiling points and atomic numbers of the noble gases.

CONNECTION The concept of screening of outer electrons by inner electrons was presented in Section 7.10, where we discussed trends in the sizes of atoms and ions.

CONCEPT TEST

Rank the following atoms in order of increasing polarizability: argon, hydrogen, krypton, and neon.

(Answers to Concept Tests are in the back of the book.)

Polarizability also explains why the boiling points of the halogens increase as their molar masses increase (**Table 10.2**). These elements exist as diatomic molecules in which equal sharing of the bonding pairs of electrons by identical atoms means that the molecules have no permanent dipoles. In this case, the molar masses of the halogens represent a measure of particle size, so boiling point increases as particle size increases. A similar trend is also observed in the boiling points of a series of straight-chain hydrocarbons (**Figure 10.3**). London's explanation of these trends was also the same—namely, larger clouds of increasing numbers of electrons per molecule are more polarizable. Greater polarizability means they are more likely to form temporary dipoles that attract molecules to each other in the liquid phase and inhibit their vaporization.

TABLE 10.2 Boiling Points of the Halogens

CONNECTION In Section 6.9 we considered the structure of straight-chain hydrocarbons.

CONCEPT TEST

Use intermolecular forces to explain why CF_4 is a gas at room temperature but CCl_4 is a liquid.

The Importance of Shape

Molecular shape, as well as size, plays a role in determining the strength of dispersion forces. Consider the molecular structures and boiling points of the three hydrocarbons in **Figure 10.4**. These compounds all have the same molecular formula (C_5H_{12}), so they all have the same molar mass (72.15 g/mol) and the same number of electrons. However, the bonds, shapes, and boiling points of the molecules are different. All three compounds are nonpolar, so none has a permanent dipole. Therefore, the only intermolecular interactions are dispersion forces due to temporary dipoles. Molecules of pentane are relatively long and straight—think of their shape as being like a piece of chalk. Pentane molecules can interact with one another over a relatively large surface area and therefore have more possibilities for dispersion forces to hold them together.

In contrast, molecules of 2,2-dimethylpropane are almost spherical because of the considerable branching of the carbon atom chains. These molecules have less surface area to interact with adjacent molecules; less interaction means weaker dispersion forces, resulting in the lowest boiling point in this set of compounds. The remaining molecule, 2-methylbutane, is neither as straight as pentane nor as spherical as 2,2-dimethylpropane—think of it as shaped like a short, forked stick. 2-Methylbutane boils at a temperature lower than pentane but higher than 2,2-dimethylpropane. In general, molecules with more branching in their structures have lower boiling points.

Dispersion forces between small atoms or molecules are weak, but large molecules have many of these interactions that can sometimes dominate a much smaller number of strong interactions in a system, as we see in the discussion of polarity and solubility in Section 10.7.

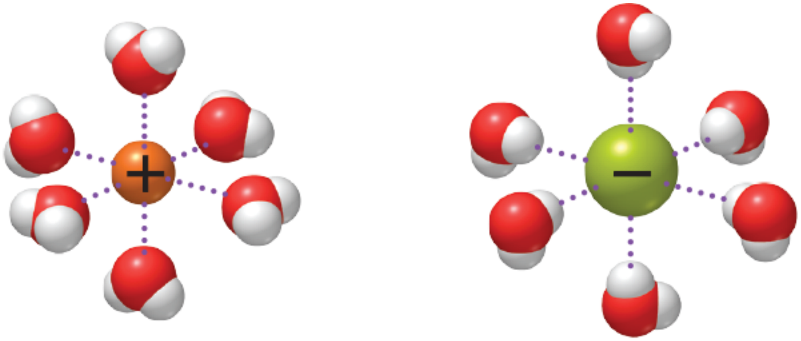
Glossary

induced dipole
: the separation of charge produced in an atom or molecule by a momentary uneven distribution of electrons.

dispersion force (also called London force)
: an intermolecular force between molecules caused by the presence of temporary dipoles in the molecules.

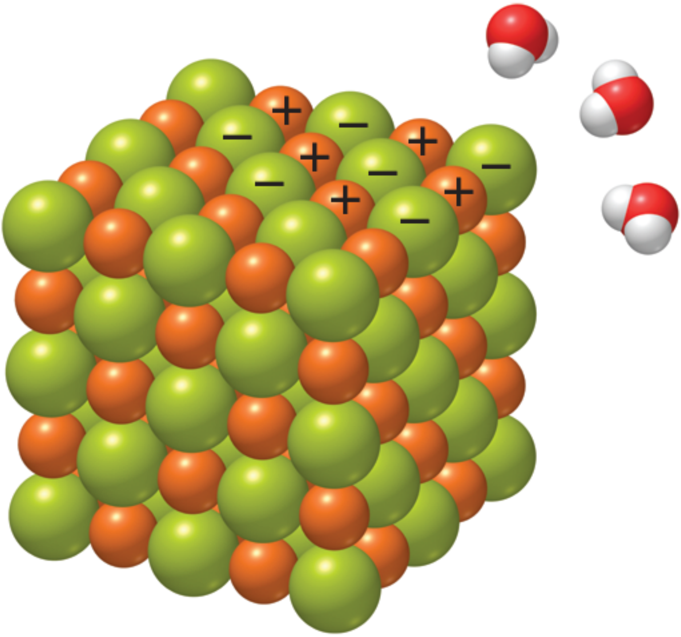
dispersion force (also called London force)
: an intermolecular force between molecules caused by the presence of temporary dipoles in the molecules.

polarizability
: the relative ease with which the electron clouds surrounding the nuclei of individual atoms or molecules can be distorted, thereby inducing temporary dipoles.



Hydrated Na^+ ion

Hydrated Cl^- ion



Solid NaCl

FIGURE 10.5 The hydrogen atoms (positive poles) of H_2O molecules are attracted to the Cl^- ions of NaCl; the O atoms (negative poles) are attracted to the Na^+ ions. Multiple ion–dipole interactions help overcome the attractive forces holding ions at the surface of the solid NaCl, causing it to dissolve.

Dipole–dipole interaction

FIGURE 10.6 Each hydrated Na^+ ion and hydrated Cl^- ion is surrounded by six water molecules that create an inner hydration sphere. Water molecules in an outer hydration sphere surround the inner sphere. The outer sphere is the result of dipole–dipole interactions between the rest of the water (known as bulk water) and the water molecules of the inner sphere. Beyond the outer hydration sphere, dipole–dipole interactions also occur between outer-sphere water molecules and molecules in bulk water.

10.3 Interactions Involving Polar Molecules

In Section 8.3 we saw how the unequal distributions of bonding pairs of electrons result in bond dipoles—that is, partial negative charges on some bonded atoms and partial positive charges on others. When bond dipoles are arranged asymmetrically within molecules, the molecules themselves have permanent dipoles. Molecules with permanent dipoles can interact with each other and with the ions in ionic compounds. The strengths of these interactions are much weaker than the strengths of ionic or covalent bonds, but they are strong enough to provide additional interactions beyond the dispersion forces that all molecules experience. For example, interactions between polar liquids and ionic solids play a key role in salts dissolving in water.

CONNECTION Bond energies of covalent bonds are discussed in Section 8.7.

CONNECTION In Chapter 4 we learned that some, but not all, ionic compounds are soluble in water.

Ion–Dipole Interactions

One reason why ionic compounds such as NaCl dissolve in water is that the sodium and chloride ions interact with the permanent dipoles of the polar water molecules, which carry both positive and negative partial charges. These attractions are called ion–dipole interactions (represented by •••••), and they occur between ions and water molecules in all aqueous solutions.

When a salt dissolves in water, ion–dipole interactions help overcome the electrostatic attractions between the ions themselves (**Figure 10.5**). As an ion is pulled away from its solid-state neighbors, it becomes surrounded by water molecules, forming a sphere of hydration (**Figure 10.6**). If the solvent were something other than water, the cluster would be called a *sphere of solvation.*

These dissolved ions are said to be *hydrated* or, for other solvents, *solvated*.

Within a sphere of hydration, the water molecules closest to the ion are oriented so that their oxygen atoms (negative poles) are directed toward a cation or their hydrogen atoms (positive poles) are directed toward an anion (Figure 10.6). The number of water molecules oriented in this way depends on the size of the ion. Typically, six water molecules hydrate an ion, but the number can range from four to nine. As Figure 10.6 shows, six water molecules surround each Na^+ ion and each Cl^- ion in an aqueous solution of NaCl.

CONNECTION In previous chapters we have indicated the presence of a hydration sphere around an ion in aqueous solution by writing (*aq*) after its symbol or formula.

Dipole–Dipole Interactions

The bulk water molecules further from the ions in Figure 10.6 are more randomly oriented than those in the inner hydration sphere. These molecules experience another type of intermolecular force, called a dipole–dipole interaction (represented by •••••), that is experienced by all polar molecules. Regions of partial positive charge and partial negative charge on neighboring polar molecules are attracted to each other. For example, the partial negative charge on the O atom of one water molecule is mutually attracted to the partial positive charges on the H atoms of up to two other water molecules. Dipole–dipole interactions are not as strong as ion–dipole interactions because dipole–dipole interactions involve only partial charges, caused by unequal sharing of the electrons in polar covalent bonds. In contrast, an ion involved in an ion–dipole interaction has lost or gained one or more electrons, so it has a full positive or negative charge (at a minimum).

To understand how dipole–dipole forces add to the dispersion interactions that exist among all molecules, let’s consider the properties of 2-methylpropane and acetone (**Figure 10.7**). These two compounds have the same molar mass (58 g/mol) and have molecular shapes that are not all that different despite the different hybridizations of their central carbon atoms.

We might expect these molecules to experience similar dispersion forces, yet the boiling points of 2-methylpropane and acetone are quite different: 261 K and 329 K, respectively. Why is the boiling point of acetone nearly 70 K higher? The answer lies in the ketone functional group in its molecular structure. The dipole created by the highly electronegative oxygen atom and the less electronegative carbon atom in the C=O bond gives acetone an overall dipole moment of 2.88 D and sets up dipole–dipole interactions between its molecules that nonpolar molecules of 2-methylpropane do not experience. Boiling a liquid requires that nearly all the intermolecular interactions between molecules in the liquid be overcome as these molecules are separated from one another entering the gas phase. Thus, polar substances with stronger interactions tend to have higher boiling points than substances with similar molar masses but weaker interactions.

CONNECTION In Section 9.3 we learned that permanent dipole moments are experimentally measured values, expressed in units of debyes, that define the polarity of molecules.

CONCEPT TEST

Dimethyl ether (CH_3OCH_3) and acetone [$CH_3C(O)CH_3$] (**Figure 10.8**), have similar formulas and molar masses, but their dipole moments are quite different: 1.30 D for dimethyl ether and 2.88 D for acetone. Predict which compound has the higher boiling point and explain why.

A molecule with a permanent dipole can create a dipole–induced dipole interaction (represented by ●●●●●) when inducing a temporary dipole in a nonpolar molecule by perturbing the electron distribution in the nonpolar molecule (**Figure 10.9**). The intermolecular interaction in this case is weaker than the dipole–dipole force between two polar molecules and is of the same order of magnitude as the dispersion forces between temporary dipoles in nonpolar molecules. The magnitude of an induced dipole depends on the polarizability of the electrons in a molecule, ion, or atom.

Hydrogen Bonds

In the preceding section we introduced dipole–dipole interactions using the attraction between H and O atoms on adjoining water molecules. These dipole–dipole interactions are particularly strong, as are those among other molecules that contain O—H bonds and among molecules that contain N—H or F—H bonds. This unusual strength is illustrated in the boiling point data plotted in **Figure 10.10**. The compounds whose boiling points are plotted are composed of molecules that each have an atom of a group 14, 15, 16, or 17 element at its center that is bonded only to enough hydrogen atoms to complete its octet. Most of the data points follow a familiar trend: boiling points increase with increasing molar masses, as we saw with the halogens in Table 10.2 and the nonpolar hydrocarbons in Figure 10.3. All the data points for the group 14 compounds fit this trend. However, the boiling points of the other three groups' compounds with the lowest molecular mass—NH_3, H_2O, and HF—are unusually high compared with the others in their series. To understand why, we need to focus on the polar covalent bonds formed between H atoms and N, O, and F atoms. The H atoms share just two electrons, and when they are shared with a highly electronegative atom of N, O, or F, the electron density on the surface of the H atom is greatly reduced, leaving the nucleus of the hydrogen atom and its positive charge with very little electron density separating it from an approaching N, O, and F atom on a neighboring polar molecule. This allows the two atoms to get close together, which increases the strength of the interaction between their partial positive and negative charges.

These unusually strong dipole–dipole interaction have their own name: they are called hydrogen bonds (represented by •••••) (**Figure 10.11**). They are the strongest dipole–dipole interactions and can be nearly one-tenth the strength of some covalent bonds.

The dipole–dipole interactions between water molecules in Figure 10.6 are hydrogen bonds, and they play a key role in defining the remarkable behavior of H_2O, which we explore in Section 10.6. **Table 10.3** summarizes the relative strengths of the intermolecular forces discussed in this chapter.

CONCEPT TEST

Use intermolecular forces to predict which compound has the higher boiling point in each of the following pairs: (a) CH_3Cl, CH_3Br; (b) CH_3CH_2OH, CH_3OH; (c) CH_3NH_2, $(CH_3)_2NH$.

TABLE 10.3 Relative Strengths of Intermolecular Forces [a] and Some Phenomena They Explain

Type of Force	Relative Strength	Phenomenon
Ion–dipole		NaCl dissolves in water Hydrogen bonding		Water expands when it freezes Dipole–dipole		The boiling point of formaldehyde (dipole–dipole interactions; $\mu = 2.33$ D) is 70°C higher than that of ethane (dispersion forces; $\mu = 0.00$ D) Dipole–induced dipole		O_2 dissolves in water Dispersion		At 298 K: Cl_2 is a gas, Br_2 is a liquid, I_2 is a solid 
CONCEPT TEST

Do you think attractive forces exist between ions and nonpolar molecules? How would you describe such interactions? Where would you place such intermolecular forces in Table 10.3?

Hydrogen bonds can also form between molecules of different substances, even when one of them has no H atoms bonded to N, O, or F atoms. For example, when acetone dissolves in water, hydrogen bonds form between the H atoms of water molecules and the O atoms of acetone molecules (**Figure 10.12**). These interactions happen even though the H atoms in acetone are bonded to C atoms and cannot form hydrogen bonds. The key to hydrogen bonding between acetone and water molecules is the negative partial charge of the O atoms in molecules of acetone, as indicated by the red color of the electrostatic potential map of acetone in Figure 10.12, and the blue-green color of the electron-deprived H atoms in molecules of H_2O.

Hydrogen bonds can also occur within the extended structures of many polymers and large biological molecules, such as proteins and DNA. As we have seen with small molecules, shape often determines behavior. Proteins are so large that their long chains of atoms tend to fold back and wrap around themselves, such that atoms may form hydrogen bonds with other atoms in an adjacent chain. The double strands of DNA (**Figure 10.13**) form a three-dimensional shape, called a double helix, in which pairs of the molecular building blocks of DNA, called nucleotides, form hydrogen bonds that keep the strands linked together. Pairs of two nucleotides named guanine (G) and cytosine (C) on adjacent DNA strands form three hydrogen bonds, whereas pairs of adenine (A) and thymine (T) form two hydrogen bonds. Because hydrogen bonds are weaker than covalent bonds, the DNA strands can be pulled apart during DNA replication (replication is discussed in greater detail in Section 20.7).

SAMPLE EXERCISE 10.1 Identifying Intermolecular Forces LO1

Figure 10.14 shows the Lewis structures of five compounds: (a) sodium chloride, (b) methane, (c) dichloromethane, (d) methylamine, and (e) acetaldehyde. Identify the intermolecular forces that the ions or molecules of the compounds experience in a pure sample and when dissolved in water.

Collect, Organize, and Analyze We have the Lewis structures of five compounds and need to use them to identify the types of intermolecular forces (IMFs) the ions and molecules in those compounds experience as pure substances or when dissolved in water. The list of IMFs includes

- dispersion forces, which all individual atoms and molecules experience
- ion–dipole forces, which ions experience when they dissolve in water and other polar solvents
- dipole–dipole interactions, which molecules with permanent dipoles experience
- hydrogen bonds, which H atoms bonded to O, N, or F atoms form with O, N, or F atoms on other molecules
- dipole–induced dipole forces, which play a key role in the solubility of nonpolar molecules in polar solvents

Solve

1. The ions in solid NaCl are held together by ionic bonds, not IMFs, but when they dissolve in water they experience ion–dipole interactions in addition to ion–ion interactions.
2. Methane, like most hydrocarbons, is nonpolar, so its molecules experience only dispersion forces, but in an aqueous solution the permanent dipoles of water molecules induce temporary dipoles in methane molecules.
3. The Lewis structure of dichloromethane appears to be symmetrical, but we learned in Chapter 9 that its tetrahedral molecular shape means that the bond dipoles in the molecule are not arranged symmetrically in three-dimensional space; so, dichloromethane molecules have permanent dipoles. This means they experience dipole–dipole interactions among themselves and with polar water molecules.
4. Methylamine contains a methyl (–CH_3) group and a polar amine group due to the asymmetry produced by the lone pair of electrons on the nitrogen atom. The presence of N—H bonds also means that methylamine molecules form hydrogen bonds among themselves and with molecules of H_2O.
5. Acetaldehyde has a polar C□O group, but none of the H atoms in acetaldehyde are bonded to a N, O, or F atom.

Therefore, it experiences dipole–dipole interaction but does not form hydrogen bonds *unless* it dissolves in water. When that happens the H atoms of water molecules form hydrogen bonds with O atoms in acetaldehyde molecules.

Think About It The key to recognizing the types of intermolecular forces that particles of a substance experience is to determine whether they are ions or polar or nonpolar molecules, and whether they are molecules that can form hydrogen bonds. In Chapter 2 we discussed how to distinguish between ionic and molecular compounds, and in Chapter 9 (and again in this exercise) we used the presence of bond dipoles and asymmetric molecular structures to identify polar molecules. The presence of H atoms bonded to N, O, or F atoms is the key to hydrogen bond formation.

Practice Exercise Identify the intermolecular forces for the five substances whose Lewis structures are shown in **Figure 10.15**: (a) nitrogen gas, (b) carbon monoxide, (c) formaldehyde, (d) trichlorofluoromethane, and (e) 2-propanol.

(Answers to Practice Exercises are in the back of the book.)

SAMPLE EXERCISE 10.2 Explaining Differences in Boiling Points LO2

Images of the molecular structures propane, dimethyl ether, and ethanol are shown in **Figure 10.16**. All three compounds have nearly the same molar mass and exactly the same number of electrons per molecule. However, the boiling points of propane, dimethyl ether, and ethanol are 231 K, 249 K, and 351 K, respectively. Explain these differences in boiling points.

Collect, Organize, and Analyze We are asked to explain the differences between the boiling points of three compounds with similar molar masses and the same number of electrons per molecule, which means they should experience similar dispersion forces. We are given their molecular structures and need to consider:

Propane is a hydrocarbon whose molecules contain only C—C bonds, which are not polar, and C—H bonds, which have little polarity. Therefore, the only intermolecular forces propane molecules are likely to experience are dispersion forces.

The other two molecules each contain an O atom bonded to atoms of less electronegative elements, so both molecules have bond dipoles. The shapes of the molecules show that the bond dipoles do not entirely offset each other, so both molecules have permanent dipoles (**Figure 10.17**). Their polarities mean that both experience dipole–dipole interactions. Ethanol molecules contain –OH groups, which means their principal dipole–dipole interactions are hydrogen bonds.

Solve Propane is essentially nonpolar, so its boiling point of 231 K is a measure of the strength of the dispersion forces that all three molecules experience because these forces must be overcome if molecules in the liquid state are to vaporize. Dipole–dipole interactions between molecules of dimethyl ether add a second attractive force between its molecules, which explains its slightly higher boiling point of 249 K. The much higher boiling point of ethanol (351 K) reflects the much stronger force of attraction produced by the hydrogen bonding between its molecules.

Think About It The only slightly higher boiling point of dimethyl ether over propane indicates that London dispersion is the primary intermolecular force for both compounds. The more than 100 K difference between the boiling points of dimethyl ether and ethanol attests to the strengths of the hydrogen bonds between ethanol molecules.

Practice Exercise 2-Propanol (molar mass 60.10 g/mol), the rubbing alcohol in your medicine cabinet, boils at 356 K. Ethylene glycol, used as automotive antifreeze, has nearly the same molar mass (62.07 g/mol) but boils at 470 K. Why do these substances (**Figure 10.18**) have such different boiling points?

Glossary

ion–dipole interaction

an attractive force between an ion and a molecule that has a permanent dipole moment.

sphere of hydration

the cluster of water molecules surrounding an ion in aqueous solution; the general term applied to such a cluster forming in any solvent is *sphere of solvation*.

dipole–dipole interaction

an attractive force between polar molecules.

dipole–induced dipole interaction

an attraction between a polar molecule and the oppositely charged pole it temporarily induces in another molecule.

hydrogen bond

the strongest dipole–dipole interaction. It occurs between a hydrogen atom bonded to a small, highly electronegative element (O, N, F) and an atom of oxygen or nitrogen in another polar molecule. Molecules of HF also form hydrogen bonds.

Learning Objectives

- Describe the types of intermolecular forces and explain how they and their strengths are related to the sizes of atoms and to the sizes, shapes, and dipole moments of molecules **Return to Sample Exercise 10.1**

- Explain the effect of intermolecular forces on the physical properties of molecular substances, including their vapor pressures and boiling points **Return to Sample Exercises 10.1, 10.2**
- Between pairs of particles of similar combined masses.Return to reference a

$$P_{\text{vap},T_2} = 47.6\ \text{torr}$$

10.4 Vapor Pressure of Pure Liquids

Water in a glass left on a kitchen countertop slowly disappears as molecules on the surface of the liquid vaporize (evaporate) over time. The rate at which the molecules make this transition from the liquid to the gas phase depends on the following factors:

1. Temperature: The higher the temperature, the greater the number of molecules with sufficient kinetic energy to break the attractive forces that hold them together in the liquid and to enter the gas phase.
2. Surface area: The larger the surface area of the liquid, the greater the number of molecules on the surface in a position to enter the gas phase.
3. Intermolecular forces: The stronger the intermolecular forces, the greater the kinetic energy needed for a molecule to escape the surface, and the smaller the number of molecules in the population that have this energy.

If a glass of water is covered (**Figure 10.19a**), molecules that evaporate are confined to the immediate space above the water. As the number of water molecules in the vapor increases at constant temperature (*T*), so does the partial pressure (P_{H2O}).

Some of the molecules of water vapor collide with the surface and return to the liquid phase, that is, they condense. The rate of condensation increases as the concentration of vapor increases because the frequency of these collisions increases. Eventually, the rates of evaporation and condensation equalize setting up a dynamic equilibrium of molecules leaving and returning to the liquid phase at the same rate with no net change in the level of the liquid in the glass over time. The resulting partial pressure of the water vapor in equilibrium with liquid water at a given temperature is called its vapor pressure. Other liquids have their own characteristic vapor pressures at room temperature. Some, such as bromine (**Figure 10.19b**), have higher pressures than that of water because, in this case, the strength of the intermolecular forces that keep Br_2 molecules together in the liquid state is weaker than the hydrogen bonds that keep molecules of liquid H_2O together. Others, such as ethylene glycol (Figure 10.18), have lower vapor pressures because the intermolecular forces between their molecules are stronger than those in water.

Vapor Pressure and Temperature

Figure 10.20 shows how the vapor pressures of several liquids increase with increasing temperature. For each of the vapor pressure curves, there is a temperature at which vapor pressure reaches 760 torr (1 atm). That temperature is called the normal boiling point of the substance. The vapor pressure of water (the dark blue curve in Figure 10.20) reaches 760 torr at a familiar temperature: 100.0°C. It is called the *normal* boiling point because most chemical reactions in nature, in our bodies, and in laboratories take place near an atmospheric pressure of 1 atm.

The sequence of the four curves and the normal boiling points of the liquids in Figure 10.20 depend on strengths of the interactions between their molecules in the liquid state. Molecules of diethyl ether experience the weakest interactions in this group of four compounds owing to their modest dipole moment (1.15 D)and because they cannot form hydrogen bonds with one another. They behave in this manner because their H atoms are bonded to C atoms, not O, N, or F atoms. On the other hand, molecules of the other three compounds *can* form hydrogen bonds. Ethanol is an alcohol with one –OH group per molecule and has a boiling point about 44°C higher than that of diethyl ether, even though ethanol molecules are smaller and experience small dispersion forces. The reason for its higher boiling point is the strength of the hydrogen bonds between its molecules. The boiling point of water is nearly 22°C higher than that of ethanol even though water molecules are smaller. In this comparison, the higher boiling point of water occurs because each of its molecules contains *two* O—H bonds that can form up to *four* hydrogen bonds. This is so because the two lone pairs of electrons on one of its O atoms can form hydrogen bonds with two H atoms on two other water molecules as shown in **Figure 10.21**. The boiling point of ethylene glycol is nearly 100°C higher than that of water because its molecules are larger (and experience stronger dispersion forces) and because each of them contains *two* –OH groups that can form up to *six* hydrogen bonds.

The curves in Figure 10.20 also show that the relationship between vapor pressure and temperature is not linear. Even so, all these compounds have significant vapor pressures well below the temperatures at which they boil. For example, at room temperature (~22°C) the vapor pressures of water, ethanol, and diethyl ether are about 20, 50, and 475 torr, respectively. If left in open containers, all three compounds should evaporate at rates directly proportional to their vapor pressures.

Liquid substances with significant vapor pressures and evaporation rates at room temperature are called *volatile* liquids. Among the substances in Figure 10.20, diethyl ether is the most volatile followed by ethanol and water. Ethylene glycol is considered a nonvolatile liquid, which is one of the reasons why it is widely used in the cooling systems of automobile engines, which operate at temperatures approaching 100°C.

CONNECTION Vapor pressure was introduced in Section 5.7 in the context of collecting gases over water.

CONCEPT TEST

Diesel fuel is made of hydrocarbons with an average of 13 carbon atoms per molecule, and gasoline is made of hydrocarbons with an average of 7 carbon atoms per molecule. Which fuel has the higher vapor pressure at room temperature?

Volatility and the Clausius–Clapeyron Equation

Although the vapor pressure of a pure substance is not a linear function of absolute temperature, plotting the natural logarithm of its vapor pressure (P_{vap}) versus $1/T$ does produce a straight line (**Figure 10.22**). The equation of such a line fits the Clausius–Clapeyron equation:

where ΔH_{vap} is enthalpy of vaporization, R is the gas constant (8.314 J/(mol · K), T is in kelvin, and C is a constant that depends on the identity of the liquid. We can solve this equation for C and write it in terms of two temperatures:

Rearranging the right and left sides of this equation, we get

This version of the Clausius–Clapeyron equation (Equation 10.2) can be used to calculate ΔH_{vap} if the vapor pressures at two temperatures are known or to calculate either the vapor pressure ($P_{\text{vap},\text{T}_2}$) at any given temperature T_2, or the temperature at any given vapor pressure, if ΔH_{vap}, $P_{\text{vap},\text{T}_1}$, and T_1 are known. Equation 10.2 is particularly useful when we know the normal boiling point (T_1) because $P_{\text{vap}} = 760$ torr $= 1$ atm.

SAMPLE EXERCISE 10.3 Calculating Vapor Pressure LO3

Dogs can’t sweat, but they can still use evaporative cooling to regulate their body temperature by panting (taking rapid, shallow breaths). What is the vapor pressure of water in the air a panting dog exhales if the temperature of the air is 35°C? The enthalpy of vaporization of water is 40.7 kJ/mol.

Collect and Organize The vapor pressure of water at any temperature can be calculated using Equation 10.2 and inserting the value of water’s heat of vaporization, which we are given, and its normal boiling point (100.0°C), which is the temperature at which P_{vap} is exactly equal to 1 atm $=$ 760 torr.

Analyze To use Equation 10.2 we must convert 100.0°C to kelvin and convert the value of ΔH_{vap} from kJ/mol to J/mol because the units of R are J/(mol · K). As noted earlier, the vapor pressure of water at 20°C is 24 torr, so the value of P_{vap} at 35°C should be above this value, perhaps near 50 torr.

Solve The values of T_1 and T_2 on the Kelvin scale are

$T_1 = 100.0°\text{C} + 273 = 373\ \text{K}$ and $T_2 = 35°\text{C} + 273 = 308\ \text{K}$

and the value of ΔH_{vap} in joules is

Inserting these values into Equation 10.2:

Think About It The calculated value is near our estimate and in agreement with the vapor pressure curve for water in Figure 10.20. Therefore, it is reasonable. We used three significant figures to report the result because normal boiling points correspond to vapor pressures of exactly 1 atm or exactly 760.

Practice Exercise The normal boiling point of pentane (C_5H_{12}) is 36°C. What is its molar heat of vaporization in kilojoules per mole if its vapor pressure at 25°C is 505 torr?

Glossary

vapor pressure	the pressure exerted by a gas at a given temperature in equilibrium with its liquid phase.
normal boiling point	the temperature at which the vapor pressure of a liquid equals 1 atm (760 torr).
Clausius–Clapeyron equation	a relationship between the vapor pressure of a substance at two temperatures and its heat of vaporization.

Learning Objectives

- Use the Clausius–Clapeyron equation to relate the vapor pressure of a liquid to its enthalpy of vaporization and temperature **Return to Sample Exercise 10.3**

10.5 Phase Diagrams: Intermolecular Forces at Work

In the previous section we discussed how the strengths of the attractive forces between particles determine the normal boiling points of liquids, noting that increasing the temperature of a liquid raises the fraction of its molecules that have enough kinetic energy to overcome these forces and to escape from the liquid phase into the gas phase. In this section we expand our examination of the effect of temperature on transitions between phases to include solid–liquid and solid–gas transitions, and we examine the effect of changing pressure on all phase changes, particularly those involving the gas phase.

Phases and Phase Transitions

Scientists use phase diagrams to show which phase of a substance is stable at given combinations of temperature (the x-coordinate) and pressure (the y-coordinate) values. Consider, for example, the phase diagram of water in **Figure 10.23**. There are three regions corresponding to the three common states of matter (solid, liquid, and gas) plus a fourth region called a *supercritical region*. The lines separating the regions represent *equilibrium lines* because the two states bordering them are at equilibrium at the combinations of temperature and pressure on each line. The blue equilibrium line separating the solid and liquid regions represents a series of freezing (or melting) points; the points on this line are combinations of temperature and pressure at which the solid and liquid states coexist. The red line separating the liquid and gas regions represents a series of boiling points or condensation points; the points on this line are combinations of temperature and pressure at which the liquid and gaseous states coexist. The green line separating the solid and gaseous states represents a series of sublimation points (solid turning to gas) or deposition points (gas turning to solid); the points on this line are combinations of temperature and pressure at which the solid and gaseous states coexist.

Notice how the red line curves from the lower left to the upper right, separating the liquid and gas regions of the phase diagram. This line represents the changing boiling point of the liquid as a function of pressure. Its shape makes sense because when the pressure above a liquid increases, the temperature required for liquid molecules to overcome intermolecular attractive forces and enter the gas phase (i.e., the boiling point) increases. Conversely, applying more pressure to a gas forces its molecules closer together, which increases the frequency with which they collide with and interact with one another, and increases the likelihood that they form clusters of molecules that condense into the liquid phase. Moreover, when a liquid vaporizes, the volume it occupies increases enormously because the liquid (and solid) phases of a substance are many times denser than its gas phase. This expansion is made more difficult if there is an increase in the opposing pressure pushing against it.

The shape of the green solid–gas curve is much the same as the red curve and for much the same reason: higher pressures make it more difficult for ice to expand into an equal mass of water vapor that occupies hundreds of times more volume, and, on a molecular level, the greater interaction between gas-phase molecules under high pressure that promotes their condensation at higher temperatures also promotes their deposition at lower temperatures.

On the other hand, the trend in the blue melting/freezing equilibrium line for water shows a *decrease* in the melting point of ice as pressure *increases*. This trend in the melting/freezing points for water is opposite the trend observed for almost all other substances (see, for example, the slope direction of the blue line for CO_2 in **Figure 10.24**). The reason for water's unusual melting/freezing behavior is that water expands when it freezes. Most other substances are denser in the solid state than in the liquid state because they contract when they freeze. Water, however, expands as it freezes because hydrogen bonding between molecules of water in the solid phase creates a structure that is more open than the structure in liquid water (see the particulate views in Figure 10.23). Applying enough pressure to ice forces it into the physical (liquid) state that takes up less volume.

CONCEPT TEST

A truck with a mass of 2000 kg is parked on an icy driveway where the temperature of the ice is $-2°C$. Is it possible that the ice under the tires of this vehicle will melt, even though the temperature remains constant? Explain your answer.

A point of special interest on a phase diagram is the one where all three lines describing the phase transitions meet. Known as the triple point, it identifies the temperature and pressure at which all three states (liquid, solid, and gas) are in equilibrium with each other. The triple point of water is just above its normal melting temperature, at 0.010°C, but at a very low pressure of 0.0060 atm.

Another point of interest is the place where the boiling/condensation equilibrium line ends. Called the critical point, this is the temperature and pressure at which the liquid and gaseous states are indistinguishable from each other. This point is reached because thermal expansion at this high temperature causes the liquid to become less dense, while the high pressure compresses the gas into a small volume, increasing its density. At the critical point, the densities of the liquid and gaseous states are equal, so one cannot be distinguished from the other.

At temperature–pressure combinations above its critical point, a substance exists as a supercritical fluid. A supercritical fluid can penetrate materials like a gas but also dissolve substances in those materials like a liquid. Above the critical temperature, the kinetic energy of the molecules is sufficient to overcome the intermolecular forces holding the molecules together as a liquid. At the critical pressure, the molecules do not have the properties associated with ideal gases, so the properties of supercritical fluids represent a balance of forces acting on molecules. Supercritical carbon dioxide is used in the food-processing industry to decaffeinate coffee and remove fat from potato chips. Supercritical carbon dioxide and water are sometimes mixed to generate fluids that can selectively dissolve specified materials from mixtures while leaving other components untouched.

In the phase diagram of CO_2 (Figure 10.24), the dashed line at $P = 1$ atm defines the phases that exist at 1 atm pressure, but notice that the blue region representing liquid CO_2 does not extend below 5.1 atm. This means that solid CO_2 does not melt into a liquid at normal temperatures and pressures. Rather, it sublimes directly to CO_2 gas. This behavior explains why the common name for solid CO_2 is *dry ice*; it is a solid that keeps things cool, as water ice does, but it forms no "wet" liquid. The critical point of CO_2 is at 31°C and 73 atm, a pressure easily achieved with compressors in laboratories, factories, and food-processing plants, which means CO_2 is readily available for use as a supercritical fluid.

SAMPLE EXERCISE 10.4 Interpreting a Phase Diagram LO4

Describe the phase changes that take place as the pressure on a sample of water at 0°C is increased from 0.0001 atm to 200 atm.

Collect and Organize We are asked to describe the phase changes water undergoes at a constant temperature as pressure is increased. We can use the phase diagram for water in **Figure 10.25a**. To read a phase diagram, remember that every point is characterized by a temperature and a pressure and that every time we cross an equilibrium line, the phase changes.

Analyze The changes take place along the vertical line (**Figure 10.25b**) that intersects the temperature axis at 0°C.

Solve Starting at the bottom of the phase diagram with the red line (Figure 10.25b) and following the dashed line at 0°C upward as pressure increases, we approximate the location of the starting pressure, 0.0001 atm, a little below and to the left of the triple point ($T = 0.010$°C and $P = 0.0060$ atm). Water at 0°C and 0.0001 atm is a gas, as indicated by the phase diagram. As we follow the 0°C dashed line up from the temperature axis, the point where this line intersects the green equilibrium line indicates that the gas solidifies to ice at a pressure below 1 atm. Increasing the pressure toward 1 atm, the dashed line intersects the blue equilibrium line at that pressure. At this pressure, then, the ice melts to liquid water. Extending the 0°C dashed line farther upward shows that the water remains a liquid at pressures up to and beyond 200 atm.

Think About It The phase changes in water, from gas to solid to liquid with increasing pressure at 0°C, make sense from a molecular point of view because higher pressures favor the densest phase. Liquid water is denser than ice, so the transitions from gas to solid to liquid are transitions from the least dense to the densest phase.

Practice Exercise Describe the phase changes that occur when the temperature of CO_2 (Figure 10.24) is increased from −100°C to 50°C at a pressure of 10 atm.

CONCEPT TEST

According to the phase diagram in Figure 10.24, does solid CO_2 float on liquid CO_2 under conditions described by any point along the blue line?

Glossary

phase diagram

a graphical representation of how the stabilities of the physical states of a substance depend on temperature and pressure.

triple point

the temperature and pressure at which all three phases of a substance coexist.

critical point

the temperature and pressure at and above which the liquid and gas phases of a substance are indistinguishable from each other.

supercritical fluid

a substance at conditions above its critical temperature and pressure, where the liquid and vapor phases are indistinguishable and have some characteristics of both a liquid and a gas.

Learning Objectives

- Identify the regions of a phase diagram and explain the effect of temperature and pressure on phase stability and phase changes **Return to Sample Exercise 10.4**

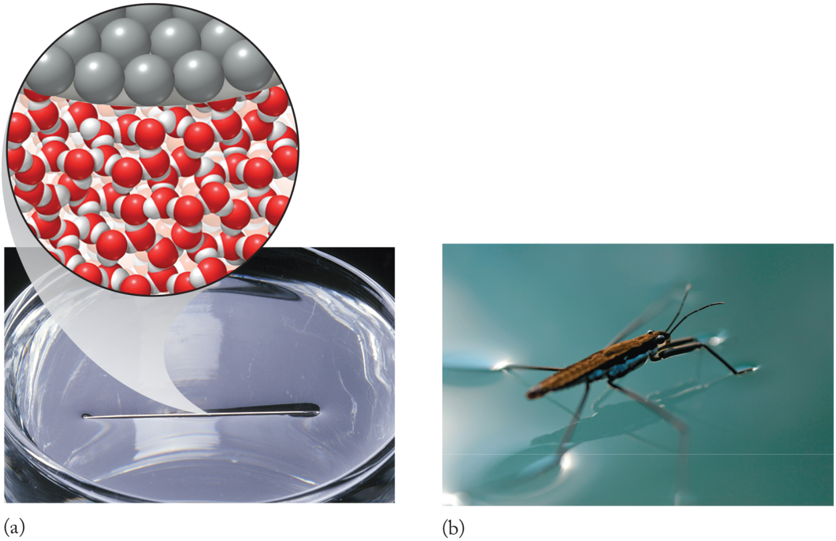

FIGURE 10.26 (a) When surface tension exceeds the downward force exerted on the surface water molecules by a denser object, such as a steel needle, the object cannot break through and floats on the surface. (b) Surface tension allows a water strider to rest on top of water without sinking.

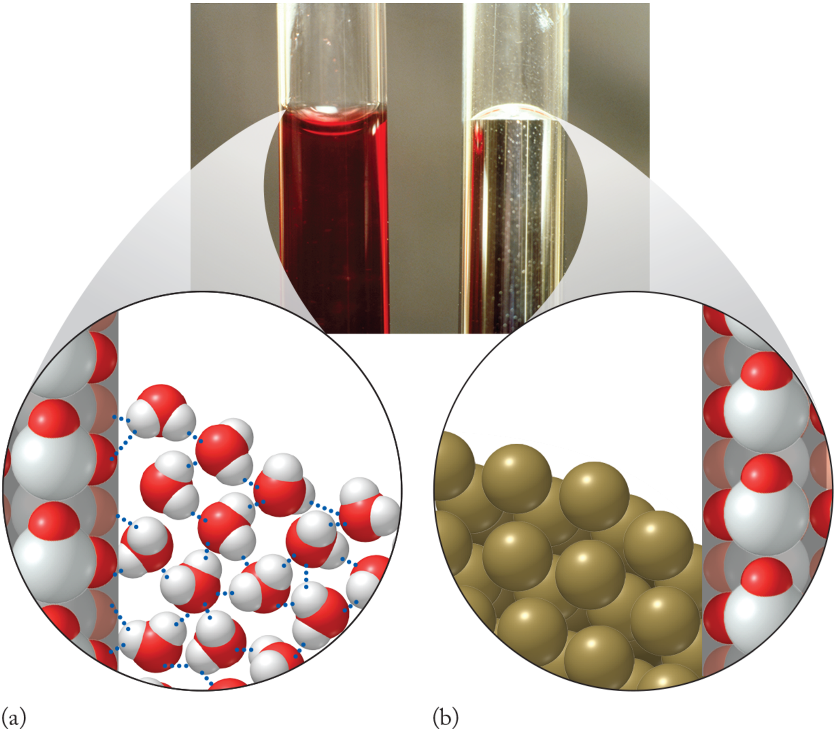

FIGURE 10.27 (a) Hydrogen bonds between the H atoms of water molecules and the O atoms of the silicon dioxide that makes up the glass are an adhesive force that causes water molecules to adhere to the glass surface and form a concave meniscus. (b) Because mercury atoms have no such attraction to the silicon dioxide in the glass, mercury forms a convex meniscus.

FIGURE 10.32 (a) As the surface water of a pond cools to 4°C, its density increases, and it sinks to the bottom, bringing the warmer, less dense water to the surface. (b) Continued cooling of the surface water below 4°C produces a less dense layer that may eventually freeze while the denser water deeper in the pond remains at 4°C.

10.6 Some More Remarkable Properties of Water

Water has many remarkable properties, including melting and boiling points that are much higher than those of any other molecular substance with a similar molar mass. The boiling point of methane (CH_4), for example, is 112 K, whereas water boils at 373 K. Also, liquid water expands when it freezes; nearly all other substances found in nature contract when they solidify. These phenomena and others that are described in this section are directly related to the shape of water molecules and the strength of the hydrogen bonds they form with one another.

Surface Tension, Capillary Action, and Viscosity

Surface tension is the resistance of a liquid to any increase in its surface area. Surface tension represents the energy required to move molecules apart on the surface of a sample of liquid water so that an object denser than water can break through the surface and settle to the bottom.

Hydrogen bonding in water creates such a high surface tension, 7.29×10^{22} J/m^2 at 25°C, that a carefully placed steel needle floats on water and insects called water striders can walk on it (**Figure 10.26**). The same needle and insect would sink in oil or gasoline.

To understand how surface tension depends on intermolecular forces, consider the microscopic view of the steel needle on the surface of the water in Figure 10.26. Water molecules in the interior of the water are surrounded by other water molecules and form hydrogen bonds to them in all directions. However, there are no molecules of liquid water above those at the surface, so those water molecules form fewer hydrogen bonds per molecule than those in bulk liquid. Gravity pulls the steel needle downward, but to move downward the needle must penetrate the surface. This means pushing aside surface water molecules, increasing the area of the surface, and turning what were once interior water molecules into surface molecules. This transformation requires breaking some of the hydrogen bonds experienced by the interior molecules, which requires about 23 kJ of energy per mole of hydrogen bonds. The downward pressure of the needle is insufficient to overcome this energy, so it floats on the surface.

Another illustration of the intermolecular forces acting in liquids is seen in the shape of the surface of the liquid when it is placed in a graduated cylinder or other small-diameter tube (**Figure 10.27**). The surface of water is concave in such a tube, but the surface of liquid mercury is convex. The curved surface, whether it is concave or convex, is called a meniscus. In both liquids, the meniscus is the result of two competing forces: *cohesive forces*, which are interactions between like particles, and *adhesive forces*, which are interactions between unlike particles. In the water sample in Figure 10.27a, the cohesive forces are hydrogen bonds between water molecules, whereas the adhesive forces are dipole–dipole interactions between water molecules and polar Si—O—Si groups on the surface of the glass. The adhesive forces are strong enough to cause the water to climb upward on the glass, creating the concave meniscus. The adhesive forces are greater than the cohesive forces in this case because surface water molecules next to the glass have less contact with other water molecules and therefore experience smaller cohesive forces.

In the mercury sample (Figure 10.27b), the cohesive forces are metallic bonds between mercury atoms, whereas the adhesive forces are interactions between induced dipoles in the mercury atoms and the polar Si—O—Si groups on the glass surface. In this case, the adhesive forces are much weaker than the cohesive forces, and mercury atoms are more attracted to one another than to the glass. As a result, they do not adhere well to the wall, forming a convex meniscus.

The fact that adhesive forces outweigh cohesive forces on the surface of water has consequences in other situations. In a narrow tube, adhesion to the tube wall draws the outer ring of water molecules upward. At the same time, cohesive forces between the outer ring molecules and those adjacent to them draw the molecules upward (**Figure 10.28**). If the tube is narrow enough (a capillary tube), this combination of adhesion and cohesion draws a column of water up the tube in a phenomenon known as capillary action. The water column reaches its maximum height when the downward force of gravity balances the upward adhesive and cohesive forces.

In a test tube or pipet, water molecules in contact with the glass move only a very small distance up the glass before the force of gravity balances the adhesive and cohesive forces. When a nurse takes a blood sample after a pinprick in your finger, however, the blood (essentially an aqueous solution) spontaneously moves into a capillary tube because of capillary action. Capillary action also contributes to the process by which water rises 100 meters or more up the trunks of tall trees.

CONCEPT TEST

Would mercury be spontaneously drawn into a glass capillary tube?

Viscosity, the resistance to flow, is another property of liquids related to the strength of their intermolecular forces (**Figure 10.29**). The viscosities of polar compounds are influenced by both dispersion forces and dipole–dipole (including hydrogen bond) interactions. Water is more viscous than gasoline, even though water molecules are much smaller than the nonpolar molecules in gasoline because of the remarkable strength of water's hydrogen bonds. On the other hand, alcohols of different molar mass, such as 1-octanol [$CH_3(CH_2)_7OH$] and ethanol (CH_3CH_2OH), have different viscosities because in addition to the hydrogen bonds that both alcohols form, the much larger molar mass of 1-octanol means that its molecules experience much stronger dispersion forces, giving it viscosity over five times that of alcohol.

The Densities of Cold Water and Ice: Their Impact on Aquatic Life

The density of water increases as it is cooled to 4°C (**Figure 10.30**). This pattern is observed for most liquids and solids and for all gases, but water then expands as it is cooled from 4°C to 0°C as the pattern of its hydrogen bonds changes with temperature. As water freezes at 0°C, its density drops even more, to about 0.92 g/mL, which causes ice to float on liquid water (**Figure 10.31**). This unusual behavior is caused by the formation of a network of hydrogen bonds in ice. With each oxygen atom covalently bonded to two hydrogen atoms and hydrogen-bonded to two other hydrogen atoms, the molecules form an extensive and open hexagonal network in the solid phase that leaves, on average, more space between the molecules than in liquid water.
